This book's use or discussion of MATLAB® software or related products does not constitute endorsement or sponsorship by The MathWorks of a particular pedagogical approach or particular use of the MATLAB® software.

The handbook is not to be used as a manual, that is, as a book containing practical instruction on how to build or modify existing vehicles or their subsystems. The publisher and the editors agree that the handbook has the only aim of explaining to readers both the relevant physical phenomena and how the solution of technical problems can be obtained by means of a scientific approach. Technical applications have then to be realized by experienced engineers only on the basis of national or international standards and/or practical rules that are often omitted in the handbook.

To the fullest extent of the law, neither the publisher nor the authors, contributors, or editors assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence, or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

Chapter 1 History of Road and Off-Road Vehicle System Dynamics 1
Masao Nagai

Part I Modeling, Analysis, and Optimization in Vehicle System Dynamics

Chapter 2 Vehicle Models and Equations of Motion 13
Werner Schiehlen

Chapter 3 Simulation Algorithms and Software Tools 45
Martin Arnold

Chapter 4 Nonlinear Solid Mechanics with Finite Elements 69
Anna Pandolfi

Chapter 5 Nonlinear Vehicle Dynamics 121
Hans True

Chapter 6 Controls and Identification 159
Stefan Jakubek and Martin Kozek

Chapter 7 Actuators and Sensors 221
Yoshihiro Suda

Chapter 8 Optimization of Ground Vehicle Systems 241
Massimiliano Gobbi and Panos Y. Papalambros

Chapter 9 Fatigue and Structural Durability of Automotive Components 263
Thomas Bruder, Holger Hanselka, Rüdiger Heim, Heinz Kaufmann, Michael Kieninger, Jürgen Nuffer, and Cetin M. Sonsino

Chapter 10 Reliability Assessment of Mechatronic Devices in Vehicles 307
Bernd Bertsche, Jochen Gäng, Holger Hanselka, Soong-Oh Han, Jürgen Nuffer, and Kai Wolf

Part II Vehicle Concepts and Aerodynamics

Chapter 11 Conceptual Design of Road Vehicles Related to Dynamics 329
Giampiero R.M. Mastinu

Chapter 12 Off-Road Vehicles (Wheeled and Tracked) 395
Günter H. Hohl

Chapter 13 Motorcycles and Three-Wheeled Vehicles 477
Robin S. Sharp

Chapter 14 Race Cars: Frame, Suspension, Aerodynamics 497
Andrea Toso

Chapter 15 Race Cars: Braking System 517
Carlo Maria Domenico Cantoni and Giorgio Previati

Chapter 16 Aerodynamics and Vehicle Dynamics 529
Andreas Wagner

Part III Pneumatic Tires and Contact Wheel-Road/Off-Road

Chapter 17 Tire as a Vehicle Component 563
Hans B. Pacejka

Chapter 18 Pneumatic Tire Models: The Detailed Mechanical Approach 625
Michael Gipser

Chapter 19 Pneumatic Tire: Construction and Testing 657
Maurizio Boiocchi and Giuseppe Matrascia

Chapter 20 Mechanics of Off-Road Vehicle–Terrain Interaction: Terramechanics 697
Jo Y. Wong

Part IV Modeling of Vehicle Subsystems

Chapter 21 Suspension Systems 727
Wolfgang Matschinsky

Chapter 22 Active and Semiactive Suspension Systems 769
Davor Hrovat, Eric H. Tseng, Michael Fodor, and Jahan Asgari

Chapter 23 Driveline 797
Andreas Laschet and Ferit Küçükay

Chapter 24 Brake System Dynamics 837
Carlo Maria Domenico Cantoni, Riccardo Cesarini, Giampiero R.M. Mastinu, Giorgio Previati, and Roberto Sicigliano

Chapter 25 Steering System 919
Ichiro Kageyama

Chapter 26 Structural and Dynamic Problems in Car Body Design 943
Giovanni Belingardi and Massimiliano Avalle

Part V Vehicle Dynamics and Active Safety

Chapter 27 Basics of Longitudinal and Lateral Vehicle Dynamics 971
Manfred Ploechl, Peter Lugner, and Johannes Edelmann

Chapter 28 Detailed Modeling, Simulation, and Analysis of Vehicle Dynamics 1023
Dieter Ammon

Chapter 29 Ride Comfort and Road Holding 1059
Karl Popp

Chapter 30 Control of Horizontal Vehicle Motion 1093
Anton van Zanten

Chapter 31 Active and Semi-Active Suspension Control 1179
Davor Hrovat

Chapter 32 Integrated Controls 1227
Masato Abe

Chapter 33 Dynamics of Heavy Commercial Vehicles and Buses 1245
John Aurell

Chapter 34 Dynamics of Off-Road Vehicles 1279
Jo Y. Wong

Chapter 35 Motorcycle Handling Dynamics 1313
Robin S. Sharp

Part VI Man–Vehicle Interaction

Chapter 36 Vehicle Comfort 1379
Karl Siebertz

Chapter 37 Subjective and Objective Evaluations of Car Handling and Ride 1395
Gwanghun Gim

Chapter 38 Driver Models in Automobile Dynamics Application 1477
Manfred Ploechl and Johannes Edelmann

Part VII Intelligent Vehicle Systems

Chapter 39 Automatic Lateral Vehicle Control 1525
Huei Peng

Chapter 40 Longitudinal Control 1549
Paul Fancher and Charles MacAdam

Part VIII Road Accident Reconstruction and Passive Safety

Chapter 41 Analysis and Reconstruction of Road Accidents 1583
Horst Ecker

Chapter 42 Automotive Structural Crashworthiness and Occupant Protection 1611
Jorge Ambrósio

Index 1663

Preface

Some years ago, Swets & Zeitlinger Publishing Company, together with International Association of Vehicle System Dynamics (IAVSD) (represented both by the former Secretary General Professor Robin Sharp and by the former editor in chief of *Vehicle System Dynamics*, Professor Peter Lugner), sent us a proposal to publish a handbook on the dynamics of road and off-road vehicles. Since then, many efforts have been made to gather distinguished contributors to the project. After Swets & Zeitlinger was acquired by Taylor & Francis Group, these efforts were intensified, and we are now finally able to show the result to the scientific and technical community.

Our aim was to publish an authoritative set of standard reference works in the area of vehicle system dynamics. Contemporary publications on the topic are either very specialized (scientific papers) or rather time consuming to read (dedicated books). This handbook is targeted toward both the beginner and the experienced engineer. It can also be used as a textbook for master's courses at universities.

The chapters of the handbook have been written by highly reputed scientists and engineers; many of them have already written full books on the topic they have dealt with in the handbook. The authors have been selected both from industry and universities in order to provide a balance between scientific and rather practical approaches.

The handbook has been written by more than 50 authors from 12 countries in Europe, America, and Asia. It consists of 42 chapters, and 23 universities and 9 prominent companies have been directly or indirectly involved in the project.

The handbook has been conceived as a series of independent chapters covering the state of the art and has been divided into eight parts (Modeling, Analysis, and Optimization in Vehicle System Dynamics; Vehicle Concepts and Aerodynamics; Pneumatic Tires and Contact Wheel-Road/Off-Road; Modeling of Vehicle Subsystems; Vehicle Dynamics and Active Safety; Man–Vehicle Interaction; Intelligent Vehicle Systems; and Road Accident Reconstruction and Passive Safety) and begins with a historical introduction.

We have tried not to overemphasize automobiles and have covered motorcycles, commercial vehicles, and off-road vehicles as well. The main focus, however, is on automobiles.

We have provided the authors with a free hand to express their remarkable experience in their chapters. The contributions were later balanced by a careful reading of all the chapters by the editors. The topics that were not covered have been respectively requested to the proper authors.

We are fully aware that the handbook will not remain up-to-date forever. Even the delay between the contributions written first and the publication date is not negligible. Anyway, the contributions have been written in a plain, informative manner and are centered on basic issues: they will be useful for a relatively long time.

The handbook is a collection of formulae and/or plots that help solve problems without any mathematical proof (left to a subsequent reading of papers or books cited in the literature). Minor technical problems have been omitted, and only high-level scientific/technical problems have been dealt with. We have tried to follow the high standards set by the book on the mechanics of pneumatic tires edited by S. K. Clark, which was published by the U.S. Department of Transportation in 1981.

We wanted this book to mirror the scientific/technical approaches that are used worldwide to solve vehicle system dynamics design problems. We have therefore allowed different views of the same topic given by different authors, assigning responsibility to the reader for a (guided) critical usage of the information collected in the handbook. Engineering is a stimulating, complex field, and allowing a single opinion on a still open question would have considerably reduced the richness of the handbook.

The handbook can be used starting from… the *bottom*, that is, by referring to the subject index to find the desired topic in the book. The experienced reader can go through the book in any order. The inexperienced reader may benefit from studying the "horizontal" chapters, positioned at the beginning of the handbook, that deal with general topics (such as system modeling, analysis, and optimization, Chapters 2 through 10). Such horizontal chapters are the basis for the subsequent reading of the "vertical" chapters that deal with special topics (such as tires and vehicle subsystems, man–vehicle interaction, and active and passive safety, Chapters 11 through 42). In any case, the subject index can help the reader identify the parts of the handbook (belonging either to the horizontal or to the vertical chapters) that are of his or her interest.

As mentioned earlier, the handbook is devoted both to the beginners wishing to acquire a basic knowledge on a topic and to the experienced engineer or scientist wishing to have an up-to-date information on a particular field. This apparently conflicting aim was achieved by asking the authors to deal with basic issues and to add proper references to specialized papers for further reading.

We would like to thank all the authors for their great efforts and for having participated enthusiastically in the project. They have patiently edited and revised their chapters and have provided a final shape to the handbook, reflecting current knowledge on road and off-road vehicle system dynamics.

It has been more than 100 years since the world's first motor vehicle was invented (Figure 1.1). Since then, automobiles have been widely accepted in society with the progress of modern industry. Moreover, as shown in Table 1.1, since the invention of the first motor vehicles, chassis technology as well as components such as the tire, steering, suspension, brake, and power train have been extensively studied and equipped on vehicles to secure their handling, driving performance, stability and also to improve ride comfort. Table 1.1 shows that the fundamental theories of vehicle dynamics including modeling of vehicle motion and tire have been presented since the 1950s. These theories lead to a large growth in the study of vehicle dynamics and great development of various types of chassis control technologies during the last 20 years of the twentieth century. This section will brief on history of vehicle system dynamics based on Table 1.1 and a number of excellent state-of-the-art papers in the last two decades.

In the study of vehicle dynamics, it is common to treat the vehicle as a rigid body, which has six degrees of freedom in motion. To take a glance at the technologies of vehicle dynamics in a systematic approach, Figure 1.2 shows a conceptual diagram of the relationship between each degree of freedom of the vehicle, and how each control input relates to each vehicle motion and vehicle performances [1].

1.1 COMPONENTS

At the top of Table 1.1, the history of components equipped in the motor vehicles is shown. The first row shows the development of the driving system, from engine to motor. Due to today's environmental problems, technology of low-emission vehicles has been developed since the last decade of the twentieth century. The second row shows the development of tires. Recently, a tire that can measure its generating forces is now in development process. In the conventional gasoline vehicle, the trend toward using an electric motor cooperating with the engine is increasing in order to improve traction performance and fuel economy. In addition, as for miniaturization of the motor,

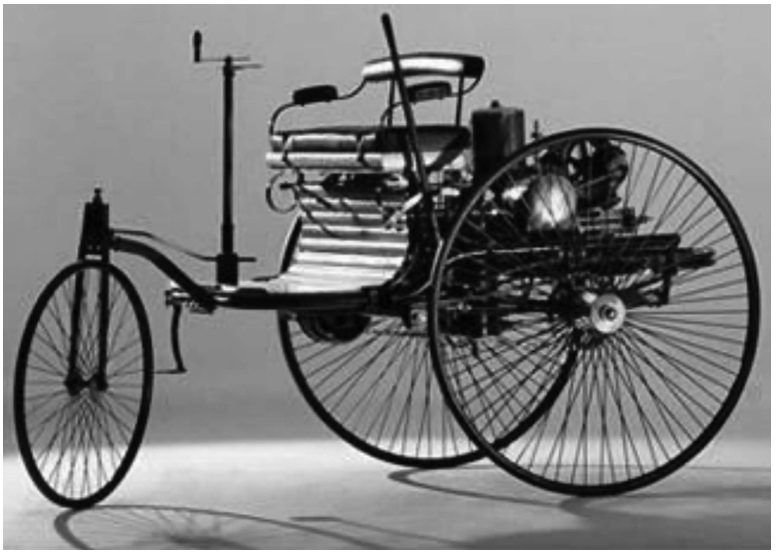

FIGURE 1.1 1886 Benz "Patent Motor Car" first high-speed single-cylinder four-stroke engine.

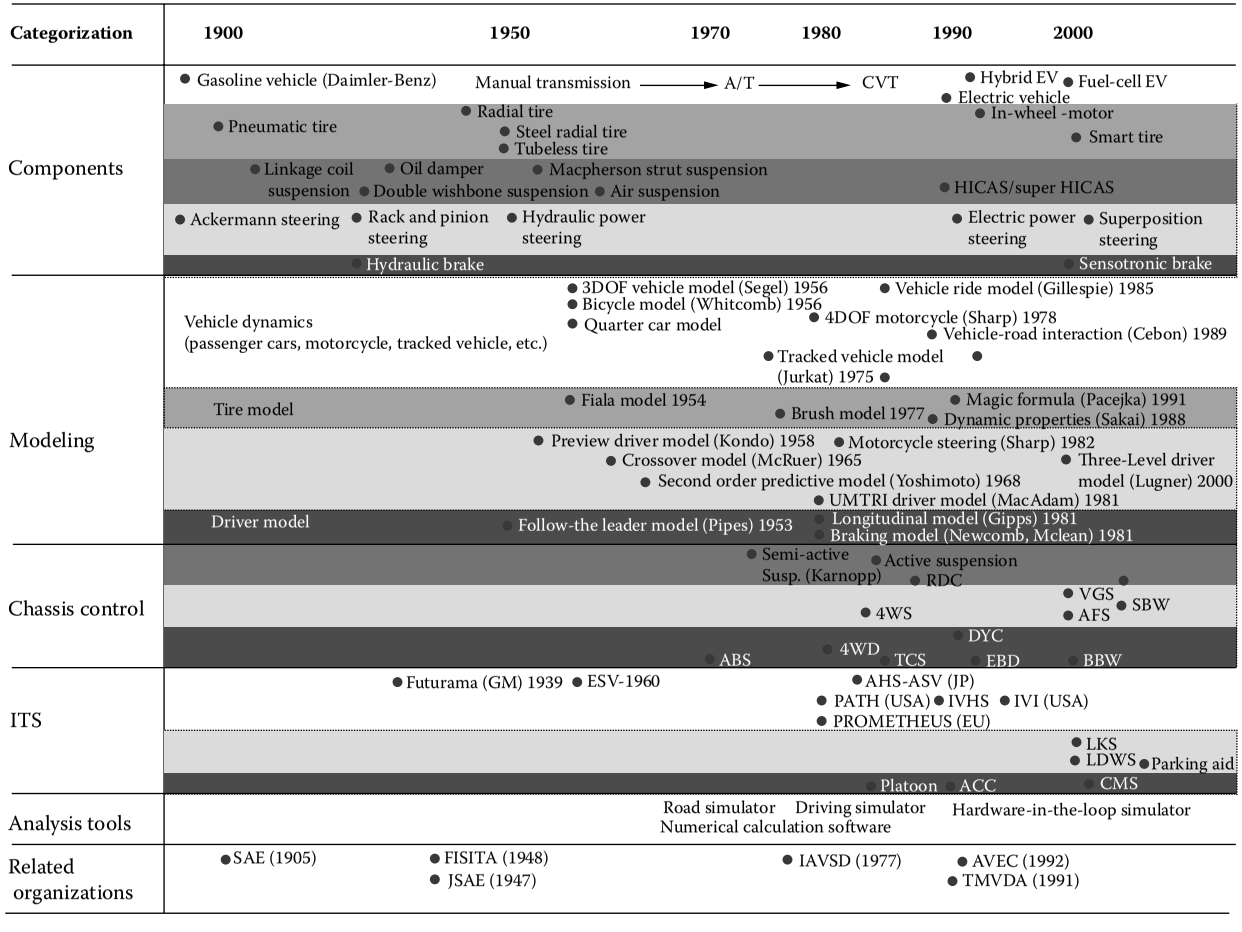
a sophisticated configuration called the "in-wheel motor" plays an important role as the main driving source of electric vehicle. The third row shows the development of the suspension system, the fourth row shows the development of the steering system, and the last row shows the development of the braking system. As for recent advance in electronic control devices, it is obvious that the mechanical linkage is going to be replaced by "mechatronics."



1.2 MODELING

A number of mathematical models used to describe vehicle and tire dynamics have been proposed since the 1950s. From Table 1.1, the modeling of vehicle dynamics can be categorized into three parts: the vehicle model, tire model, and driver model.

1.2.1 Vehicle Model (Chapters 27 through 35)

In modeling vehicle motion, a road vehicle treated as a rigid body has six degrees of freedom, which are lateral, longitudinal, vertical, yawing, pitching, rolling directions. However, in order to analyze characteristics of vehicle motion, a simpler model is more attractive to employ. Segel presented a three-degree-of-freedom model considering lateral, yawing, and rolling motion to describe vehicle-cornering characteristics in 1956 [2]. Moreover, Whitcomb and Milliken presented a well-known two-wheel vehicle model in 1956 neglecting rolling motion and this is a useful model in theoretical analysis of lateral motion and control until now [3]. A quarter car model for analyzing characteristics of a suspension system was also presented around the same time. Gillespie presented a vehicle ride model in 1985 for simulating dynamic tire forces [4]. Besides four-wheel motor vehicles, in 1978, Sharp presented a four-degree-of-freedom model of a motorcycle considering rolling motion in the two-wheel model and also explained the theory of steering behavior of motorcycles by calculating eigenvectors for (straight-line) weave and wobble modes, etc. [5,6]. Modeling of an articulated vehicle is also studied to analyze the braking stability and phenomena of jackknifing. Cebon reviewed vehicle–road interaction characteristics in [7] and contributed a number of technical papers on vehicle-generated road damage and also running on a bridge [8]. Besides models of road vehicles, tracked vehicle dynamics, including mobility over soft terrain, ride dynamics over rough surfaces,

TABLE 1.1
Historic Synopsis of Vehicle System Dynamics

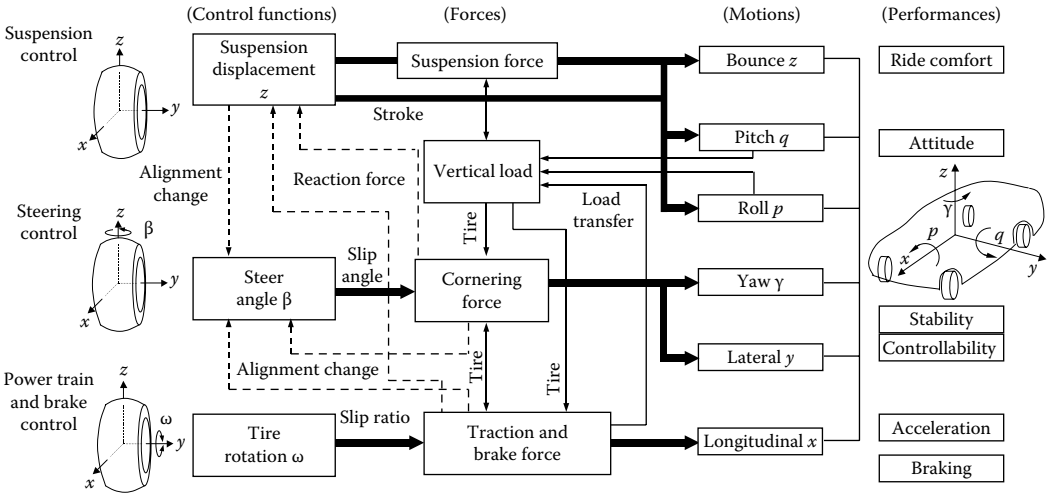


FIGURE 1.2 Conceptual diagram of vehicle dynamics and control. (From Kizu, R. et al., Electronic control of car chassis—Present status and future perspective, *IEEE International Congress on Transportation Electronics*, 88CH2533-8, 1988, pp. 173–188.)

and maneuverability, is also one of our interests. The empirical approach to the modeling of tracked vehicle mobility is best exemplified by the work of the U.S. Army Engineer Waterways Experiment Station in 1975. Wong presented models known as NTVPM for flexible tracks, and RTVPM for rigid link tracks with a long track pitch used in agricultural vehicles and construction vehicles, and reviewed the simulation models [9] (see Chapters 20 and 34).

1.2.2 Tire Model (Chapters 17 through 20)

Tire models play an important key role in chassis control system design and analysis of vehicle dynamics. A very simple approach for the tire model is a spring constant for vertical deflections (as used with quarter car models) and a linear relationship between slip angle and lateral force generation (as used with two-wheel models). Theoretical approaches for modeling nonlinear characteristics of longitudinal and lateral forces of tires with respect to slip phenomenon were presented by Fiala and the well-known Brush model. Mixed longitudinal and lateral slip can be taken into consideration by a characteristic curve, groups of curves, or by suitable approximation functions, for example, works by Bakker et al. [10]. Moreover, the dynamic tire characteristics require further details: in the simplest approaches, a first-order differential equation approximates the tire force buildup, presented by Sakai [11]. For more precise reproduction of forces due to short-wave road unevenness, further refinements of the tire model structure are necessary as found in F-Tire or RmodK, presented by Gipser [12]. A detailed nonlinear dynamic finite element method (FEM) like DNS-Tire, also presented by Gipser, may be necessary in the case of investigations of extreme situations. FEM plays a significant role in the field of tire mechanics as shown by Knothe et al. who reviewed tire–road contact mechanics in [13]. Moreover, tire–road contact is an important topic in studying vehicle dynamics and stability, as demonstrated by Knothe and Boehm who reviewed running stability and its historic synopsis in [14].

1.2.3 Driver Model (Chapter 38)

Due to the limited scope of this section, the emphasis here is on the control aspect of the human driver and his/her modeling. In the investigation of vehicle dynamics and design of chassis control, human factors are inevitably involved in the procedures. Even though development in chassis design and control can greatly enhance vehicle performance, one thing that cannot be neglected

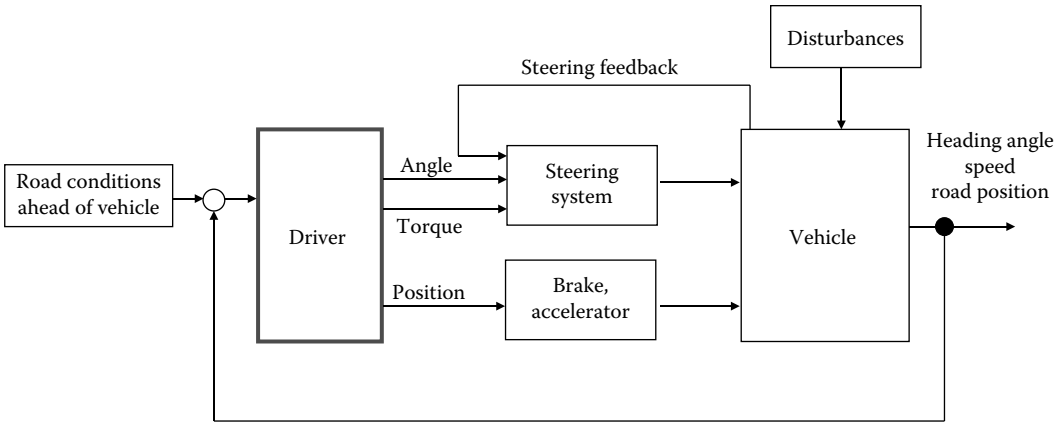

FIGURE 1.3 Hypothetical vehicle control loop including driver.

is the characteristics of the driver who operates the vehicle by recognizing the road environment as a closed-loop system, as shown in Figure 1.3. In addition, in the development of autonomous vehicles and driver assistance systems, human factors become more and more important in the design of such systems than in the past. In near future, the importance of studying the driver model will increase in supporting the design of a driver–environment-adaptive vehicle control system, as shown in Figure 1.4 [15]. From 1950s, the proposed driver modeling can be classified into two groups: the longitudinal driver model and the lateral driver model [16,17]. Complete treatments of the driver modeling effort and associated measurements of driver–vehicle system responses have emerged, particularly with the increased use of computers and driving simulators.

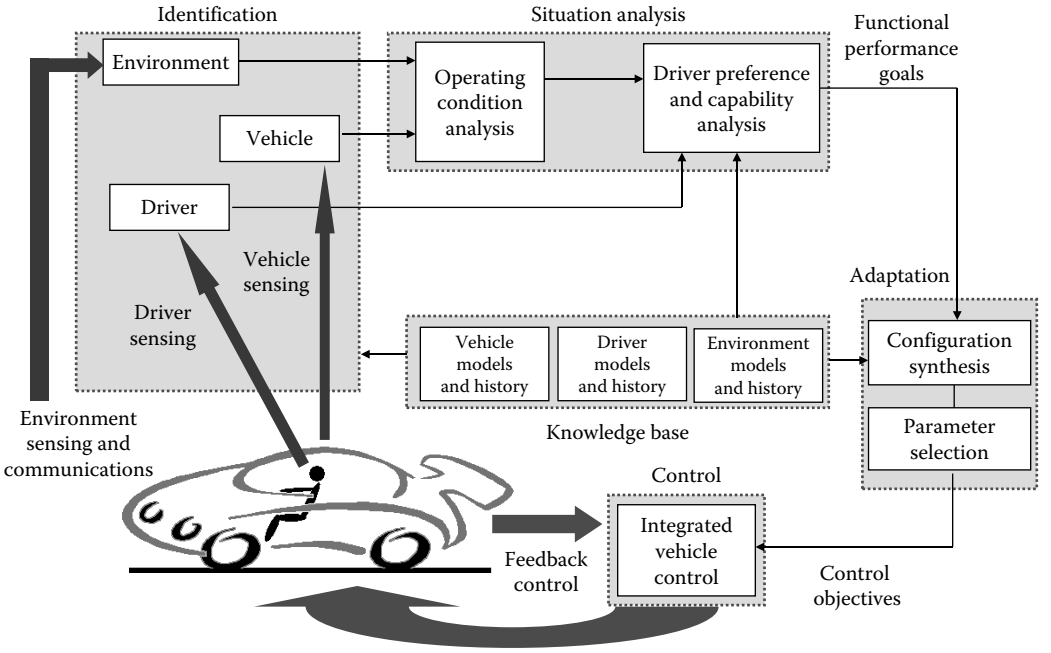

FIGURE 1.4 Design concept of driver–environment–adaptive vehicle control system. (From Schilke, N.A. et al. Integrated vehicle control, *Proceedings of International Congress on Transportation Electronics, IEEE/SAE Convergence*, 88, Michigan, USA, 1988, pp. 97–106.)

The concept that the human driver must look ahead becomes the first representative concept in modeling the lateral driver model. Kondo and Ajimine's work focused on measuring the driver "sight point" ahead of the vehicle and developed steering based on deviations between the sight point and the desired course [18]. Yoshimoto included a "second prediction term" into the preview driver model to represent driver anticipation when entering a curve [19]. To model the adaptive control behavior of the human driver, McRuer and Jex offered the now well-known crossover model for automobile drivers [20]. Ploechl and Lugner proposed the three-level driver model, anticipatory control, compensatory control, and local control, and explained its application to driving simulations [21]. There is also an attempt to develop a driver model capability applicable to nonlinear, near-limit operating conditions, for example, when a tire blows out, as in the GM/UMTRI (General Motors/The University of Michigan, Transportation Research Institute) driver model presented by MacAdam [22].

Examination of technical papers related to the longitudinal driver model reveals that models and associated studies of driver braking/acceleration control behavior are relatively sparse when compared to work related to lateral steering control. Pipes suggested a linear follow-the-leader model, in which the driver accelerates the vehicle in proportion to the speed difference between the leading vehicle and the following vehicle, in 1953 [23]. Gipps proposed a switching vehicle speed model based on two competing considerations: to keep a safe distance from the lead vehicle and to converge to the desired free flow speed [24]. Newcomb and McLean provide examples of modeling of the driver–vehicle system during longitudinal braking [25]. As for the development of adaptive cruise control (ACC), researchers employ a longitudinal vehicle model to design and analyze the behavior. The works of Fancher et al. are primarily concerned with the headway control behavior of typical drivers and their interaction with ACC systems during highway driving [26]. Peng's recent work using a modified version of Gipps' model is likewise advancing the modeling effort in the headway control area and accurately represents traffic flow behavior of human drivers [27].

1.3 CHASSIS CONTROL [28,29] (CHAPTERS 30 THROUGH 32)

In the last three decades, in the field of vehicle system dynamics, the largest number of technical papers presented and published is on the topic of chassis control system development, in both theoretical and experimental studies. As shown in Figure 1.2, the vehicle chassis control is, in general, to control lateral, vertical, and longitudinal vehicle motions in order to improve handling performance, ride comfort, traction/braking performance, and active safety of the vehicle. As for the major developments of vehicle modeling including tire modeling, the theory of vehicle dynamics shows its potential in applications to the design of chassis control technology to enhance driving performance as well as driving safety. The first representative chassis control technology is the brake system, which is well known as the "antilock-braking system" (ABS). At present, it is the standard equipment in passenger cars. To enhance ride comfort of the vehicle, employing a quarter car vehicle model aids in the design of semi-active suspension and active suspension. Active suspension control can also be adapted to the design of roll distribution control to improve roll stability, especially in heavy duty vehicles. To improve traction performance especially on slippery roads, a traction control system (TCS) has been presented and now is a standard equipment in high-class passenger cars along with ABS.

From the mid-1980s, researchers paid more attention to the chassis control technology in lateral motion. As vehicle speed increases, the vehicle tends to lose its cornering stability due to the increment of centrifugal acceleration. The first technology that improved vehicle lateral motion is four-wheel steering system (4WS). Steering the rear wheel together with the front wheel improves not only low-speed maneuverability but also high-speed stability and handling response. Most of the research on 4WS uses zero-sideslip response as a control objective; thus, the ratio of rear steer angle to front steer angle becomes a function of vehicle speed. In real applications, Sano et al. proposed a type of 4WS in which the rear wheel is steered as a nonlinear function of steering wheel angle [30].

Sato et al. proposed a type of 4WS, which makes use of feedforward of steering wheel angle and feedback of yaw rate to make the control system more robust to external disturbances [31]. Shibahata et al. proposed a 4WS system, which uses a feedforward control for controlling rear wheel steering angle dynamically [32]. A feature of this system is that the rear wheels are steered in the opposite direction to the front wheels when the steering wheel is turned quickly. However, since 4WS control depends on the tire lateral force, in a range where the lateral acceleration is comparatively high, the lateral force becomes saturated and the 4WS cannot perform its control effectively anymore.

To overcome this problem, a new strategy using tire longitudinal forces to control vehicle lateral motion was proposed, and called direct yaw-moment control (DYC). At the International Conference on Advanced Vehicle Control, AVEC'92, there were a number of technical papers on this technology. As a common approach for vehicles in productions, by utilizing the existing ABS hardware or traction force distribution control, DYC system can be realized in real applications. As a representative concept of using DYC to stabilize vehicle motion, Shibahata et al. proposed a "β-method" which points out that instability of vehicle lateral motion is caused by the decrease of restoring yaw moment as the vehicle-sideslip angle becomes larger [33]. It is suggested that DYC should be designed not only to control the vehicle yaw motion but also to control the sideslip motion. Nowadays, in the automobile market, DYC is commonly used for the objective of sideslip prevention, and also for rollover prevention, especially for commercial vehicles. However, control performance of DYC greatly depends on sideslip angle sensing and estimation accuracy, which becomes one of the most important topics in recent years. Since the sideslip angle within the nonlinear region is closely related to the friction coefficient μ between the tire and road surface, it is important to simultaneously detect or estimate the μ value. A number of studies on estimation of β and μ and the sensing and estimation of tire lateral force have been reported since the sessions of Sensors and Actuators in AVEC'94.

In the last few years of the twentieth century, researchers paid attention to the active steering control of the front wheel by electronic control instead of conventional mechanical linkage. The technique of steer-by-wire (SBW) system or power-assisted steering (HPS, EPS) is applied to the steering system to realize active front steering (AFS) [34]. Additional steering control of the front wheel is proposed, to make steering maneuvers easier for drivers, such as in variable gear-ratio steering, and for disturbance compensation, for example, μ-split, wind gust. To improve the driver's feel for steering, techniques of steering reaction torque control are also applied to the system. By analyzing the control characteristics of the driver–vehicle closed-loop system, the design of active control of the front wheel angle and steering reaction torque can be considered in various approaches.

Moreover, combining these chassis control technologies can more effectively enhance vehicle handling and stability. There are many approaches of integrated control, which have been proposed by many researchers. On lateral control, technique of a model following control method is applied to determine each control input to track the desired steering responses [35–37]. In addition, study on optimizing tire force usage for vehicle dynamics control is being conducted in order to achieve maximum vehicle dynamics performance from the viewpoint of tire limit performance [38,39]. Recently, Gordon et al. also provided the scope, methodologies, and architectures for the design and development of interacting control systems in road vehicles in [40].

1.4 INTELLIGENT TRANSPORT SYSTEMS [41–44] (CHAPTERS 39 AND 40)

Following the contents of this handbook, the history of intelligent vehicle–highway systems (IVHS) and advanced vehicle control systems (AVCS) will be mentioned here. The control systems can be categorized into lateral control and longitudinal control. Research on lateral control mainly focuses on the use of an automatic steering device to track lanes automatically. The lane sensing system can be considered as a structure using inductive cables and magnetic markers embedded in the pavement along the lane centerline, or as a machine vision system, with cameras mounted on the vehicle, and image processing software used to identify the location and alignment of the vehicle relative to

the lane markers. Machine vision for road vehicle guidance is recently becoming the main approach to real systems. Applications of this system are the lane-keeping assistance system and the lane departure avoidance system. Besides the lane-keeping control system which focuses mainly in high-speed regions, a driver assistance system in low-speed regions like the Parking Assistance System utilizing an electric power steering device to park a car in the position that the driver desires can also be categorized in this field.

For almost four decades, vehicle longitudinal control has a longer and richer history relevant to AVCS than lateral control. While lateral control is a function of each individual vehicle relative to the roadway reference, longitudinal control adds the complication of potential interactions among multiple controlled vehicles. Control algorithms proposed can be roughly grouped into two categories: (1) fixed block control or point following control and (2) vehicle following control. The largest volume of research in this area is in vehicle-following longitudinal control systems, with the objectives of providing greater lane capacity and reducing traffic congestions. The works on ACC and platoon driving are the main core of this field. An interesting aspect of longitudinal control for automated vehicles is the concept of "string stability." The term string stability refers to the propagation of a vehicle speed perturbation, in other words the amplified response of distance between vehicles, from one end toward the other end of a string of vehicles. For longitudinal collision avoidance, there are systems like head-on crash warning and control systems utilizing automatic braking system such as the collision mitigation system (CMS), which has been already released in the Japanese market.

1.5 ANALYSIS TOOLS [45] (CHAPTERS 2 THROUGH 10)

Numerical simulations are increasingly focused on ride and handling development processes. The simplest models like mass point models and two wheel models can be expressed in classical programming languages such as FORTRAN, C, and C++. They can also be applied with system simulation software such as MATLAB®/Simulink® and Matrix/System Build. Complete solutions for calculating complex models are available on the market, such as Ve-Dyna or Carsim that shows attractive animation. Multi-Body System (MBS) tools like ADAMS from MDI, DADS from LMS, and Simpack from INTEC are based on the simulation of mechanical basic elements such as mass, joints, and springs, and are complemented by numerous component models.

Another way to investigate the vehicle dynamics or effectiveness of the proposed chassis control system by avoiding proving ground tests is using a simulator. Hardware-in-the-Loop (HIL) Simulation techniques allow the integration of real components, for example, tire, steering, braking, etc., into the loop of numerical calculations, which is useful in evaluating and validating the component on virtual driving environments. The driving simulator, specifically the human driver-in-the-loop simulator, is well known for studying the human–machine interface, vehicle handling investigations, and ride comfort.

1.6 RELATED ORGANIZATIONS AND EVENTS

Finally, in reviewing the history of vehicle dynamics, it is impossible to neglect the associations and symposiums that have been organized with the purpose of bringing engineers and researchers from around the world together to share ideas and advance the technological development of the automobile. Society of Automotive Engineers (SAE), founded in 1905, was the first organization deeply related to motor vehicle technology. Next, the International Federation of Automotive Engineer Societies (FISITA) was found in 1948 in Paris and organizes world congress every 2 years. The International Association of Vehicle System Dynamics (IAVSD), found in 1977 in Vienna, is the organization most related to the topics on this handbook. IAVSD organizes a symposium every 2 years where technical papers on not only road vehicles but also rail vehicles are presented and discussed. The International Symposium on AVEC was first organized in 1992 in Yokohama, Japan,

in order to share information on control technology related to automobile applications. At last, the International Tyre Colloquium: Tyre Models for Vehicle Dynamics Analysis (TMVDA), first held in 1991 in the Netherlands, has been organized to address recent investigations and developments in the field of road–tire–vehicle interactions.

Finally, from the reviewed history, we hope the reader could gain a macroscopic view of vehicle system dynamics, and realize that there still remains a number of research challenges and issues to analyze vehicle dynamics and implement vehicle advanced control technologies for future vehicles. The contents that follow this chapter will be extensively contributed in detail by experts in their specialized fields.

2.1 INTRODUCTION

Performance, safety, and comfort of a vehicle are related to its low-frequency motions. The corresponding mechanical models are characterized for all kinds of vehicles by stiff parts represented as rigid bodies and soft components like springs, dampers, and actuators (Figure 2.1). The method of multi-body systems is most appropriate for the analysis of vehicle motions and vibrations up to 50 Hz. In this contribution, the derivation of the equations of motions of multi-body systems is shown step by step up to the computer-aided evaluation of these equations.

The roots and perspectives of multi-body system dynamics have been summarized in Ref. [1]. The fundamentals of vehicle system dynamics are presented in textbooks by Popp and Schiehlen [2], Ammon [3], Dukkipati [4], and Wong [5]. Many references are also available from the proceedings of the biennial international symposia on the dynamics of vehicles on roads and tracks, edited, for example, by Berg and Stensson Trigell [6]. Some computational aspects and characteristic benchmarks of multi-body dynamics are presented in the *Multibody System Handbook* [7], and multi-body computer codes in vehicle system dynamics are considered by Kortüm and Sharp [8].

Starting with kinematics for rigid body vehicle systems, the foundations of dynamics together with the principles of d'Alembert and Jourdain are used to get the equations of motion. Then, some aspects

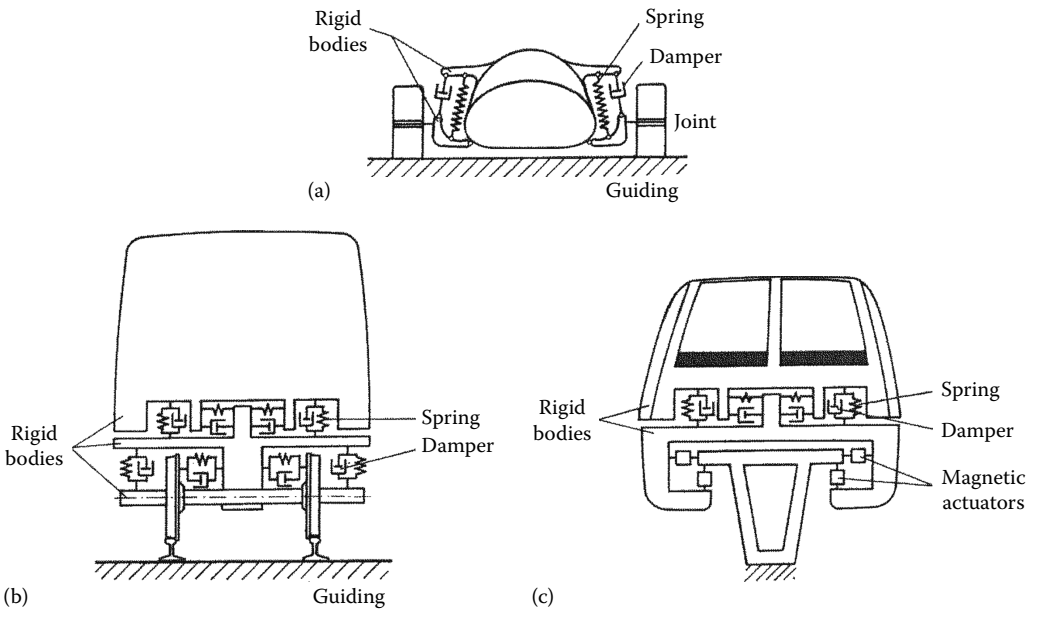

FIGURE 2.1 Multi-body models of vehicles: (a) road vehicle, (b) rail vehicle, and (c) magnetically levitated vehicle.

of multi-body dynamics formalisms and computer codes for vehicle dynamics will be discussed. This contribution is based on original German edition of the monograph by Popp and Schiehlen [2]. Some revisions are found in the English edition and the Chinese translation.

2.2 KINEMATICS

The elements of multi-body systems for vehicle modeling (see Figure 2.1) include rigid bodies, which may also degenerate to particles, coupling elements like springs, dampers, or force-controlled actuators as well as ideal, that is, rigid kinematical connecting elements like joints, bearings, rails, and motion-controlled actuators. The coupling and connection elements are generating internal forces and torques between the bodies of the system and external forces with respect to the environment. Both of them are considered as massless elements.

The kinematical constraints resulting from the connecting elements may be holonomic or non-holonomic, scleronomic or rheonomic, respectively. Holonomic constraints reduce the motion space of the system while non-holonomic constraints reduce the velocity space in addition. The constraint equations are called rheonomic if they depend explicitly on time, or scleronomic otherwise. Real vehicle systems are subject to holonomic constraints only which may be given by geometrical or integrable kinematical conditions. However, in more simplified models, for example, rolling of a rigid wheel or wheelset on a rigid plane, non-holonomic constraints may occur. Some designs of holonomic connecting elements are listed in Table 2.1 depending on the number of degrees of freedom characterizing the remaining possibilities of motion.

Now the motion of vehicle parts will be described mathematically depending on space and time. This is the task of kinematics.

2.2.1 Frames of Reference for Vehicle Kinematics

A prerequisite for the mathematical description of position, velocity, and acceleration of a mechanical system is the definition of appropriate frames of reference. The frames required in vehicle dynamics are shown in Figure 2.2 with the details summarized in Table 2.2. They will be used

TABLE 2.1
Designs for Holonomic Connecting Elements

	Degrees of Freedom		
Motion	**1**	**2**	**3**
Rotary	Revolute joint	Universal joint	Spherical joint
Linear	Prismatic joint	Planar joint	
Mixed	Screw joint	Cylindric joint	General planar joint

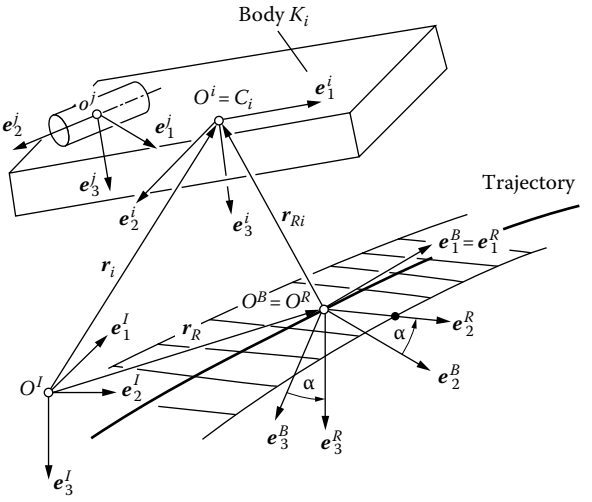

FIGURE 2.2 Frames of reference.

TABLE 2.2
Frames of Reference

Frame of Reference	**Origin of Frame**	**Orientation of Axes**
Inertial frame	O^I	$\boldsymbol{e}_1^I$, $\boldsymbol{e}_2^I$ in horizontal plane
$\left\{O^I, \boldsymbol{e}_\upsilon^I\right\}$	Space fixed	$\boldsymbol{e}_3^I$ perpendicular
Moving trihedron	O^B	$\boldsymbol{e}_1^B \equiv \boldsymbol{e}_t$ tangential to trajectory
$\left\{O^B, \boldsymbol{e}_\upsilon^B\right\}$	Trajectory fixed	$\boldsymbol{e}_2^B \equiv \boldsymbol{e}_1^B$ normal to trajectory
		$\boldsymbol{e}_{31}^B \equiv \boldsymbol{e}_b$ binormal to trajectory
Reference frame	O^R	$\boldsymbol{e}_1^R \equiv \boldsymbol{e}_1^B$
$\left\{O^R, \boldsymbol{e}_\upsilon^R\right\}$	Trajectory fixed	$\boldsymbol{e}_2^R$ in guideway plane
		$\boldsymbol{e}_3^R$ normal to guideway plane
Body-fixed frame	$O^i = C_i$	
$\left\{O^i, \boldsymbol{e}_\upsilon^i\right\}$	Body fixed in center of mass	$\boldsymbol{e}_\upsilon^i$ principle inertia axes
Local frame	O^j	
$\left\{O^j, \boldsymbol{e}_\upsilon^j\right\}$	Arbitrary	$\boldsymbol{e}_\upsilon^j$ locally specified axes

only right-handed Cartesian frames with the unit base vectors $\boldsymbol{e}_\upsilon$, $|\boldsymbol{e}_\upsilon| = 1$ where the Greek indices generally take the integers 1, 2, 3. A basis or frame $\{O, \boldsymbol{e}_\upsilon\}$, respectively, is completely defined by its origin O and its base vectors $\boldsymbol{e}_\upsilon$. For distinction between different frames, the upper right index is used if necessary.

The inertial frame $\left\{O^I, \boldsymbol{e}_\upsilon^I\right\}$ serves as the general reference frame, in particular for the evaluation of the acceleration. The given trajectory of the vehicle is assumed to be a space curve with the moving frame $\left\{O^B, \boldsymbol{e}_\upsilon^B\right\}$ also known as Frenet frame or moving trihedron. The origin O^B is moving with a given speed tangential to the trajectory. The reference frame $\left\{O^R, \boldsymbol{e}_\upsilon^R\right\}$ is closely related to the moving frame. Its origin and the first unit vector coincide with the moving frame $O^R = O^B$, $\boldsymbol{e}_1^R = \boldsymbol{e}_1^B$. The second base vector $\boldsymbol{e}_2^R$, however, is parallel to the guideway surface considering the bank of the road or the track, respectively, pointing to the right with respect to the direction of motion.

The body-fixed frame $\left\{O^i, \boldsymbol{e}_\upsilon^i\right\}$ is the principal axis frame of the rigid body K_i located in its center of mass C_i. This frame describes uniquely the position in space of the body. Finally, there is a defined local frame $\left\{O^j, \boldsymbol{e}_\upsilon^j\right\}$ to describe constraint elements between bodies. It is oriented according to the local specifications like the direction of a joint axis. In the following, a frame is simply identified by its name (upper right index) only.

2.2.2 Kinematics of a Rigid Body in an Inertial Frame

First of all, some definitions and remarks on the nomenclature are presented.

The position of a particle P in space is uniquely defined by the position vector $\boldsymbol{x}$ represented in the inertial frame $\left\{O^I, \boldsymbol{e}_\upsilon^I\right\}$ by its coordinates x_υ as

$$\boldsymbol{x} = x_1\, \boldsymbol{e}_1 + x_2\, \boldsymbol{e}_2 + x_3\, \boldsymbol{e}_3. \tag{2.1}$$

This set of coordinates may be summarized in a column matrix $\boldsymbol{x}^I$ often simply called a vector, that is,

$$\mathbf{x}^{\mathrm{I}} = \begin{bmatrix} x_1 \\ x_2 \\ x_3 \end{bmatrix} \equiv \begin{bmatrix} x_1 & x_2 & x_3 \end{bmatrix}^{\mathrm{T}}, \tag{2.2}$$

where upper right index defines the frame in which the coordinates are measured. This index will often be deleted if there is not any possibility for a mix-up of frames or if there is used only one frame identified in the text. The goal is to present all vector and tensor quantities in one common frame, for example, the inertial frame I. Then, it is possible to integrate subsystems easily into the complete system.

For a particle P moving in time its coordinates are time-dependent too, and they define a trajectory in space. The mathematical representation results in the vector equation $\boldsymbol{x} = \boldsymbol{x}(t)$ equivalent to three scalar equations according to the three degrees of freedom of the particle in the 3D space. The velocity $\boldsymbol{v}(t)$ and the acceleration $\boldsymbol{a}(t)$ of the particle followed by differentiation with respect to time as

$$\boldsymbol{v}(t) = \frac{d^I \boldsymbol{x}(t)}{dt}, \quad \boldsymbol{v}^I(t) = \dot{\boldsymbol{x}}^I(t) = \begin{bmatrix} \dot{x}_1 & \dot{x}_2 & \dot{x}_3 \end{bmatrix}^{\mathrm{T}}, \tag{2.3}$$

$$\boldsymbol{a}(t) = \frac{d^I \boldsymbol{v}(t)}{dt}, \quad \boldsymbol{a}^I(t) = \dot{\boldsymbol{v}}^I(t) = \ddot{\boldsymbol{x}}(t) = \begin{bmatrix} \ddot{x}_1 & \ddot{x}_2 & \ddot{x}_3 \end{bmatrix}^{\mathrm{T}}. \tag{2.4}$$

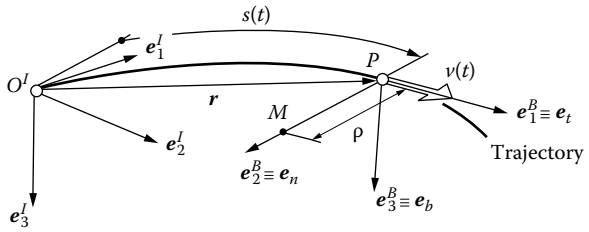

FIGURE 2.3 Trajectory of particle *P*.

The upper right index refers to the frame of reference in which the operations, in particular the differentiation, have to be executed. In the inertial frame *I*, the differentiation of vectors is just performed by differentiation of the scalar coordinates.

The motion of a particle *P* on a curvilinear trajectory in space may be shown in the moving frame *B* too. The position of the point is uniquely identified by the arc length $s(t)$ as a generalized coordinate (Figure 2.3). Then, the position vector $\boldsymbol{r}$ is a function of the arc length, $\boldsymbol{r} = \boldsymbol{r}(s)$. For the velocity and acceleration vector, it yields, see, for example, Magnus and Müller [9],

$$\boldsymbol{v}(t) = \frac{d^I \boldsymbol{r}(t)}{dt} = \frac{d^I \boldsymbol{r}(\mathrm{s})}{ds}\frac{ds}{dt} = v\boldsymbol{e}_t, v = \dot{s},$$

$$\boldsymbol{v}^{\mathrm{B}}(t) = \begin{bmatrix} \dot{s} & 0 & 0 \end{bmatrix}^{\mathrm{T}}, \tag{2.5}$$

$$\boldsymbol{a}(t) = \frac{d^I \boldsymbol{v}(t)}{dt} = a_t \boldsymbol{e}_t + a_n \boldsymbol{e}_n = \dot{v}\boldsymbol{e}_t + \frac{v^2}{\rho}\boldsymbol{e}_n,$$

$$\boldsymbol{a}^{\mathrm{B}}(t) = \begin{bmatrix} \ddot{s} & s^2/\rho & 0 \end{bmatrix}^{\mathrm{T}}, \tag{2.6}$$

where ρ is the curvature of the trajectory in point *P*. Further, it is

$v = \dot{s}$ is the tangent velocity

$a_t = \dot{v} = \ddot{s}$ is the tangent acceleration

$a_n = v^2/\rho = \dot{s}^2/\rho$ is the normal or centripedal acceleration

Special cases of the general motion in space are the motion in a straight line ($\rho \to \infty$), and the motion on a circle (ρ = constant). Often the functions $s(t)$, $\dot{s}(t)$, $\ddot{s}(t)$, $\dot{s}(s)$, $\ddot{s}(s)$, $\ddot{s}(\dot{s})$ are depicted in kinematical diagrams for graphical visualization of the motion along a track.

The translational motion of a rigid body K_i is completely described by the general relations for a particle applied to the center of mass C_i of the rigid body and its position vector $\boldsymbol{r}_i$ (see Figure 2.4).

The rotational motion of a rigid body K_i follows from the relative position of two frames, where one of them is a body-fixed frame. For coinciding origins, an arbitrary position of the body-fixed frame *i* relative to the inertial frame *I* is uniquely defined by three rotation angles according to the three rotational degrees of freedom of a rigid body in space. Both systems are related to each other by three elementary rotations performed successively around different base vectors using three rotation angles. If, for example, the frame *i* is revolved around the coinciding three axes of frame

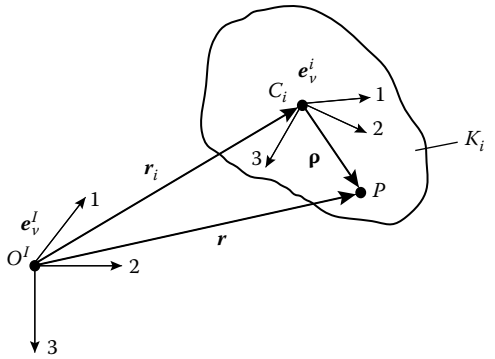

FIGURE 2.4 Position of a rigid body in inertial frame *I*.

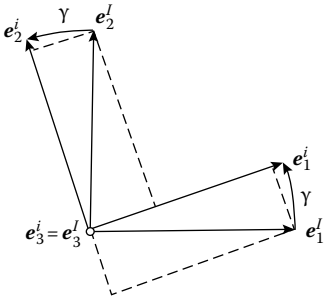

FIGURE 2.5 Elementary rotation from frame *I* to frame *i* around three axes.

I and *i* by the angle γ, the relation of the corresponding base vectors is given by the matrix $\boldsymbol{S}^{Ii}$ as shown in Figure 2.5 and reads as

$$\begin{bmatrix} e_1^I \\ e_2^I \\ e_3^I \end{bmatrix} = \underbrace{\begin{bmatrix} \cos\gamma & -\sin\gamma & 0 \\ \sin\gamma & \cos\gamma & 0 \\ 0 & 0 & 1 \end{bmatrix}}_{\mathbf{S}^{Ii}=\gamma_3} \begin{bmatrix} e_1^i \\ e_2^i \\ e_3^i \end{bmatrix}. \tag{2.7}$$

The row ν of the elementary rotation matrix γ_3 is composed of the coordinates of the base vector $\boldsymbol{e}_\upsilon^I$ in frame *i*. The corresponding matrices for positive rotations around the remaining axes read as

$$\boldsymbol{\alpha}_1 = \begin{bmatrix} 1 & 0 & 0 \\ 0 & \cos\alpha & -\sin\alpha \\ 0 & \sin\alpha & \cos\alpha \end{bmatrix}, \quad \boldsymbol{\beta}_2 = \begin{bmatrix} \cos\beta & 0 & \sin\beta \\ 0 & 1 & 0 \\ -\sin\beta & 0 & \cos\beta \end{bmatrix}, \tag{2.8}$$

where the elementary rotation matrices are characterized by the name of the rotation angle while the index defines the axis of rotation. There are numerous possibilities to choose the name of the angle and the sequence of the rotation axes used which is not commutative. In vehicle dynamics, the Cardan angles α, β, γ are often used (see Figure 2.6), which are different from the well-known Euler angles ψ, ϑ, φ.

The resulting rotation matrices $\boldsymbol{S}^{Ii}$, which present the relation between frames *I* and *i*, are obtained by the corresponding matrix multiplications:

$$\boldsymbol{S}^{Ii}(\alpha,\beta,\gamma) = \boldsymbol{\alpha}_1 \boldsymbol{\beta}_2 \boldsymbol{\gamma}_3, \quad S^{Ii}(\psi,\vartheta,\varphi) = \boldsymbol{\psi}_3 \boldsymbol{\vartheta}_1 \boldsymbol{\varphi}_3. \tag{2.9}$$

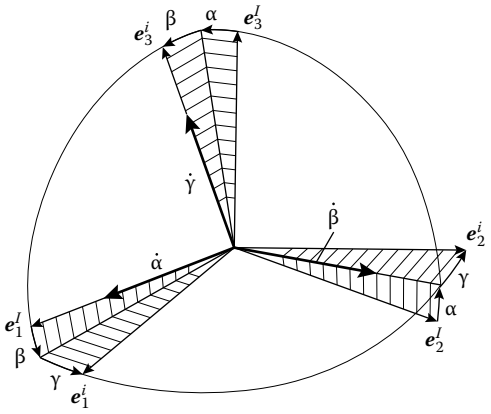

FIGURE 2.6 Spatial rotation from frame *I* to frame *i* by Cardan angles α, β, γ.

Since matrix products are not commutative, the sequence of the elementary rotations has to be strongly observed. The Cardan and Euler angles, respectively, are defined by successive rotations around the 1, 2, 3 axes and 3, 1, 3 axes, respectively, starting from the inertial frame *I*. The sequence of the elementary rotations is uniquely identified by the sequence of the indices of the elementary rotation matrices as shown in 2.9.

The rotation matrices are orthogonal matrices:

$$\left(\boldsymbol{S}^{\boldsymbol{Ii}}\right)^{-1} = \left(\boldsymbol{S}^{\boldsymbol{Ii}}\right)^{\mathrm{T}} = \boldsymbol{S}^{\boldsymbol{iI}}\ , \quad det\boldsymbol{S} = +1, \tag{2.10}$$

where the inversion is also represented by the exchange of the upper indices. The inverse rotation matrix $\boldsymbol{S}^{iI}$ is simply found by transposition of the original rotation matrix $\boldsymbol{S}^{Ii}$.

Using Cardan angles, the rotation matrix reads explicitly as

$$\boldsymbol{S}^{Ii}\left(\alpha,\beta,\gamma\right) = \begin{bmatrix} c\beta c\gamma & -c\beta s\gamma & s\beta \\ c\alpha s\gamma + s\alpha s\beta c\gamma & c\alpha c\gamma - s\alpha s\beta s\gamma & -s\alpha c\beta \\ s\alpha s\gamma - c\alpha s\beta c\gamma & s\alpha c\gamma + c\alpha s\beta s\gamma & c\alpha c\beta \end{bmatrix}, \tag{2.11}$$

where the abbreviations *c* and *s* stand for cos and sin, respectively. In application, often, small rotations are found, $\alpha, \beta, \gamma \ll 1$, resulting in the linearized rotation matrix

$$\boldsymbol{S}^{Ii}\left(\alpha,\beta,\gamma\right) = \begin{bmatrix} 1 & -\gamma & \beta \\ \gamma & 1 & -\alpha \\ -\beta & \alpha & 1 \end{bmatrix}. \tag{2.12}$$

This result is also obtained if the elementary rotation matrices are linearized and multiplied with each other. Due to the vector property of small rotations, the sequence of the multiplications has no longer to be considered. For small rotations, the Cardan angles may be assigned directly to the rotational motions around the body-fixed axes (Figure 2.7). In vehicle engineering, the following notations are used:

α, roll motion
β, pitch motion
γ, yaw motion

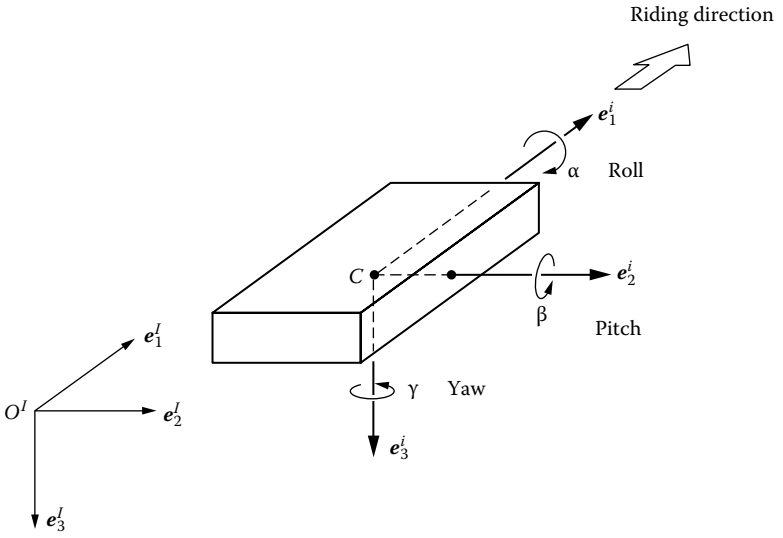

FIGURE 2.7 Notation of rotational vehicle motions.

The coordinates of a vector $\boldsymbol{x}$ read differently for different frames. The relation between the coordinates $\boldsymbol{x}^i$ in frame i and the coordinates $\boldsymbol{x}^I$ in frame I is given by the transformation law for vector coordinates as

$$\boldsymbol{x}^i = \boldsymbol{S}^{iI}\boldsymbol{x}^I \quad \text{and} \quad \boldsymbol{x}^I = \boldsymbol{S}^{Ii}\boldsymbol{x}^i, \tag{2.13}$$

respectively, which is easily proven by 2.10. Please observe that the same indices appear in both forms in a neighboring sequence. This property is often helpful in applications. Further, it has to be pointed out that the rotation matrix $\boldsymbol{S}$ is a function of time, $\boldsymbol{S} = \boldsymbol{S}(t)$, which has to be considered for time derivations.

The position of a rigid body K_i in the inertial frame is uniquely described by the position quantities $\{\boldsymbol{r}_i, \boldsymbol{S}^{Ii}\}$, which characterize the body-fixed frame $\left\{C^i, \boldsymbol{e}_\upsilon^i\right\}$. During motion, the position quantities are functions of time. Thus, the position coordinates of an arbitrary particle P of the rigid body K_i read in the inertial frame I as

$$\boldsymbol{r}^I(t) = \boldsymbol{r}_i^I(t) + \boldsymbol{\rho}^I(t), \quad \boldsymbol{\rho}^I(t) = \boldsymbol{S}^{Ii}(t)\boldsymbol{\rho}^i, \tag{2.14}$$

where it yields in the body-fixed frame ρ^i = constant (see also Figure 2.4).

The motion of a rigid body K_i will be now presented in the inertial frame I, too. The change of the position of its particle P with respect to time relative to frame I is found by differentiation of 2.14 as

$$\dot{\boldsymbol{r}}^I(t) = \dot{\boldsymbol{r}}_i^I(t) + \dot{\boldsymbol{S}}^{Ii}(t)\boldsymbol{\rho}^i = \dot{\boldsymbol{r}}_i^I(\mathrm{t}) + \dot{\boldsymbol{S}}^{Ii}(t)\boldsymbol{S}^{\mathrm{iI}}(t)\boldsymbol{\rho}^I(t). \tag{2.15}$$

The first term on the right-hand side represents the translational velocity of the origin C_i of the body-fixed frame I. The second term is obviously related to the rotation of the body-fixed frame and represents the body's rotation. This term will now be discussed in more detail. The matrix product

$\dot{\boldsymbol{S}}(t)\boldsymbol{S}^{\mathrm{T}}(t)$ is screw symmetric, that is, $[\bullet] = -[\bullet]^{\mathrm{T}}$, which follows immediately from the differentiation of the orthogonality condition $\boldsymbol{S}(t)\boldsymbol{S}^{\mathrm{T}}(t) = \boldsymbol{E}$ according to 2.10:

$$\begin{aligned}\frac{\mathrm{d}}{\mathrm{d}t}\left[\boldsymbol{S}(t)\boldsymbol{S}^{\mathrm{T}}(t)\right] &= \dot{\boldsymbol{S}}(t)\boldsymbol{S}^{\mathrm{T}}(t) + \boldsymbol{S}(t)\dot{\boldsymbol{S}}^{\mathrm{T}}(t) \\ &= \dot{\boldsymbol{S}}(t)\boldsymbol{S}^{\mathrm{T}}(t) + \left[\dot{\boldsymbol{S}}(t)\boldsymbol{S}^{\mathrm{T}}(t)\right]^{\mathrm{T}} = 0. \end{aligned} \tag{2.16}$$

The matrix product $[\bullet]$ will be abbreviated by the symbol $\tilde{\boldsymbol{\omega}}(t)$ and identified by the corresponding three coordinates $\boldsymbol{\omega}_{\mathrm{v}} = \boldsymbol{\omega}_{\mathrm{v}}(t)$ as follows:

$$\dot{\boldsymbol{S}}^{Ii}\left(\boldsymbol{S}^{Ii}\right)^{\mathrm{T}} = \dot{\boldsymbol{S}}^{Ii}\boldsymbol{S}^{iI} = \tilde{\boldsymbol{\omega}}_{Ii}^{I}(t) := \begin{bmatrix} 0 & -\omega_3 & \omega_2 \\ \omega_3 & 0 & -\omega_1 \\ -\omega_2 & \omega_1 & 0 \end{bmatrix}, \quad \boldsymbol{\omega}_{Ii}^{I} = \begin{bmatrix} \omega_1 \\ \omega_2 \\ \omega_3 \end{bmatrix}. \tag{2.17}$$

Both quantities, the screw-symmetric tensor $\tilde{\boldsymbol{\omega}}_{Ii}^{I}$ and the corresponding rotational velocity vector $\boldsymbol{\omega}_{Ii}^{I}$, respectively, describe the rotational motion of system i or body K_i, respectively, relative to the inertial frame I. The upper indices indicate that both quantities are represented in the inertial frame I. If there is no chance for mixing up the frames, the upper and lower index I is simply deleted. The screw-symmetric tensor corresponding with a vector $(\bullet)$ is identified by the symbol $(\tilde{\bullet})$ and it replaces the vector product

$$\tilde{\boldsymbol{\omega}}\boldsymbol{\rho} \equiv \boldsymbol{\omega} \times \boldsymbol{\rho}. \tag{2.18}$$

In coordinates, in any frame, one gets accordingly

$$\tilde{\boldsymbol{\omega}}\boldsymbol{\rho} = \begin{bmatrix} 0 & -\omega_3 & \omega_2 \\ \omega_3 & 0 & -\omega_1 \\ -\omega_2 & \omega_1 & 0 \end{bmatrix} \begin{bmatrix} \rho_1 \\ \rho_2 \\ \rho_3 \end{bmatrix} = \begin{bmatrix} \omega_2\rho_3 - \omega_3\rho_2 \\ \omega_3\rho_1 - \omega_1\rho_3 \\ \omega_1\rho_2 - \omega_2\rho_1 \end{bmatrix}. \tag{2.19}$$

This notation of the vector product is most valuable for numerical computations since the vector product is not defined in matrix calculus.

The rotational velocity vector $\boldsymbol{\omega}_{Ii}^{i}$ in the body-fixed frame i follows from transformation or direct evaluation, respectively. The application of transformation 2.13 to 2.19 results in

$$\tilde{\boldsymbol{\omega}}_{Ii}^{i} = \boldsymbol{S}^{iI}\tilde{\boldsymbol{\omega}}_{Ii}^{I}\boldsymbol{S}^{Ii} = \boldsymbol{S}^{iI}\left(\dot{\boldsymbol{S}}^{Ii}\boldsymbol{S}^{iI}\right)\boldsymbol{S}^{Ii} = \boldsymbol{S}^{iI}\dot{\boldsymbol{S}}^{Ii} = \left(\boldsymbol{S}^{Ii}\right)^{T}\dot{\boldsymbol{S}}^{Ii}. \tag{2.20}$$

The first and second terms of 2.20 represent the transformation law for tensor coordinates where the same indices appear again in a neighboring sequence, the first and last terms show the direct evaluation. The corresponding vector to 2.20 is $\boldsymbol{\omega}_{Ii}^{i} = \boldsymbol{S}^{iI}\boldsymbol{\omega}_{Ii}^{I}$, where the transformation law for vector coordinates has to be used again.

From 2.15 and 2.17, it follows for rigid body K_i

$$\boldsymbol{v}^{I}(t) = \boldsymbol{v}_i^{I}(t) + \tilde{\boldsymbol{\omega}}_{Ii}^{I}(t)\boldsymbol{\rho}^{I}(t). \tag{2.21}$$

Considering 2.18, this is the relation for rigid body kinematics well known from each mechanics textbook as

$$\boldsymbol{v}(t) = \boldsymbol{v}_i(t) + \boldsymbol{\omega}_{Ii}(t) \times \rho(t). \tag{2.22}$$

The relations 2.21 or 2.22, respectively, represent the motion of a rigid body composed by an absolute translational velocity $\boldsymbol{v}_i$ of the body-fixed reference point $O^i = C^i$, and a rotation with the angular velocity $\boldsymbol{\omega}_{Ii}$. The fundamental kinematical quantities $\{\boldsymbol{v}_i, \boldsymbol{\omega}_{Ii}\}$ are also denoted as twist characterizing uniquely the motion of a rigid body.

2.2.3 Kinematics of a Rigid Body in a Moving Reference Frame

From a mathematical point of view, the kinematical description of the motion of a rigid body is most convenient in the inertial frame I resulting in a more simple representation of the fundamental laws of mechanics. In engineering applications, however, a moving reference frame R related to the vehicle or the guideway, respectively, turns out to be more adequate. The frame R allows a problem-oriented choice of the coordinates and an efficient description of the forces and torques acting on the system. Moving reference frames are also useful in experiments since many measurement data are not related to the inertial frame. The choice of the reference frame R depends on the problem under consideration. In many cases, the frame R characterizes the large nonlinear reference motion of a vehicle while the small deviation from the reference motion results in linear kinematical relations even for rotations.

In the following, the motion of a rigid body is represented in a moving reference frame R the motion of which is known in the inertial frame I by the position vector $\boldsymbol{r}_R(t)$ of its origin, and rotation matrix $\boldsymbol{S}^{IR}(t)$ (see also Figure 2.8). This means that the translational and angular guidance velocities are also known, $\boldsymbol{v}_R^I = \dot{\boldsymbol{r}}_R^I$, $\tilde{\omega}_{IR}^I = \dot{\boldsymbol{S}}^{IR}\boldsymbol{S}^{RI}$ according to 2.3 and 2.17. Considering Figure 2.8, the absolute position quantities $\{\boldsymbol{r}_i, \boldsymbol{S}^{Ii}\}$ of the rigid body read as

$$\boldsymbol{r}_i^I(t) = \boldsymbol{r}_R^I(t) + \boldsymbol{S}^{IR}(t)\boldsymbol{r}_{Ri}^R(t), \tag{2.23}$$

$$\boldsymbol{S}^{Ii}(t) = \boldsymbol{S}^{IR}(t)\boldsymbol{S}^{Ri}(t). \tag{2.24}$$

The absolute motion $\{\boldsymbol{v}_i, \omega_{Ii}\}$ of the rigid body K_i is now found by formal differentiation in frame I and subsequent transformation in frame R as

$$\boldsymbol{v}_i^R(t) = \boldsymbol{v}_R^R(t) + \tilde{\boldsymbol{\omega}}_{IR}^R(t)\boldsymbol{r}_{Ri}^R(t) + \dot{\boldsymbol{r}}_{Ri}^R(t), \tag{2.25}$$

$$\boldsymbol{\omega}_{Ii}^R = \boldsymbol{\omega}_{IR}^R + \boldsymbol{\omega}_{Ri}^R. \tag{2.26}$$

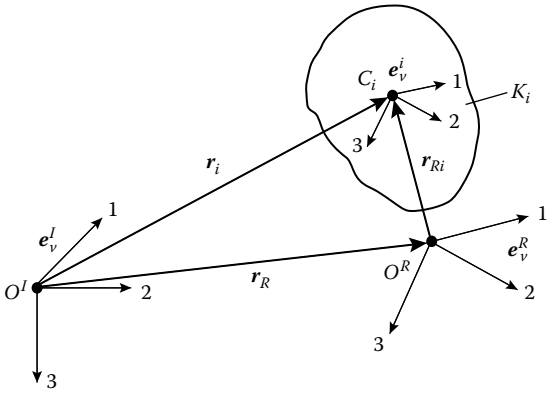

FIGURE 2.8 Position of a rigid body in reference frame R.

Due to the rotation of the frame R, the guidance motion and the relative motion characterized by the indices IR and Ri, respectively, are not simply added but there appears an additional term in 2.25. This implies the well-known law of differentiation in a rotating frame

$$\frac{\mathrm{d}^I}{\mathrm{d}t}\boldsymbol{r}(t) = \frac{\mathrm{d}^R}{\mathrm{d}t}\boldsymbol{r}(t) + \boldsymbol{\omega}_{IR}(t) \times \boldsymbol{r}(t). \tag{2.27}$$

By formal differentiation with respect to the inertial frame indicated by [*] or application of 2.27 to 2.25 and 2.26, one gets finally the absolute translational and rotational acceleration of the rigid body K_i again written in the reference frame R as

$$\boldsymbol{a}_i^R(t) = \boldsymbol{v}^{*R}_R + \left(\dot{\tilde{\boldsymbol{\omega}}}^R_{IR} + \tilde{\boldsymbol{\omega}}^R_{IR}\,\tilde{\boldsymbol{\omega}}^R_{IR}\right)\boldsymbol{r}^R_{Ri} + 2\tilde{\boldsymbol{\omega}}^R_{IR}\,\dot{\boldsymbol{r}}^R_{Ri} + \ddot{\boldsymbol{r}}^R_{Ri}, \tag{2.28}$$

$$\boldsymbol{\alpha}^R_{Ii}(t) = \dot{\boldsymbol{\omega}}^R_{IR} + \tilde{\boldsymbol{\omega}}^R_{IR}\,\boldsymbol{\omega}^R_{Ri} + \dot{\boldsymbol{\omega}}^R_{Ri}. \tag{2.29}$$

Thus, in addition to the guidance and relative acceleration the Coriolis acceleration with the characteristic factor 2 is found for translations.

2.2.4 Kinematics of Multi-Body Systems

So far only one free rigid body K_i was considered the position of which is uniquely described in the inertial frame I as

$$\boldsymbol{r}_i^I = \left[r_{i1}\, r_{i2}\, r_{i3}\right]^{\mathrm{T}}, \quad \boldsymbol{S}^{Ii} \equiv \boldsymbol{S}_i = \boldsymbol{S}_i(\alpha_i, \beta_i, \gamma_i). \tag{2.30}$$

There are six position coordinates, which are summarized in a 6×1 column matrix, simply called local position vector, as

$$\boldsymbol{x}_i(t) = \left[r_{i1}\, r_{i2}\, r_{i3}\;\; \alpha_i\, \beta_i\, \gamma_i\right]^{\mathrm{T}}. \tag{2.31}$$

For a free multi-body system consisting of p dismantled rigid bodies K_i, $i = 1(1)p$, there remain $6p$ position coordinates resulting in a $6p \times 1$ global position vector of an unconstrained system

$$\boldsymbol{x}(t) = [\boldsymbol{x}_1^{\mathrm{T}} \ldots \boldsymbol{x}_p^{\mathrm{T}}]^{\mathrm{T}}. \tag{2.32}$$

Assembling the free system, there appear constraints between the position coordinates and their derivatives. In realistic models of vehicles, only holonomic constraints are found restricting the motion of the position coordinates by geometric or integrable kinematic constraints. These constraints are implicitly described by algebraical equations, which may be time-dependent (rheonomic), too:

$$\varphi_j(\boldsymbol{x}, t) = 0, \quad j = 1(1)q. \tag{2.33}$$

Due to q constraints, there remain f linear-independent position coordinates characterizing $f = 6p - q$ degrees of freedom. The f-independent position coordinates are also called generalized coordinates and may be summarized in a $f \times 1$ column matrix as global position vector of the constraint system:

$$\boldsymbol{y}(t) = \left[\, y_1 \ldots y_f \,\right]^{\mathrm{T}}. \tag{2.34}$$

By 2.33 and 2.34, the vector $\boldsymbol{x}$ is an explicit function of the f-generalized coordinates representing the constraints explicitly,

$$\boldsymbol{x} = \boldsymbol{x}(\boldsymbol{y}, t). \tag{2.35}$$

The choice of generalized coordinates is not unique. For example, some of the local position coordinates (absolute coordinates) or differences between local coordinates (relative coordinates) may be chosen as generalized coordinates. However, there exists a unique relation between different sets of generalized coordinates represented by a regular, time-invariant $f \times f$ matrix $\boldsymbol{T}$ resulting in the transformation

$$\boldsymbol{y}(t) = \boldsymbol{T}\,\overline{\boldsymbol{y}}(t), \tag{2.36}$$

where $\boldsymbol{y}$ and $\overline{\boldsymbol{y}}$ are the corresponding global position vectors.

The position variables 2.30 may be rewritten for the whole system as

$$\boldsymbol{r}_i(t) = \boldsymbol{r}_i(y, t), \quad \boldsymbol{S}^{Ii}(t) \equiv \boldsymbol{S}_i(t) = \boldsymbol{S}_i(\boldsymbol{y}, t), \quad i = 1(1)p. \tag{2.37}$$

The corresponding velocity variables $\{\boldsymbol{v}_i, \boldsymbol{\omega}_i\}$, $\boldsymbol{\omega}_i = \boldsymbol{\omega}_{Ii}$ are obtained by differentiation as

$$\boldsymbol{v}_i(t) = \dot{\boldsymbol{r}}_i(t) = \frac{\partial \boldsymbol{r}_i}{\partial \boldsymbol{y}^{\mathrm{T}}}\,\dot{\boldsymbol{y}} + \frac{\partial \boldsymbol{r}_i}{\partial t} = \boldsymbol{J}_{Ti}(\boldsymbol{y}, t)\dot{\boldsymbol{y}} + \overline{\boldsymbol{v}}_i(\boldsymbol{y}, t), \tag{2.38}$$

$$\boldsymbol{\omega}_i(t) = \dot{\boldsymbol{s}}_i(t) = \frac{\partial \boldsymbol{s}_i}{\partial \boldsymbol{y}^{\mathrm{T}}}\,\dot{\boldsymbol{y}} + \frac{\partial \boldsymbol{s}_i}{\partial t} = \boldsymbol{J}_{Ri}(\boldsymbol{y}, t)\dot{\boldsymbol{y}} + \overline{\boldsymbol{\omega}}_i(y, t), \tag{2.39}$$

where $\partial \boldsymbol{s}_i$ describes the 3×1 vector of the infinitesimal rotation following from the rotation matrix analogously to the rotational velocity 2.17 as

$$\partial \tilde{\boldsymbol{s}}_i = \partial \boldsymbol{S}_i \boldsymbol{S}_i^{\mathrm{T}} = \begin{bmatrix} 0 & -\partial s_{i3} & \partial s_{i2} \\ \partial s_{i3} & 0 & -\partial s_{i1} \\ -\partial s_{i2} & \partial s_{i1} & 0 \end{bmatrix}, \quad \partial \boldsymbol{s}_i = \begin{bmatrix} \partial s_{i1} \\ \partial s_{i2} \\ \partial s_{i3} \end{bmatrix}. \tag{2.40}$$

The $3 \times f$ functional or Jacobian matrices $\boldsymbol{J}_{Ti}, \boldsymbol{J}_{Ri}$ of translation and rotation, respectively, identify the relation between the local and the generalized or global coordinates. The formation of these matrices is defined using the rules of matrix multiplication as shown for the translation matrix:

$$\frac{\partial \boldsymbol{r}_i}{\partial \boldsymbol{y}^T} = \partial \boldsymbol{r}_i \left(\frac{1}{\partial \boldsymbol{y}^T} \right) = \boldsymbol{J}_{Ti} = \begin{matrix} \\ \\ \\ \end{matrix} \begin{matrix} \dfrac{\partial r_{i1}}{\partial y_1} & \dfrac{\partial r_{i1}}{\partial y_2} & \cdots & \dfrac{\partial r_{i1}}{\partial y_f} \\ \dfrac{\partial r_{i2}}{\partial y_1} & \dfrac{\partial r_{i2}}{\partial y_2} & \cdots & \dfrac{\partial r_{i2}}{\partial y_f} \\ \dfrac{\partial r_{i3}}{\partial y_1} & \dfrac{\partial r_{i3}}{\partial y_2} & \cdots & \dfrac{\partial r_{i3}}{\partial y_f} \end{matrix}. \tag{2.41}$$

From 2.38 and 2.39, one obtains by a second differentiation the acceleration variables $\{\boldsymbol{a}_i, \alpha_i\}$ depending on the position vector $\boldsymbol{y}$ and its derivatives:

$$\boldsymbol{a}_i(t) = \dot{\boldsymbol{v}}_i(t) = \boldsymbol{J}_{Ti}(\boldsymbol{y}, t)\ddot{\boldsymbol{y}} + \frac{\partial \boldsymbol{v}_i}{\partial \boldsymbol{y}^{\mathrm{T}}}\dot{\boldsymbol{y}} + \frac{\partial \boldsymbol{v}_i}{\partial t}, \tag{2.42}$$

$$\boldsymbol{\alpha}_i(t) = \dot{\boldsymbol{\omega}}_i(t) = \boldsymbol{J}_{Ri}(\boldsymbol{y}, t)\ddot{\boldsymbol{y}} + \frac{\partial \boldsymbol{\omega}_i}{\partial \boldsymbol{y}^{\mathrm{T}}}\dot{\boldsymbol{y}} + \frac{\partial \boldsymbol{\omega}_i}{\partial t}. \tag{2.43}$$

For scleronomic, time-invariant constraints, the partial time derivatives in 2.38, 2.39, 2.42, and 2.43 are vanishing.

In addition to the real motions, the virtual motions are required in the next chapter dealing with dynamics. A virtual motion is defined as an arbitrary, infinitesimally small variation of the position completely compatible with the constraints at any time. Rheonomic constraints are considered to be frozen at the time under consideration. The symbol δ of the virtual motion has the properties

$$\delta\boldsymbol{r} \neq \boldsymbol{0}, \delta t \equiv 0. \tag{2.44}$$

The symbol δ follows the rules of calculus, that is, it yields

$$\delta(c\boldsymbol{r}) = c\delta\boldsymbol{r}, \quad \delta(\boldsymbol{r}_1 + \boldsymbol{r}_2) = \delta\boldsymbol{r}_1 + \delta\boldsymbol{r}_2, \quad \delta\boldsymbol{r}(\boldsymbol{y}) = \frac{\partial \boldsymbol{r}}{\partial \boldsymbol{y}^T}\delta\boldsymbol{y}. \tag{2.45}$$

Thus, the virtual motion of a multi-body system reads as

$$\delta\boldsymbol{r}_i = \boldsymbol{J}_{Ti}\delta\boldsymbol{y}, \quad \delta\boldsymbol{s}_i = \boldsymbol{J}_{Ri}\,\delta\boldsymbol{y}, \quad i = 1(1)p. \tag{2.46}$$

This completes the kinematics for rigid body vehicle systems.

2.3 DYNAMICS

For the generation of the equations of motion of multi-body systems, in addition to kinematics, the inertia of the bodies and the acting forces have to be considered. The Newton–Euler approach, also called the synthetic method, uses the free-body diagram resulting in full set of local equations, which may be reduced by the principles of d'Alembert and Jourdain to the equations of motion. The Lagrangian approach, representing the analytical method, is based on energy considerations and the equations of motions are found directly but without any information on the reaction forces.

2.3.1 Inertia Properties

The inertia of a rigid body K_i is characterized by its mass m_i and its inertia tensor $\boldsymbol{I}_{Ci}$. The coordinates of the inertia tensor read in the body-fixed frame $\left\{C_i, \boldsymbol{e}_{\upsilon}^{i}\right\}$ (see Figure 2.4) as

$$\boldsymbol{I}_{Ci}^{i} = \int_{m_i}(\rho^{\mathrm{T}}\rho\boldsymbol{E} - \rho\rho^{\mathrm{T}})\,dm = \begin{bmatrix} I_{11} & I_{12} & I_{13} \\ I_{21} & I_{22} & I_{23} \\ I_{31} & I_{32} & I_{33} \end{bmatrix}_{C_i} = \text{constant}. \tag{2.47}$$

The vector $\boldsymbol{\rho} \equiv \boldsymbol{\rho}^i = [\rho_1\ \rho_2\ \rho_3]^{\mathrm{T}}$ describes a material point with mass dm with respect to the center of mass C_i and $\boldsymbol{E}$ means the 3×3 identity matrix. The inertia tensor $\boldsymbol{I}_{Ci}^i$ is symmetric and positive definite, and constant in the body-fixed frame.

The coordinates of the inertia tensor depend on the mass distribution and on the choice of the reference frame. For a parallel displacement of the body-fixed frame from the center of mass C_i to an arbitrary body-fixed point O_i characterized by the vector $\boldsymbol{s}$, one gets

$$\boldsymbol{I}_{Oi}^i = \boldsymbol{I}_{Ci}^i + (\boldsymbol{s}^{\mathrm{T}}\boldsymbol{s}\boldsymbol{E} - \boldsymbol{s}\boldsymbol{s}^{\mathrm{T}})m_i. \tag{2.48}$$

Thus, the diagonal elements of an inertia tensor are minimal for the center of mass.

For a homogeneous, purely rotational displacement by the rotation matrix $\boldsymbol{S}^{ii'}$ from frame $\boldsymbol{e}_\upsilon^i$ to $\boldsymbol{e}_\upsilon^{i'}$ around the center of mass the transformation law for tensors applies as

$$\boldsymbol{I}_{Ci}^i = \boldsymbol{S}^{ii'}\boldsymbol{I}_{Ci}^{i'}\boldsymbol{S}^{i'i} \quad \text{or} \quad \boldsymbol{I}_{Ci}^{i'} = \boldsymbol{S}^{i'i}\boldsymbol{I}_{Ci}^i\boldsymbol{S}^{ii'}. \tag{2.49}$$

Please note that the inertia tensor may be time-variant if the frame $\left\{C_i, \boldsymbol{e}_\upsilon^{i'}\right\}$ is not body fixed. This is especially true if the inertial frame is chosen, $i' \equiv I$, due to $\boldsymbol{S}^{iI} = \boldsymbol{S}^{iI}(t)$.

For all reference points, there exists a special body-fixed frame in which the off-diagonal elements of the inertia tensor are vanishing, for example,

$$\boldsymbol{I}_{Ci}^{i'} = \mathrm{diag}\left[I_1\ \ I_2\ \ I_3\right] = \text{constant}. \tag{2.50}$$

The remaining diagonal elements I_υ are called principal moments of inertia with reference to C_i and the corresponding axes are the principal inertia axes. Both quantities follow from the eigenvalue problem:

$$(I_\upsilon \boldsymbol{E} - \boldsymbol{I}_{Ci}^{i'})\boldsymbol{x}_\upsilon = \boldsymbol{0}. \tag{2.51}$$

Thus, the principal moments of inertia are the eigenvalues of the matrix $\boldsymbol{I}_{Ci}^{i'}$ and the eigenvectors $\boldsymbol{x}_\upsilon = \boldsymbol{e}_\upsilon^i$ define the principal inertia axes which have to be unit vectors $\boldsymbol{x}_\upsilon^{\mathrm{T}}\boldsymbol{x}_\upsilon = 1$.

2.3.2 Newton–Euler Equations

The synthetic method is based on the laws of Newton (1687) and Euler (1758) relating the translational motion represented by the momentum $\boldsymbol{p}$ of a body K to the sum of the external forces $\boldsymbol{f}$ and the rotational motion represented by the moment of momentum $\boldsymbol{h}_O$ to the sum of the external torques $\boldsymbol{l}_O$,

$$\frac{\mathrm{d}^I}{\mathrm{d}t}\boldsymbol{p} = \boldsymbol{f}, \quad \frac{\mathrm{d}^I}{\mathrm{d}t}\boldsymbol{h}_O = \boldsymbol{l}_O. \tag{2.52}$$

The time derivatives of the momentum $\boldsymbol{p}$ and the moment of momentum $\boldsymbol{h}_O$ have to be evaluated in the inertial frame I. The common reference point O of the moment of momentum and the resulting external torque may be an inertially fixed point like the origin of the inertial frame, $O \equiv O_I$, or the moving center of mass of the body, $O \equiv C$.

The fundamental laws (2.52) will now be applied to the rigid body K_i, $i = 1(1)p$, of a multi-body system and appropriate frames are chosen. First of all, the bodies K_i are dismantled and the constraints are replaced by reaction forces acting then externally on the bodies involved in the same

size but with opposite sign according to the counteraction principle (action = reaction). Further, the center of mass is used as reference point for all bodies, $O \equiv C_i$.

In the inertial frame, I momentum and moment of momentum for a rigid body K_i using the inertia properties m_i, $\boldsymbol{I}_{Ci}$ read as

$$\boldsymbol{p}_i^I = m_i \boldsymbol{v}_{Ci}^I, \quad m_i = \text{constant}, \tag{2.53}$$

$$\boldsymbol{h}_{Ci}^I = \boldsymbol{I}_{Ci}^I \boldsymbol{\omega}_i^I, \quad \boldsymbol{I}_{Ci}^I = \boldsymbol{I}_{Ci}^I(t), \tag{2.54}$$

where $\boldsymbol{v}_{Ci}^I$ and $\boldsymbol{\omega}_i^I$ mean absolute velocities. Introducing 2.53 and 2.54 in 2.52 and omitting the index C, one finally gets Newton's and Euler's equations:

$$m_i \dot{\boldsymbol{v}}_i^I = \boldsymbol{f}_i^I, \quad m_i = \text{constant}, \tag{2.55}$$

$$\boldsymbol{I}_i^I \dot{\boldsymbol{\omega}}_i^I + \tilde{\boldsymbol{\omega}}_i^I \boldsymbol{I}_i^I \boldsymbol{\omega}_i^I = \boldsymbol{l}_i^I, \quad \boldsymbol{I}_i^I = \boldsymbol{I}_i^I(t). \tag{2.56}$$

In a second step, these equations are transformed in a body-fixed frame resulting in

$$m_i \dot{\boldsymbol{v}}_i^i = \boldsymbol{f}_i^i, \; m_i = \text{constant}, \tag{2.57}$$

$$\boldsymbol{I}_i^i \dot{\boldsymbol{\omega}}_i^i + \tilde{\boldsymbol{\omega}}_i^i \boldsymbol{I}_i^i \boldsymbol{\omega}_i^i = \boldsymbol{l}_i^i, \boldsymbol{I}_i^i = \text{constant}. \tag{2.58}$$

Equations 2.55 and 2.56, and 2.57 and 2.58 look completely identical. If there is only one body like in gyrodynamics, then 2.58 is preferable due to the time invariance of the inertia tensor. In multibody dynamics, however, this advantage is fading. Equation 2.58 is also known as Euler's equation of gyrodynamics. It can be found with the moment of momentum given in the body-fixed frame from 2.52 directly using the law of differentiation in a rotating frame (2.27),

$$\frac{\mathrm{d}^I}{\mathrm{d}t} \boldsymbol{h}_i^i = \dot{\boldsymbol{h}}_i^i + \tilde{\boldsymbol{\omega}}_i^i \boldsymbol{h}_i^i = \boldsymbol{l}_i^i, \; \boldsymbol{h}_i^i = \boldsymbol{I}_i^i \boldsymbol{\omega}_i^i. \tag{2.59}$$

Finally, in an arbitrarily moving reference frame R Newton's and Euler's equations are also available (see, e.g., Schiehlen and Eberhard [10]):

$$m_i \ddot{\boldsymbol{r}}_{Ri} + m_i \left[\overset{**}{\boldsymbol{r}}_R + (\dot{\tilde{\boldsymbol{\omega}}}_R + \tilde{\boldsymbol{\omega}}_R \, \tilde{\boldsymbol{\omega}}_R) \boldsymbol{r}_{Ri} + 2 \tilde{\boldsymbol{\omega}}_R \, \dot{\boldsymbol{r}}_{Ri} \right] = \boldsymbol{f}_i, \tag{2.60}$$

$$\boldsymbol{I}_i \dot{\boldsymbol{\omega}}_{Ri} + \tilde{\boldsymbol{\omega}}_{Ri} \, \boldsymbol{I}_i \boldsymbol{\omega}_{Ri} + \left[\boldsymbol{I}_i \boldsymbol{\omega}_R + \tilde{\boldsymbol{\omega}}_R \, \boldsymbol{I}_i \, \boldsymbol{\omega}_R + \tilde{\boldsymbol{\omega}}_R \, \boldsymbol{\omega}_{Ri} \, sp \, \boldsymbol{I}_i + 2 \tilde{\boldsymbol{\omega}}_{Ri} \, I_i \, \boldsymbol{\omega}_R \right] = \boldsymbol{l}_i. \tag{2.61}$$

Now, the coordinates of all vectors and tensors are related to the reference frame R where $[\overset{**}{\boldsymbol{r}}_R]$ means that the second-time derivation has to be made before in the inertial frame. As a matter of fact, a large number of additional inertia forces and torques appear due to the relative motion.

The Newton–Euler equations represent a set of $6p$ scalar equations for $6p$ unknowns, which are composed of unknown velocity and position variables and unknown reaction forces and torques. In an unconstrained system, reactions do not exit, that is, there are $6p$ ordinary differential equations (ODEs) to be solved. In a completely constrained system, motion does not occur at all, that is, altogether $6p$ algebraical equations have to be solved. In vehicle dynamics, due to a certain number of constraints between the bodies, motions and reactions appear featuring a set of differential-algebraical equations (DAEs). However, by the principles of dynamics, a minimal set of f ODEs can be found facilitating the solution and simulation of the problem.

2.3.3 Principles of d'Alembert and Jourdain

Equations of motion represent a minimal set of ODEs. They can be found from the Newton–Euler equations by elimination of the reaction forces and torques. This is achieved computationally efficient by the principles of dynamics considering the virtual work of a constrained multi-body system. For this purpose, the external forces acting on the dismantled bodies of the system are subdivided into applied forces $\boldsymbol{f}_i^{(a)}$ and torques $\boldsymbol{l}_i^{(a)}$ as well as reaction forces $\boldsymbol{f}_i^{(r)}$ and torques $\boldsymbol{l}_i^{(r)}$. The latter ones do not contribute to the virtual work of the system

$$\delta W^r = \sum_{i=1}^{p} (\boldsymbol{f}_i^{(r)\mathrm{T}}\, \delta \boldsymbol{r}_i + \boldsymbol{l}_i^{(r)\mathrm{T}}\, \delta \boldsymbol{s}_i) = 0, \tag{2.62}$$

where the virtual motions $\delta \boldsymbol{r}_i$, $\delta \boldsymbol{s}_i$ are known from 2.46. Equation 2.62 can be interpreted as a generalized orthogonality condition. For this purpose, in addition to the generalized coordinates $\boldsymbol{y}$, generalized reaction forces g_j, $j = 1(1)q$ are introduced and summarized in a $q \times 1$ vector as

$$\boldsymbol{g}(t) = \left[g_1 \dots g_q \right]^{\mathrm{T}}. \tag{2.63}$$

The number of generalized constraint forces is determined by the number q of constraints. The local constraint forces and torques follow from the implicit constraint equations (2.33) as

$$\boldsymbol{f}_i^{(r)\mathrm{T}} = \sum_{j=1}^{q} g_j \frac{\partial \varphi_j}{\partial \boldsymbol{r}_i^{\mathrm{T}}} = \sum_{j=1}^{q} g_j \frac{\partial \varphi_j}{\partial \boldsymbol{x}^{\mathrm{T}}} \frac{\partial \boldsymbol{x}}{\partial \boldsymbol{r}_i^{\mathrm{T}}}, \tag{2.64}$$

$$\boldsymbol{l}_i^{(r)\mathrm{T}} = \sum_{j=1}^{q} g_j \frac{\partial \varphi_j}{\partial \boldsymbol{s}_i^{\mathrm{T}}} = \sum_{j=1}^{q} g_j \frac{\partial \varphi_j}{\partial \boldsymbol{x}^{\mathrm{T}}} \frac{\partial \boldsymbol{x}}{\partial \boldsymbol{s}_i^{\mathrm{T}}}, \quad i = 1(1)p. \tag{2.65}$$

In matrix notation, the $3 \times q$ Jacobians $\boldsymbol{F}_{Ti}$, $\boldsymbol{F}_{Ri}$ are found from 2.64 and 2.65, and the condition 2.62 is rewritten as

$$\begin{aligned} \delta W^r &= \boldsymbol{g}^{\mathrm{T}} \sum_{i=1}^{p} (\boldsymbol{F}_{Ti}^{\mathrm{T}}\, \delta \boldsymbol{r}_i + \boldsymbol{F}_{Ri}^{\mathrm{T}} \delta \boldsymbol{s}_i) \\ &= \boldsymbol{g}^{\mathrm{T}} \sum_{i=1}^{p} (\boldsymbol{F}_{Ti}^{\mathrm{T}}\, \boldsymbol{J}_{Ti} + \boldsymbol{F}_{Ri}^{\mathrm{T}}\, \boldsymbol{J}_{Ri})\, \delta \boldsymbol{y} = 0. \end{aligned} \tag{2.66}$$

Finally, the global $6p \times q$ distribution matrix $\bar{\boldsymbol{Q}}$, and the global $6p \times f$ Jacobian matrix $\bar{\boldsymbol{J}}$ are introduced:

$$\bar{\boldsymbol{Q}} = [\boldsymbol{F}_{T1}^{\mathrm{T}} \ldots \boldsymbol{F}_{Tp}^{\mathrm{T}}\, \boldsymbol{F}_{R1}^{\mathrm{T}} \ldots \boldsymbol{F}_{Rp}^{\mathrm{T}}]^{\mathrm{T}},$$

$$\bar{\boldsymbol{J}} = [\boldsymbol{J}_{T1}^{\mathrm{T}} \ldots \boldsymbol{J}_{Tp}^{\mathrm{T}}\, \boldsymbol{J}_{R1}^{\mathrm{T}} \ldots \boldsymbol{J}_{Rp}^{\mathrm{T}}]^{\mathrm{T}}. \tag{2.67}$$

Then, one gets from 2.66 simply

$$\bar{\boldsymbol{Q}}^{\mathrm{T}} \bar{\boldsymbol{J}} = \bar{\boldsymbol{J}}^{\mathrm{T}} \bar{\boldsymbol{Q}} = \boldsymbol{0}, \tag{2.68}$$

which clearly shows the generalized orthogonality between motion and constraint. The orthogonality condition or the vanishing virtual work, respectively, is independent from the coordinates chosen, and it is valid for all constrained mechanical systems.

d'Alembert's principle (1743) follows now from the Newton–Euler equations (2.55) and (2.56) after subdividing the external forces

$$\boldsymbol{f}_i = \boldsymbol{f}_i^{(e)} + \boldsymbol{f}_i^{(r)}, \quad \boldsymbol{l}_i = \boldsymbol{l}_i^{(e)} + \boldsymbol{l}_i^{(r)}, \tag{2.69}$$

and considering the orthogonality (2.62) as

$$\sum_{i=1}^{p} [(m_i \dot{\boldsymbol{v}}_i - \boldsymbol{f}_i^{(e)})^{\mathrm{T}} \delta \boldsymbol{r}_i + (\boldsymbol{I}_i \dot{\boldsymbol{\omega}}_i + \tilde{\boldsymbol{\omega}}_i \boldsymbol{I}_i\, \boldsymbol{\omega}_i - \boldsymbol{l}_i^{(e)})^{\mathrm{T}} \delta \boldsymbol{s}_i] = 0. \tag{2.70}$$

Obviously, the reaction forces are eliminated in 2.70.

Analogously, Jourdain's principle (1908) can be stated which is based on the fact that the virtual power of the reaction forces is vanishing, too,

$$\delta P^r = \sum_{i=1}^{p} \left[\boldsymbol{f}_i^{(r)\mathrm{T}}\, \delta' \boldsymbol{v}_i + \boldsymbol{l}_i^{(r)\mathrm{T}}\, \delta' \boldsymbol{\omega}_i \right] = 0. \tag{2.71}$$

The virtual velocities $\delta' \boldsymbol{v}_i$, $\delta' \boldsymbol{\omega}_i$ are arbitrary, infinitesimal small variations of the velocities completely compatible with the constraints at any time and at any position. Thus, it yields

$$\delta' \boldsymbol{v}_i \neq 0\,, \quad \delta' \boldsymbol{\omega}_i \neq 0\,, \quad \delta' \boldsymbol{r}_i \equiv 0\,, \quad \delta' \boldsymbol{s}_i \equiv 0\,, \quad \delta' t \equiv 0. \tag{2.72}$$

Moreover, the symbol δ' follows the rules of calculus. Then, it remains as Jourdain's principle as

$$\sum_{i=1}^{p} [(m_i \dot{\boldsymbol{v}}_i - \boldsymbol{f}_i^{(e)})^{\mathrm{T}} \delta' \boldsymbol{v}_i + (\boldsymbol{I}_i \dot{\boldsymbol{\omega}}_i + \tilde{\boldsymbol{\omega}}_i \boldsymbol{I}_i \boldsymbol{\omega}_i - \boldsymbol{l}_i^{(e)})^{\mathrm{T}} \delta' \boldsymbol{\omega}_i] = 0. \tag{2.73}$$

Similar to d'Alembert's principle, all the reactions disappeared. However, the virtual displacements are replaced by the virtual velocities and the sometimes cumbersome evaluation of the virtual rotations is dropped. Further, Jourdain's principle handles nonlinear and non-holonomic constraints, too, which may appear in controlled vehicle systems.

In the American literature, Jourdain's principle is referred to as Kane's equations and the virtual velocities are denoted as partial velocities (see Kane and Levinson [11]). Applying these principles for the generation of the equations of motion, the reactions have not to be considered at all. Therefore, the principles may be also classified as an analytical approach.

2.3.4 Energy Considerations and Lagrange's Equations

An alternative for the generation of the equations of motion is the analytical method by Lagrange (1788) based on energy considerations. The kinetic energy T of a rigid body reads as

$$T = \frac{1}{2} m \boldsymbol{v}_C^2 + \frac{1}{2} \boldsymbol{\omega} \cdot \boldsymbol{I}_C \cdot \boldsymbol{\omega}, \tag{2.74}$$

where the inertia properties $\{m, \boldsymbol{I}_C\}$ and the velocity properties $\{\boldsymbol{v}_C, \omega\}$ are related to the center of mass. The kinetic energy is composed by the translational and rotational energy of the body; it is a scalar quantity, which may be computed in different frames, too.

The kinetic energy of a multi-body system consisting of the bodies K_i, $i = 1(1)p$ comprises the kinetic energy of all bodies as

$$T = \frac{1}{2} \sum_{i=1}^{p} \left[(\boldsymbol{v}_i^I)^{\mathrm{T}} m_i \, \boldsymbol{v}_i^I + (\boldsymbol{\omega}_i^I)^{\mathrm{T}} \boldsymbol{I}_i^I \boldsymbol{\omega}_i^I \right], \tag{2.75}$$

written consistently in the inertial frame I and related to the center of mass C_i of each body K_i. If the work of the applied forces is independent of the path, then the forces have a potential U and it yields

$$\boldsymbol{f}^{(e)} = -\operatorname{grad} U, \tag{2.76}$$

where U is a scalar function of the position. Forces satisfying 2.76 are called conservative; they do not change the total energy of the system. In contrary, nonconservative forces change the total energy; they are called dissipative since the total energy is decreasing. Conservative forces may be due to gravity, $f_G = mg$, or elasticity, $f_F = -ks$. The corresponding potentials read as

$$U_G = m \, g \, z, \quad U_F = \frac{1}{2} k s^2, \tag{2.77}$$

where

z represents the vertical displacement of the center of mass of a body with mass m in the direction of gravity with acceleration g

s means the displacement of an elastic spring with coefficient k

To the potentials, a constant may be added, that is, the origin of a potential can be arbitrarily chosen. The potential energy U of a multi-body system is given by the sum of the body potentials $U = \sum U_j$. Multi-body systems subject to conservative forces only are called conservative systems. For such systems, it yields the energy conservation law:

$$T + U = T_0 + U_0 = \text{constant}. \tag{2.78}$$

The energy conservation law may be derived from Newton's and Euler's law, that is, it does not contain new information. Its application is advantageous for conservative systems with one degree of freedom to evaluate a relation between the position and velocity variable. If there are two different positions known, the unknown velocity can be found from 2.78.

Based on energy expressions, the equations of motion of multi-body systems may be found, too. This will be shown for multi-body systems with holonomic constraints. In contrary to the synthetic method, the bodies of the system have not to be dismantled, the system is considered as a whole. For this purpose, the generalized coordinates $\boldsymbol{y}$ are defined, and the position and the velocity variables (2.37 through 2.39) are evaluated. As a result, the kinetic energy is available as a function of $y_k(t)$ and $\dot{y}_k(t)$, $k = 1(1)f$,

$$T = T(y_k, \dot{y}_k). \tag{2.79}$$

The applied forces and torques are projected in the direction of the generalized coordinates and composed to the generalized forces

$$q_k = \sum_{i=1}^{p} \left[\left(\frac{\partial \boldsymbol{r}_i^I}{\partial y_k} \right)^{\mathrm{T}} \boldsymbol{f}_i^{(e)I} + \left(\frac{\partial \boldsymbol{s}_i^I}{\partial y_k} \right)^{\mathrm{T}} \boldsymbol{l}_i^{(e)I} \right], \quad \boldsymbol{k} = 1(1)f, \tag{2.80}$$

where the rows of the Jacobian matrices (2.41) are used. The generalized forces may be also found by decomposition of the total work of the applied forces and torques

$$\delta W^e = \sum_{i=1}^{p} \left[\boldsymbol{f}_i^{(e)\mathrm{T}} \delta \boldsymbol{r}_i + \boldsymbol{l}_i^{(e)\mathrm{T}} \delta \boldsymbol{s}_i \right] = \sum_{k=1}^{f} q_k \delta y_k. \tag{2.81}$$

In any case, the reaction forces and torques do not appear.

Now the Lagrangian equations of the second kind read as, see, for example, Magnus and Müller [9],

$$\frac{\mathrm{d}}{\mathrm{d}t} \left(\frac{\partial T}{\partial \dot{y}_k} \right) - \frac{\partial T}{\partial y_k} = q_k \,, \quad k = 1(1)f. \tag{2.82}$$

For the evaluation of the equations of motion, two partial and one total differentiations have to be performed with respect to one scalar function $T(y_k, \dot{y}_k)$.

As a result, the minimal number f of equations of motion is found. However, the reaction forces are completely lost and cannot be regained.

For conservative systems, the generalized forces follow immediately from the potential

$$q_k = -\frac{\partial U}{\partial y_k}. \tag{2.83}$$

From 2.82 and 2.83, it remains

$$\frac{\mathrm{d}}{\mathrm{d}t} \left(\frac{\partial T}{\partial \dot{y}_k} \right) - \frac{\partial T}{\partial y_k} + \frac{\partial U}{\partial y_k} = 0 \,, \quad k = 1(1)f. \tag{2.84}$$

Introducing the Lagrange function $L = T - U$, also called the kinetic potential, 2.84 is even more simplified and reads

$$\frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{\partial L}{\partial \dot{y}_k}\right) - \frac{\partial L}{\partial y_k} = 0\,, \quad L = T - U, \quad k = 1(1)f. \tag{2.85}$$

For some engineering applications, it is advantageous to use surplus coordinates $\bar{y}_j$, $j = 1(1)f + r$, in addition to the f-generalized coordinates y_k, $k = 1(1)f$. Then, there exist r geometric constraints between the surplus coordinates

$$\varphi_n = \varphi_n(\bar{y}_j) = 0, \quad n = 1(1)r. \tag{2.86}$$

The equations of motion are now extended by r Lagrangian multipliers λ_n, $n = 1(1)r$, representing generalized constraint forces

$$\frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{\partial T}{\partial \dot{\bar{y}}_j}\right) - \frac{\partial T}{\partial \bar{y}_j} = \bar{q}_j + \sum_{n=1}^{r} \lambda_n \frac{\partial \varphi_n}{\partial \bar{y}_j}, \quad j = 1(1)f + r. \tag{2.87}$$

Thus, a set of differential-algebraic equations (DAEs) remain.

2.4 EQUATIONS OF MOTION

In Section 2.2, there has been presented two methods for the generation of the equations of motion: the synthetic method by Newton–Euler and the analytic method by d'Alembert, Jourdain, or Lagrange, respectively. The principal steps in the generation process by Newton–Euler and Lagrange are shown in Figure 2.9 as block diagram. Common starting point is the mechanical model of the vehicle composed by the elements of multi-body systems. Common result are the equations of motion; they are identical with both methods if the same generalized coordinates are used. However, the effort is different. During the generation of the equations of motion using Lagrange's equations, there appear terms in $\mathrm{d}/\mathrm{d}t\,(\partial T/\partial \dot{y}_i)$ which are afterward eliminated by $\partial T/\partial y_i$ according to 2.82. This means an useless computational effort which is not required with the Newton–Euler approach, see, e.g., Schiehlen and Eberhard [10]. On the other hand, in the Newton–Euler equations, the reactions have to be eliminated. Thus, both of these approaches have disadvantages, which are avoided by a combination of the Newton–Euler equations with the principles presented in Section 2.3.3.

The resulting equations of motion are always ODEs. However, their form depends on the type of the multi-body system. There are ideal and nonideal systems: the first ones are characterized by applied forces and torques independent from any reaction while the second ones show a dependency. For example, gravitational forces, spring, and damper forces are independent from any reactions while sliding friction forces and slip-dependent contact forces, regularly found with tires in vehicle dynamics, are a function of the normal or reaction forces, respectively.

Within the class of ideal systems, ordinary and general multi-body systems are distinguished. Ordinary multi-body systems are due to holonomic constraints and applied forces depending only on position and velocity quantities; they can be always represented by a system of differential equations of the second order. For non-holonomic constraints and/or general force laws, one gets general multi-body systems.

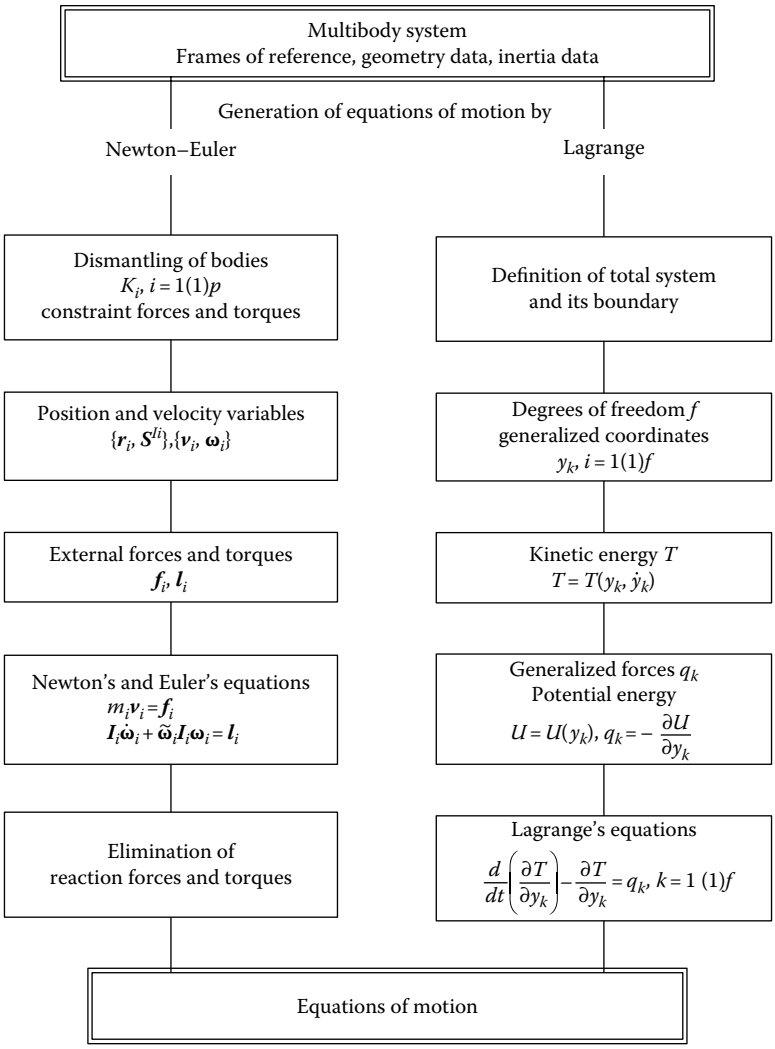

FIGURE 2.9 Generation of equations of motion for multi-body systems by Newton–Euler and Lagrange.

The equations of ordinary multi-body systems read as

$$\boldsymbol{M}(\boldsymbol{y}, t)\,\ddot{\boldsymbol{y}}(t) + \boldsymbol{k}(\boldsymbol{y}, \dot{\boldsymbol{y}}, t) = \boldsymbol{q}(\boldsymbol{y}, \dot{\boldsymbol{y}}, t), \tag{2.88}$$

where

$\boldsymbol{y}$ is the $f \times 1$ position vector of the generalized coordinates
$\boldsymbol{M}$ is the $f \times f$ symmetric inertia matrix
$\boldsymbol{k}$ is a $f \times 1$ vector of generalized gyroscopic forces including the Coriolis and centrifugal forces as well as the gyroscopic torques
$f \times 1$ vector $\boldsymbol{q}$ represents generalized applied forces

The equations of motion resulting from the analytical method have always the form (2.88) while the synthetic method often requires some calculations to get a symmetric inertia matrix.

In vehicle dynamics, the deviations $\tilde{\boldsymbol{y}}(t)$ from a reference motion $\boldsymbol{y} = \boldsymbol{y}_R(t)$ are often small:

$$\boldsymbol{y}(t) = \boldsymbol{y}_R(t) + \tilde{\boldsymbol{y}}(t). \tag{2.89}$$

Then, it follows by a Taylor series expansion under assumption of differentiable vector functions, and skipping of the second- and higher-order terms from 2.88 the linearized equations of motion, see also Müller and Schiehlen [12],

$$\boldsymbol{M}(t)\ddot{\tilde{\boldsymbol{y}}}(t)+\boldsymbol{P}(t)\dot{\tilde{\boldsymbol{y}}}(t)+\boldsymbol{Q}(t)\tilde{\boldsymbol{y}}(t)=\boldsymbol{h}(t), \tag{2.90}$$

where

$\boldsymbol{M}(t)$ is the symmetric, positive definite inertia matrix
$\boldsymbol{P}(t)$ and $\boldsymbol{Q}(t)$ characterize the velocity- and position-dependent forces
the vector $\boldsymbol{h}(t)$ represents the external excitations

If all these matrices are time-invariant and subdivided in a symmetrical and skew-symmetrical part, then the equations of motion of a linear ordinary and time-invariant multi-body system are found reading as

$$\boldsymbol{M}\ddot{\boldsymbol{y}}(t)+(\boldsymbol{D}+\boldsymbol{G})\dot{\boldsymbol{y}}(t)+(\boldsymbol{K}+\boldsymbol{N})\,\boldsymbol{y}(t)=\boldsymbol{h}(t), \tag{2.91}$$

where $\tilde{\boldsymbol{y}}$ used in 2.90 is simply replaced by $\boldsymbol{y}$ and the $f\times f$ matrices have the properties

$$\boldsymbol{M}=\boldsymbol{M}^{\mathrm{T}}>\boldsymbol{0}\,,\quad \boldsymbol{D}=\boldsymbol{D}^{\mathrm{T}},\quad \boldsymbol{G}=-\boldsymbol{G}^{\mathrm{T}},\quad \boldsymbol{K}=\boldsymbol{K}^{\mathrm{T}},\quad \boldsymbol{N}=-\boldsymbol{N}^{\mathrm{T}}. \tag{2.92}$$

These matrices have a physical meaning which can be identified after pre-multiplication of 2.92 from the left by $\dot{\boldsymbol{y}}^{\mathrm{T}}$ resulting in the total time derivative of an energy expression:

$$\underbrace{\dot{\boldsymbol{y}}^{\mathrm{T}}\boldsymbol{M}\ddot{\boldsymbol{y}}}+\underbrace{\dot{\boldsymbol{y}}^{\mathrm{T}}\boldsymbol{D}\dot{\boldsymbol{y}}}+\underbrace{\dot{\boldsymbol{y}}^{\mathrm{T}}\boldsymbol{G}\dot{\boldsymbol{y}}}+\underbrace{\dot{\boldsymbol{y}}^{\mathrm{T}}\boldsymbol{K}\boldsymbol{y}}+\underbrace{\dot{\boldsymbol{y}}^{\mathrm{T}}\boldsymbol{N}\boldsymbol{y}}=\underbrace{\dot{\boldsymbol{y}}^{\mathrm{T}}\boldsymbol{h}}, \tag{2.93}$$

$$\frac{\mathrm{d}}{\mathrm{d}t}T+2R+0+\frac{\mathrm{d}}{\mathrm{d}t}U+2S=P. \tag{2.94}$$

The inertia matrix $\boldsymbol{M}$ determines the kinetic energy $T=\frac{1}{2}\dot{\boldsymbol{y}}^{T}\boldsymbol{M}\,\dot{\boldsymbol{y}}$ and, therefore, the inertia forces, from $T>0$ it follows again the positive definiteness of the inertia matrix. The damping matrix $\boldsymbol{D}$ defines via Rayleigh's dissipation function $R=\frac{1}{2}\dot{\boldsymbol{y}}^{T}\boldsymbol{D}\,\dot{\boldsymbol{y}}$ the damping forces while the gyro matrix $\boldsymbol{G}$ describes the gyroscopic forces, which do not change the total energy of the system. The stiffness matrix determines the potential energy $U=\frac{1}{2}\boldsymbol{y}^{T}\boldsymbol{K}\,\boldsymbol{y}$ and, therefore, the conservative position forces while the matrix $\boldsymbol{N}$ identifies the circulatory forces also known as nonconservative position forces. Furthermore, P describes the power of the external excitation forces. For $\boldsymbol{D}=0$, $\boldsymbol{N}=0$, and $\boldsymbol{h}=0$, the multi-body system is conservative, that is, the total energy is constant for all motions,

$$T+U=\text{constant}. \tag{2.95}$$

The matrix properties (2.92) allow often to check the equations of motion with respect to the physical phenomena involved.

In general, multi-body systems exist a broader variety of standard representations, which will not be discussed in detail; anyway, the reader can refer to [10] for additional information.

2.5 FORMALISMS FOR MULTI-BODY SYSTEMS

The generation of equations of motion for large multi-body systems is a nontrivial task requiring numerous steps during the evaluation of the fundamental relations. Beginning with the space age in the middle of the 1960s, the generation of equations of motion was more formalized. The resulting formalisms were used for the development of computer codes for multi-body systems; they are the basis of computational multi-body dynamics. Twenty-five years later, in 1990, there were known 20 formalisms described in the *Multibody System Handbook* [7]. Many of them are used today.

Multi-body system formalisms are based on Newton–Euler equations or Lagrange's equations, respectively, as described in Sections 2.3.2 and 2.3.3. Regarding the computational procedure, numerical and symbolical formalisms are distinguished (Figure 2.10). Numerical formalisms supply the elements of the system matrices as numbers for linear time-invariant multi-body systems (2.91). In the case of linear time-variant systems (2.90) and nonlinear systems (2.88), a numerical formalism provides the numbers in the equations of motion necessary for each time step required by the simulation program. In contrary, symbolical formalisms generate the equations of motion only once with the computer how it is done with paper and pencil. The advantage is that variations of the system parameters and, for time-variant systems, the current time have to be inserted in the symbolical equations of motion only (see Figure 2.10). Symbolical formalisms are especially helpful for optimizations and control design.

Furthermore, non-recursive and recursive formalisms are distinguished. Recursive formalisms make use of special topology properties of multi-body systems.

2.5.1 Non-Recursive Formalisms

First of all, the symbolical formalism NEWEUL is presented. NEWEUL is a research software based on the Newton–Euler equations and the principles of d'Alembert and Jourdain; it was developed by Kreuzer at the University of Stuttgart, and recently revised in Matlab as Neweul-M power 2 (Neweul M squared), see [13]. NEWEUL generates equations of motion in minimal form (2.88) and (2.90), respectively, which may be solved by any integration code for ODEs. The formalisms comprise five steps, which may be evaluated by hand for smaller multi-body systems, too.

Step 1: System specification and input data.

At first the multi-body system is defined and treated as whole. The number of degrees of freedom is determined and the generalized coordinates y_k, $k = 1(1)f$ are chosen. The inertial frame I and

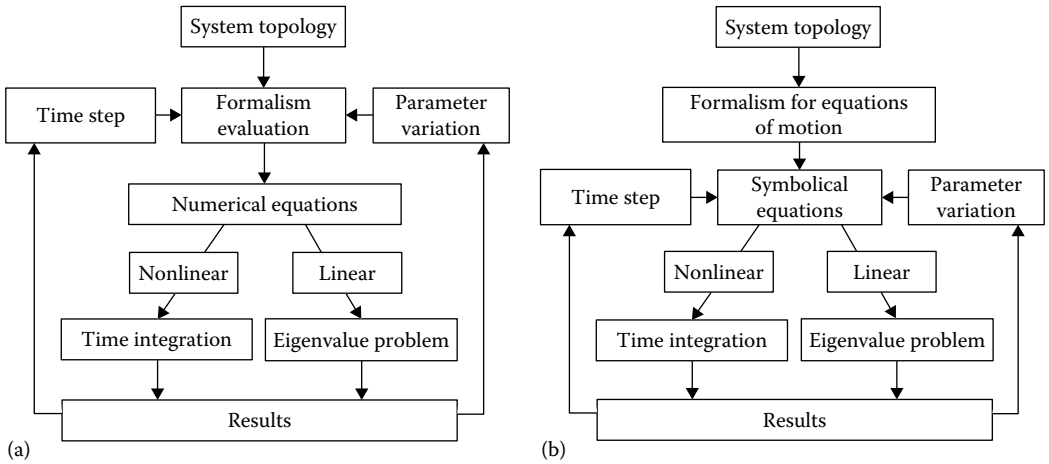

FIGURE 2.10 Flow diagrams of multi-body dynamical analysis by (a) numerical formalisms and (b) symbolical formalisms.

the body-fixed frames i are chosen. Each body K_i, $i = 1(1)p$ is dismantled, and the corresponding inertia parameters $\{m_i, \boldsymbol{I}_i\}$, the position variables $\left\{ \boldsymbol{r}_i^I, \boldsymbol{S}^{Ii} \right\}$, as well as the applied forces and torques $\left\{ \boldsymbol{f}_i^{(e)I}, \boldsymbol{l}_i^{(e)I} \right\}$ are specified. The quantities $\boldsymbol{I}_i^I$ and $\boldsymbol{l}_i^{(e)I}$ are related to the corresponding center of mass C_i. The input data read as

$$f, \boldsymbol{y} = [y_1, \ldots, y_j, \ldots, y_f]^{\mathrm{T}}, \tag{2.96}$$

$$p, \ \left\{ m_i, \boldsymbol{I}_i^i \right\}, \ \left\{ \boldsymbol{r}_i^I, \boldsymbol{S}^{Ii} \right\}, \ \left\{ \boldsymbol{f}_i^{(e)I}, \boldsymbol{l}_i^{(e)I} \right\}, \quad i = 1(1)p, \tag{2.97}$$

$$\boldsymbol{r}_i^I = \left[r_{i1} \ \ r_{i2} \ \ r_{i3} \right]^{\mathrm{T}}, \quad \boldsymbol{S}^{Ii} = \boldsymbol{S}^{Ii}\left(\alpha_i, \beta_i, \gamma_i \right) \equiv \boldsymbol{S}_i, \quad i = 1(1)p. \tag{2.98}$$

The rotation matrices are described by three angles, for example, the Cardan angles α_i, β_i, γ_i.

Step 2: Element consideration, local equations.

At first, the elements of the inertia tensors are computed in the inertial frame I by the transformation

$$\boldsymbol{I}_i^I = \boldsymbol{S}^{Ii} \boldsymbol{I}_i^i \boldsymbol{S}^{iI}. \tag{2.99}$$

Now, there are all quantities available in the inertial frame I which is the only frame further used. Thus, the right upper index is no longer required and just skipped. The local equations of motion for each body K_i read as

$$m_i \dot{\boldsymbol{v}}_i = \boldsymbol{f}_i^{(e)} + \boldsymbol{f}_i^{(r)}, \quad i = 1(1)p, \tag{2.100}$$

$$\boldsymbol{I}_i \dot{\boldsymbol{\omega}}_i + \tilde{\boldsymbol{\omega}}_i \boldsymbol{I}_i \boldsymbol{\omega}_i = \boldsymbol{l}_i^{(e)} + \boldsymbol{l}_i^{(r)}, \quad i = 1(1)p, \tag{2.101}$$

where the external forces and torques are subdivided in the known applied forces and torques and the unknown reactions. The reactions are eliminated later and, therefore, they are not to be specified.

Step 3: Relation between local and global quantities.

The relation between the position (2.98) of a single body K_i and the generalized coordinates (2.96) is given by the holonomic, and in general, also by rheonomic constraints. These relations are known from the input data as

$$\boldsymbol{r}_i = \boldsymbol{r}_i(\boldsymbol{y}, t), \quad \boldsymbol{S}_i = \boldsymbol{S}_i(\boldsymbol{y}, t), \quad i = 1(1)p, \tag{2.102}$$

and the corresponding velocities $\{\boldsymbol{v}_i, \omega_i\}$ and accelerations $\{\boldsymbol{a}_i, \alpha_i\}$ are computed as

$$\boldsymbol{v}_i = \dot{\boldsymbol{r}}_i = \frac{\partial \boldsymbol{r}_i}{\partial \boldsymbol{y}^{\mathrm{T}}} \dot{\boldsymbol{y}} + \frac{\partial \boldsymbol{r}_i}{\partial t} = \boldsymbol{J}_{Ti}(\boldsymbol{y}, t) \dot{\boldsymbol{y}} + \overline{\boldsymbol{v}}_i(\boldsymbol{y}, t), \tag{2.103}$$

$$\boldsymbol{\omega}_i = \dot{\boldsymbol{s}}_i = \frac{\partial \boldsymbol{s}_i}{\partial \boldsymbol{y}^{\mathrm{T}}} \dot{\boldsymbol{y}} + \frac{\partial \boldsymbol{s}_i}{\partial t} = \boldsymbol{J}_{Ri}(\boldsymbol{y}, t) \dot{\boldsymbol{y}} + \overline{\boldsymbol{\omega}}_i(\boldsymbol{y}, t), \tag{2.104}$$

$$\boldsymbol{a}_i = \dot{\boldsymbol{v}}_i = \boldsymbol{J}_{Ti}(\boldsymbol{y}, t) \ddot{\boldsymbol{y}} + \frac{\partial \boldsymbol{v}_i}{\partial \boldsymbol{y}^{\mathrm{T}}} \dot{\boldsymbol{y}} + \frac{\partial \boldsymbol{v}_i}{\partial t}, \tag{2.105}$$

$$\boldsymbol{a}_i = \dot{\boldsymbol{\omega}}_i = \boldsymbol{J}_{Ri}(\boldsymbol{y},t)\,\ddot{\boldsymbol{y}} + \frac{\partial \boldsymbol{\omega}_i}{\partial \boldsymbol{y}^{\mathrm{T}}}\,\dot{\boldsymbol{y}} + \frac{\partial \boldsymbol{\omega}_i}{\partial t}. \tag{2.106}$$

For scleronomic constraints, the partial time derivatives are disappearing.

The $3 \times f$ Jacobian matrices $\boldsymbol{J}_{Ti}$, $\boldsymbol{J}_{Ri}$ of translation and rotation, respectively, present the relation between the local and global coordinates as shown by the virtual motion:

$$\delta \boldsymbol{r}_i = \boldsymbol{J}_{Ti}\,\delta \boldsymbol{y}, \quad \delta s_i = \boldsymbol{J}_{Ri}\,\delta \boldsymbol{y}, \quad i = 1(1)p. \tag{2.107}$$

These matrices are available from kinematics from the relations (2.103) and (2.104).

After these preparatory computations, the local equations (2.100) and (2.101) of body K_i of the multi-body system are evaluated as functions of the generalized coordinates and their derivatives.

Step 4: System consideration, global equations.

At first the local equ ations, depending on the generalized coordinates, are composed in global matrices and vectors. For this purpose, the $6p \times 6p$ diagonal matrix $\overline{\overline{\boldsymbol{M}}}$ of the inertia quantities is introduced

$$\overline{\overline{\boldsymbol{M}}} = \mathrm{diag}\,[m_1\,\boldsymbol{E}, m_2\,\boldsymbol{E}, \ldots, m_p\,\boldsymbol{E}, \boldsymbol{I}_1, \boldsymbol{I}_2, \ldots, \boldsymbol{I}_p], \tag{2.108}$$

where $\boldsymbol{E}$ means the 3×3 unit matrix. Further, the $6p \times 1$ vectors $\overline{\boldsymbol{q}}^{(e)}$, $\overline{\boldsymbol{q}}^{(r)}$, $\boldsymbol{k}$ are used to summarize all applied reaction, Coriolis and gyro forces, and torques. These three vectors are defined as follows:

$$\overline{\boldsymbol{q}} = \left[\boldsymbol{f}_1^{\mathrm{T}}, \ldots, \boldsymbol{f}_p^{\mathrm{T}}, \boldsymbol{l}_1^{\mathrm{T}}, \ldots, \boldsymbol{l}_p^{\mathrm{T}}\right]^{\mathrm{T}} \tag{2.109}$$

And finally, the global $6p \times f$ Jacobian matrix is introduced as

$$\overline{\boldsymbol{J}} = [\boldsymbol{J}_{T1}^{\mathrm{T}}, \ldots, \boldsymbol{J}_{Tp}^{\mathrm{T}}, \boldsymbol{J}_{R1}^{\mathrm{T}}, \ldots, \boldsymbol{J}_{Rp}^{\mathrm{T}}]^{\mathrm{T}}. \tag{2.110}$$

The global Newton–Euler equations are now represented as one $6p \times 1$ vector equation:

$$\overline{\overline{\boldsymbol{M}}}\,\overline{\boldsymbol{J}}\,\ddot{\boldsymbol{y}} + \overline{\boldsymbol{k}}(\boldsymbol{y}, \dot{\boldsymbol{y}}, t) = \overline{\boldsymbol{q}}^{(e)}(\boldsymbol{y}, \dot{\boldsymbol{y}}, t) + \overline{\boldsymbol{q}}^{(r)}. \tag{2.111}$$

These $6p$ equations are reduced to the minimal number of f ODEs by left pre-multiplication with the transposed $f \times 6p$ Jacobian matrix $\overline{\boldsymbol{J}}^{\mathrm{T}}$,

$$\overline{\boldsymbol{J}}^{\mathrm{T}}\overline{\overline{\boldsymbol{M}}}\,\overline{\boldsymbol{J}}\ddot{\boldsymbol{y}} + \overline{\boldsymbol{J}}^{\mathrm{T}}\overline{\boldsymbol{k}}(\boldsymbol{y}, \dot{\boldsymbol{y}}, t) = \overline{\boldsymbol{J}}^{\mathrm{T}}\overline{\boldsymbol{q}}^{(e)}(\boldsymbol{y}, \dot{\boldsymbol{y}}, t), \tag{2.112}$$

where the term $\overline{\boldsymbol{J}}^{\mathrm{T}}\boldsymbol{q}(r)$ is vanishing due to 2.62.

Summarizing the matrix products, one gets the equations of motion with symmetric inertia matrix

$$\boldsymbol{M}(\boldsymbol{y}, t)\ddot{\boldsymbol{y}}(t) + \boldsymbol{k}(\boldsymbol{y}, \dot{\boldsymbol{y}}, t) = \boldsymbol{q}(\boldsymbol{y}, \dot{\boldsymbol{y}}, t),$$

$$\boldsymbol{M} = \boldsymbol{M}^{\mathrm{T}} = \overline{\boldsymbol{J}}^{\mathrm{T}}\overline{\overline{\boldsymbol{M}}}\,\overline{\boldsymbol{J}}, \quad \boldsymbol{k} = \overline{\boldsymbol{J}}^{\mathrm{T}}\overline{\boldsymbol{k}}, \quad \boldsymbol{q} = \overline{\boldsymbol{J}}^{\mathrm{T}}\overline{\boldsymbol{q}}^{(e)} \tag{2.113}$$

in complete agreement with 2.88.

Optional step 5: Computation of the reaction forces and torques.

In contrary to Lagrange's approach, the reactions can be regained if the global distribution matrix $\bar{\boldsymbol{Q}}$ according to 2.62 and the generalized constraint forces $\boldsymbol{g}$ from 2.63 are employed. Then, it yields

$$\bar{\boldsymbol{q}}^{(r)} = \bar{\boldsymbol{Q}}\boldsymbol{g}. \tag{2.114}$$

Due to the orthogonality condition (2.68), the left pre-multiplication of 2.111 with $\bar{\boldsymbol{Q}}^{\mathrm{T}}\overline{\overline{\boldsymbol{M}}}^{-1}$ results in linear, completely algebraic reaction equations

$$\hat{\boldsymbol{N}}(\boldsymbol{y},t)\,\boldsymbol{g}(t) + \hat{\boldsymbol{q}}(\boldsymbol{y},\dot{\boldsymbol{y}},t) = \hat{\boldsymbol{k}}(\boldsymbol{y},\dot{\boldsymbol{y}},t),$$

$$\hat{\boldsymbol{N}} = \hat{\boldsymbol{N}}^{\mathrm{T}} = \bar{\boldsymbol{Q}}^{\mathrm{T}}\overline{\overline{\boldsymbol{M}}}^{-1}\bar{\boldsymbol{Q}},\ \hat{\boldsymbol{q}} = \bar{\boldsymbol{Q}}^{\mathrm{T}}\overline{\overline{\boldsymbol{M}}}^{-1}\bar{\boldsymbol{q}}^{(e)},\ \hat{\boldsymbol{k}} = \bar{\boldsymbol{Q}}^{\mathrm{T}}\overline{\overline{\boldsymbol{M}}}^{-1}\bar{\boldsymbol{k}}, \tag{2.115}$$

where $\hat{\boldsymbol{N}}$is the symmetric, generally positive definite $q \times q$ reaction matrix while the $q \times 1$ vectors $\hat{\boldsymbol{q}}$, $\hat{\boldsymbol{k}}$ show the influence of the applied and gyroscopic forces and torques on the reactions. On the other hand, by elimination of $\ddot{\boldsymbol{y}}$ in 2.111, one gets

$$\bar{\boldsymbol{q}}^{(r)} = \bar{\boldsymbol{Q}}\boldsymbol{g} = [\boldsymbol{E} - \overline{\overline{\boldsymbol{M}}}\ \bar{\boldsymbol{J}}(\bar{\boldsymbol{J}}^{\mathrm{T}}\overline{\overline{\boldsymbol{M}}}\,\bar{\boldsymbol{J}})^{-1}\bar{\boldsymbol{J}}^{\mathrm{T}}](\bar{\boldsymbol{k}} - \bar{\boldsymbol{q}}^{(e)}). \tag{2.116}$$

Then, by partitioning of 2.116, only some of the constraint forces and torques may be computed.

In vehicle dynamics, often contact forces are found resulting in nonideal multi-body systems. Then, the f equations of motion (2.113) have to be solved simultaneously with the q equations of reaction (2.115).

The presented five steps show that the NEWEUL formalism is based on the Newton–Euler equations; however, they are supplemented by typical features of the analytical method like generalized coordinates and generalized reactions. The required computations include summation, multiplication, and differentiation of vectors and matrices, simplification of trigonometric expressions, and linearization of expressions. These computations are symbolically performed in NEWEUL. But the underlying formalism may also be executed by any formula manipulation software, for example, by MAPLE. More details on NEWEUL are found on the web: www.itm.uni-stuttgart.de/research/neweul/neweulm2_en.php

The most widely used numerical formalism in vehicle engineering is MSC.ADAMS. The software MSC.ADAMS generate numerical solutions of the original nonreduced Newton–Euler equations (2.55) and (2.56) rewritten as

$$\overline{\overline{\boldsymbol{M}}}\ \ddot{\boldsymbol{x}} + \boldsymbol{k}\left(\boldsymbol{x},\dot{\boldsymbol{x}},t\right) = \bar{\boldsymbol{q}}^{(e)}\left(\boldsymbol{x},\dot{\boldsymbol{x}},t\right) + \bar{\boldsymbol{Q}}\boldsymbol{g},\quad \bar{\boldsymbol{Q}}^{\mathrm{T}} = -\frac{\partial \boldsymbol{\Phi}}{\partial \boldsymbol{x}^{\mathrm{T}}} = -\boldsymbol{\Phi}_x, \tag{2.117}$$

where the $6p \times 1$ vector $\boldsymbol{x}(t)$ is composed by Cartesian coordinates and the $6p \times q$ distribution matrix $\bar{\boldsymbol{Q}}$ of the reactions is found from the implicit constraints (2.33).

After two total time derivatives of 2.33, a set of $6p + q$ linear equations remains for the unknowns $\ddot{\boldsymbol{x}}$and $\boldsymbol{g}$,

$$\begin{bmatrix} \overline{\overline{\boldsymbol{M}}} & \boldsymbol{\Phi}_x^{\mathrm{T}} \\ \boldsymbol{\Phi}_x & \boldsymbol{0} \end{bmatrix}\begin{bmatrix} \ddot{\boldsymbol{x}} \\ \boldsymbol{g} \end{bmatrix} = \begin{bmatrix} \boldsymbol{q}^{(e)} - \boldsymbol{k} \\ -\boldsymbol{\Phi}_t - \dot{\boldsymbol{\Phi}}_x\dot{\boldsymbol{x}} \end{bmatrix}. \tag{2.118}$$

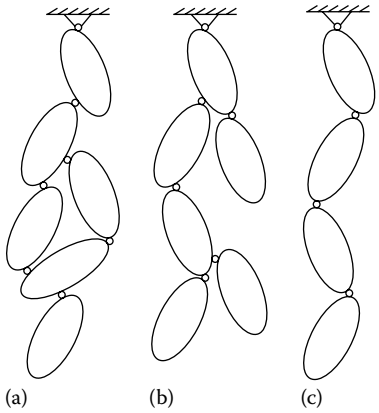

FIGURE 2.11 Topology of multi-body systems. (a) Loop, (b) tree, (c) chain.

Here, $\overline{\boldsymbol{M}}$ is a block diagonal $6\,p \times 6\,p$ matrix which allows the application of sparse matrix techniques. Equation 2.118 represents DAEs, which are solved within the MSC.ADAMS software with special integration codes (see also Chapter 3). As with all commercial codes, a graphical interface is used, and mathematical equations are not to be handled. For more details, search for ADAMS under www.mscsoftware.com

2.5.2 Recursive Formalisms

For time integration of holonomic systems, the mass matrix in 2.88 or 2.113, respectively, has to be inverted what is numerically costly for systems with many degrees of freedom

$$\ddot{\boldsymbol{y}}(t) = \boldsymbol{M}^{-1}(\boldsymbol{y},t)\left[\boldsymbol{q}(\boldsymbol{y},\dot{\boldsymbol{y}},t) - \boldsymbol{k}(\boldsymbol{y},\dot{\boldsymbol{y}},t)\right]. \tag{2.119}$$

Recursive algorithms avoid this matrix inversion. The fundamental requirement, however, is a chain or tree topology of the multi-body system as shown in Figure 2.11. Loop topologies are not included. Contributions on recursive algorithms are due, for example, to Hollerbach [14], Bae and Haug [15], Brandl et al. [16], and Schiehlen [17].

2.5.2.1 Kinematics

Recursive kinematics uses the relative motion between two neighboring bodies and the related constraints as shown in Figure 2.12. The absolute translational and rotational velocity vector $\boldsymbol{w}_i$ of body i, also denoted as twist, is related to the absolute velocity vector w_{i-1} of body $(i-1)$ and the generalized coordinates $\boldsymbol{y}_i$ of the joint i between this two bodies. It yields

$$\underbrace{\begin{bmatrix}\boldsymbol{v}_{Oi}\\ \boldsymbol{\omega}_i\end{bmatrix}}_{\boldsymbol{w}_i} = \underbrace{\boldsymbol{S}^{i,i-1}\begin{bmatrix}\boldsymbol{E} & -\tilde{\boldsymbol{r}}_{Oi-1,Oi}\\ \boldsymbol{0} & \boldsymbol{E}\end{bmatrix}}_{\boldsymbol{C}_i}\underbrace{\begin{bmatrix}\boldsymbol{v}_{Oi-1}\\ \boldsymbol{\omega}_{i-1}\end{bmatrix}}_{\boldsymbol{w}_{i-1}} + \underbrace{\boldsymbol{S}^{i,i-1}\begin{bmatrix}\boldsymbol{J}_{Ti}\\ \boldsymbol{J}_{Ri}\end{bmatrix}}_{\boldsymbol{J}_i}\dot{\boldsymbol{y}}_i. \tag{2.120}$$

Using the fundamentals of relative motion of rigid bodies, it remains for the absolute acceleration

$$\boldsymbol{b}_i = \boldsymbol{C}_i\,\boldsymbol{b}_{i-1} + \boldsymbol{J}_i\;\ddot{\boldsymbol{y}}_i + \beta_i(\dot{\boldsymbol{y}}_i, \boldsymbol{w}_{i-1}), \tag{2.121}$$

where the vector $\boldsymbol{b}_i$ summarizes the translational and rotational accelerations of body i as well.

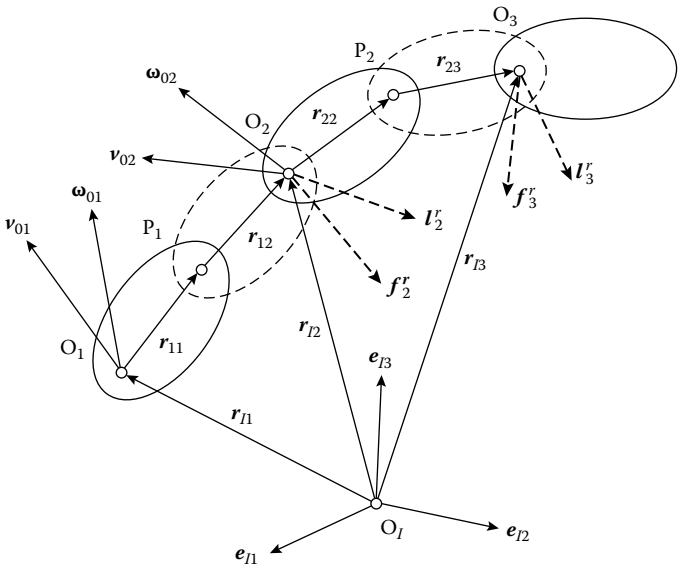

FIGURE 2.12 Three-body system with two joints.

For the total system, one gets for the absolute acceleration in matrix notation

$$\boldsymbol{b} = \boldsymbol{C}\ \boldsymbol{b} + \boldsymbol{J}\,\ddot{\boldsymbol{y}} + \beta, \tag{2.122}$$

where the geometry matrix $\boldsymbol{C}$ is a lower block-sub-diagonal matrix and the Jacobian $\boldsymbol{J}$ is a block-diagonal matrix as follows:

$$\boldsymbol{C} = \begin{bmatrix} 0 & 0 & 0 & \cdots & 0 \\ \boldsymbol{C}_2 & 0 & 0 & \cdots & 0 \\ 0 & \boldsymbol{C}_3 & 0 & \cdots & 0 \\ \vdots & \vdots & \ddots & \ddots & 0 \\ 0 & 0 & 0 & \boldsymbol{C}_p & 0 \end{bmatrix}, \quad \boldsymbol{J} = \begin{bmatrix} \boldsymbol{J}_1 & 0 & 0 & \cdots & 0 \\ 0 & \boldsymbol{J}_2 & \boldsymbol{0} & \cdots & 0 \\ 0 & 0 & \boldsymbol{J}_3 & \cdots & 0 \\ \vdots & \vdots & \ddots & \ddots & \vdots \\ 0 & 0 & 0 & 0 & \boldsymbol{J}_p \end{bmatrix}. \tag{2.123}$$

From 2.122, it follows the non-recursive form of the absolute accelerations as

$$\boldsymbol{b} = \left(\boldsymbol{E} - \boldsymbol{C}\right)^{-1} \boldsymbol{J}\,\ddot{\boldsymbol{y}} + \bar{\beta}, \tag{2.124}$$

where the global Jacobian matrix $\bar{\boldsymbol{J}}$ is found again (see 2.67 or 2.110)

$$\bar{\boldsymbol{J}} = \left(\boldsymbol{E} - \boldsymbol{C}\right)^{-1} \boldsymbol{J} = \begin{bmatrix} \boldsymbol{J}_1 & 0 & 0 & \cdots & 0 \\ \boldsymbol{C}_2\boldsymbol{J}_1 & \boldsymbol{J}_2 & 0 & \cdots & 0 \\ \boldsymbol{C}_3\boldsymbol{C}_2\boldsymbol{J}_1 & \boldsymbol{C}_3\boldsymbol{J}_2 & \boldsymbol{J}_3 & \cdots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ * & * & * & \cdots & \boldsymbol{J}_p \end{bmatrix}. \tag{2.125}$$

Due to the chain topology, the global Jacobian matrix is a lower triangular matrix.

2.5.2.2 Newton–Euler Equations

Newton's and Euler's equations are now written for body i in its body fixed frame at the joint position O_i using the absolute accelerations and the external forces $\boldsymbol{q}_i$ acting on the body with holonomic constraints:

$$\underbrace{\begin{bmatrix} m_i\boldsymbol{E} & m_i\tilde{\boldsymbol{r}}_{OiCi}^T \\ m_i\tilde{\boldsymbol{r}}_{OiCi} & \boldsymbol{I}_{Oi} \end{bmatrix}}_{\boldsymbol{M}_i = \text{constant}} \underbrace{\begin{bmatrix} \boldsymbol{a}_{Oi} \\ \boldsymbol{\alpha}_i \end{bmatrix}}_{\boldsymbol{b}_i} + \underbrace{\begin{bmatrix} m_i\tilde{\boldsymbol{\omega}}_i\tilde{\boldsymbol{\omega}}_i\boldsymbol{r}_{OiCi} \\ \tilde{\boldsymbol{\omega}}_i\boldsymbol{I}_{Oi}\boldsymbol{\omega}_i \end{bmatrix}}_{\boldsymbol{k}_i} = \underbrace{\begin{bmatrix} \boldsymbol{f}_i \\ \boldsymbol{l}_{Oi} \end{bmatrix}}_{\boldsymbol{q}_i}. \tag{2.126}$$

Moreover, the external forces are composed of applied forces $\boldsymbol{q}_i^{(e)}$ and constraints forces $q_i^{(r)}$ where the generalized constraint forces of the joint i and joint $(i+1)$ appear:

$$\boldsymbol{q}_i = \boldsymbol{q}_i^{(e)} + \boldsymbol{q}_i^{(r)}, \quad \boldsymbol{q}_i^{(r)} = \boldsymbol{Q}_i\boldsymbol{g}_i - \boldsymbol{C}_{i+1}^{\mathrm{T}}\boldsymbol{Q}_{i+1}\boldsymbol{g}_{i+1}. \tag{2.127}$$

2.5.2.3 Equations of Motion

For the total system, a set of 18 scalar equations remains from 2.122, 2.126, and 2.127

$$\boldsymbol{b} = \bar{\boldsymbol{J}}\ \ddot{\boldsymbol{y}} + \bar{\beta}, \tag{2.128}$$

$$\bar{\bar{\boldsymbol{M}}}\boldsymbol{b} + \bar{\boldsymbol{k}} = \boldsymbol{q}^{(e)} + \boldsymbol{q}^{(r)}, \tag{2.129}$$

$$\boldsymbol{q}^{(r)} = \left(\boldsymbol{E} - \boldsymbol{C}\right)^{\mathrm{T}}\ \boldsymbol{Q}\,\boldsymbol{g} = \bar{\boldsymbol{Q}}\,\boldsymbol{g} \tag{2.130}$$

with 18 unknowns in the vectors $\boldsymbol{b}$, $\boldsymbol{y}$, $\boldsymbol{q}^{(r)}$, $\boldsymbol{g}$.

Now, 2.128 and 2.130 are inserted in 2.129 and the global orthogonality $\bar{\boldsymbol{J}}^T\,\bar{\boldsymbol{Q}} = \boldsymbol{0}$ is used again, resulting in the standard form (2.113) of the equations of motion. The mass matrix is completely full, again, and the vector $\boldsymbol{k}$ depends not only on the generalized velocities but also on the absolute velocities:

$$\boldsymbol{M} = \begin{bmatrix} \boldsymbol{J}_1^t\left(\boldsymbol{M}_1 + \boldsymbol{C}_2^t\left(\boldsymbol{M}_2 + \boldsymbol{C}_3^t\boldsymbol{M}_3\boldsymbol{C}_3\right)\boldsymbol{C}_2\right)\boldsymbol{J}_1 & \boldsymbol{J}_1^t\boldsymbol{C}_2^t\left(\boldsymbol{M}_2 + \boldsymbol{C}_3^t\boldsymbol{M}_3\boldsymbol{C}_3\right)\boldsymbol{J}_2 & \boldsymbol{J}_1^t\boldsymbol{C}_2^t\boldsymbol{C}_3^t\boldsymbol{M}_3\boldsymbol{J}_3 \\ \boldsymbol{J}_2^t\left(\boldsymbol{M}_2 + \boldsymbol{C}_3^t\boldsymbol{M}_3\boldsymbol{C}_3\right)\boldsymbol{C}_2\boldsymbol{J}_1 & \boldsymbol{J}_2^t\left(\boldsymbol{M}_2 + \boldsymbol{C}_3^t\boldsymbol{M}_3\boldsymbol{C}_3\right)\boldsymbol{J}_2 & \boldsymbol{J}_2^t\boldsymbol{C}_3^t\boldsymbol{J}_3 \\ \boldsymbol{J}_3\boldsymbol{M}_3\boldsymbol{C}_3\boldsymbol{C}_2\boldsymbol{J}_1 & \boldsymbol{J}_3^t\boldsymbol{M}_3\boldsymbol{C}_3\boldsymbol{J}_2 & \boldsymbol{J}_3^t\boldsymbol{M}_3\boldsymbol{J}_3 \end{bmatrix}, \tag{2.131}$$

$$\boldsymbol{k} = \boldsymbol{k}\left(\boldsymbol{y}, \dot{\boldsymbol{y}}, \boldsymbol{w}\right). \tag{2.132}$$

However, the mass matrix shows now a characteristic structure, which can be used for a Gauss transformation.

2.5.2.4 Recursion

There are three steps required to obtain the generalized accelerations:

1. Forward recursion to get the absolute motion starting with $i = 1$.
2. Backward recursion using a Gauss transformation starting with $i = p$. As a result, the system

$$\hat{\boldsymbol{M}}\,\ddot{\boldsymbol{y}} + \hat{\boldsymbol{k}} = \hat{\boldsymbol{q}} \tag{2.133}$$

is obtained where $\hat{\boldsymbol{M}}$ is a lower triangular matrix

$$\overset{\Delta}{\boldsymbol{M}} = \begin{bmatrix} \boldsymbol{J}_1^t \tilde{\boldsymbol{M}}_1 \boldsymbol{J}_1 & 0 & 0 \\ \boldsymbol{J}_2^t \tilde{\boldsymbol{M}}_2 \boldsymbol{C}_2 \boldsymbol{J}_1 & \boldsymbol{J}_2^t \tilde{\boldsymbol{M}}_2 \boldsymbol{J}_2 & 0 \\ \boldsymbol{J}_3^t \tilde{\boldsymbol{M}}_3 \boldsymbol{C}_3 \boldsymbol{C}_2 \boldsymbol{J}_1 & \boldsymbol{J}_3^t \tilde{\boldsymbol{M}}_3 \boldsymbol{C}_3 \boldsymbol{J}_2 & \boldsymbol{J}_3^t \tilde{\boldsymbol{M}}_3 \boldsymbol{J}_3 \end{bmatrix}, \tag{2.134}$$

$$\tilde{\boldsymbol{M}}_{i-1} = \boldsymbol{M}_{i-1} + \boldsymbol{C}_i^t \left(\tilde{\boldsymbol{M}}_i - \tilde{\boldsymbol{M}}_i \boldsymbol{J}_i \left(\boldsymbol{J}_i^t \tilde{\boldsymbol{M}}_i \boldsymbol{J}_i \right)^{-1} \boldsymbol{J}_i^t \tilde{\boldsymbol{M}}_i \right) \boldsymbol{C}_i \tag{2.135}$$

the block elements of which follow from the recursion formula (2.135).

3. Forward recursion for the generalized accelerations starting with $i = 1$.

The recursion requires some computational overhead. Therefore, the recursive algorithms are more efficient than the matrix inversion for more than $p = 8$–10 bodies.

There are also some extensions of the recursive approach to loop topologies (see Bae and Haug [18] and Saha and Schiehlen [19]). Further, it is mentioned that there are two commercial codes based on recursive formalisms: SIMPACK and RecurDyn. For more details, see www.simpack.de and www.functionbay.co.kr

3.1 INTRODUCTION

Model-based simulation in vehicle system dynamics relies on advanced methods for model setup, robust and efficient numerical solution techniques, and powerful simulation tools for industrial applications.

Most frequently, the mechanical components are described by rigid or flexible multi-body system models that interact with electrical, hydraulic, and other system components [1,2] (see also [3] for a summary of recent developments and [4] for a comprehensive overview on methods and algorithms that are tailored to industrial simulation packages). The first systematic treatment of numerical

problems and numerical methods in multi-body dynamics from the viewpoint of vehicle system dynamics is the monograph of Eich-Soellner and Führer [5] (see also [6]).

In its simplest form, the equations of motion of a multi-body system are given by a nonlinear second-order system of ordinary differential equations (ODEs) of moderate dimension that may be solved numerically by standard methods.

The structure of the model equations gets more complicated if the multi-body system has kinematically *closed loops* [7]. Multi-body system models of wheel suspensions may be considered as a typical example in road vehicle simulation. The complex kinematics is modeled by *constraints*; the resulting model equations form a second-order differential-algebraic equation (DAE).

Robust and efficient DAE time integration methods are the backbone of state-of-the-art multi-body system simulation software. Another important issue in simulation is the handling of *discrete* controllers that are beyond the classical time continuous world of mechanics.

Advanced multi-body system simulation packages have been open to multidisciplinary applications for a long time. The classical approach to the integration of hydraulic and electrical system components in multi-body models are special force elements with time continuous or time discrete inner state variables [3].

Alternatively, novel modeling and simulation techniques for multi-physical technical systems may be used in more complex multidisciplinary applications. Here, the multidisciplinary aspect is considered by universal modeling languages like Modelica [8] or by the coupling of several monodisciplinary simulation packages in a co-simulation environment [9].

In this chapter, we give an overview on classical and more advanced simulation algorithms in vehicle system dynamics that are closely related to multi-body numerics and multi-body system simulation packages.

The material is organized as follows: Basic simulation algorithms in multi-body system analysis are summarized in Section 3.2. In Section 3.3, we discuss the general structure of model equations including closed-loop systems, inner state variables of force elements, and time discrete subsystems. Special DAE time integration methods for the robust and efficient numerical solution of these model equations are presented in Section 3.4. Finally, in Section 3.5, we focus on algorithms and tools for multidisciplinary applications.

Throughout this chapter, distributed physical phenomena like the elastic deformation of car components or the temperature field in disk brakes are considered only by low-dimensional modal approximations. Modeling and numerical solution by finite element techniques are studied separately in the subsequent chapter on FEM (see Chapter 4).

3.2 BASIC SIMULATION ALGORITHMS

If a mechanical multi-body system is described by a minimum set of generalized coordinates $\boldsymbol{y}(t) \in \mathbb{R}^{n_y}$, the equations of motion form a second-order ODE

$$\boldsymbol{M}(\boldsymbol{y})\ddot{\boldsymbol{y}}(t) = \boldsymbol{f}(\boldsymbol{y}, \dot{\boldsymbol{y}}, t) \tag{3.1}$$

with the symmetric, positive definite mass matrix $\boldsymbol{M}(\boldsymbol{y})$ containing mass and inertia properties of all bodies and the vector of applied and gyroscopic forces $\boldsymbol{f}(\boldsymbol{y}, \dot{\boldsymbol{y}}, t)$ [7,10].

Despite its implicit structure, Equation (3.1) can be solved numerically with a complexity that grows only linearly with the number N of bodies in the system. These $\mathcal{O}(N)$ *formalisms* exploit the topology of the multi-body system to evaluate the right-hand side $\boldsymbol{M}^{-1}(\boldsymbol{y})\boldsymbol{f}(\boldsymbol{y}, \dot{\boldsymbol{y}}, t)$ for given $t, \boldsymbol{y}, \dot{\boldsymbol{y}}$ (*explicit* formalisms, for example, [11,12]) or the residual $\boldsymbol{r}(\boldsymbol{y}, \dot{\boldsymbol{y}}, \boldsymbol{a}, t) := \boldsymbol{M}(\boldsymbol{y})\boldsymbol{a} - \boldsymbol{f}(\boldsymbol{y}, \dot{\boldsymbol{y}}, t)$ for given $t, \boldsymbol{y}, \dot{\boldsymbol{y}}, \boldsymbol{a}$ (*residual* formalisms, for example, [13]) efficiently.

In contrast to structural dynamics, the standard time integration methods of multi-body dynamics are not tailored to the second-order structure of (3.1) since additional first-order equations

have to be considered frequently in practical applications (see Section 3.3). With the velocity vector $\boldsymbol{v} := \dot{\boldsymbol{y}}$, the equations of motion get the state space form

$$\dot{\boldsymbol{x}}(t) = \varphi(\boldsymbol{x}, t) \quad \text{with } \boldsymbol{x}(t) := \begin{pmatrix} \boldsymbol{y}(t) \\ \boldsymbol{v}(t) \end{pmatrix}, \quad \varphi(\boldsymbol{x}, t) := \begin{pmatrix} \boldsymbol{v} \\ [\boldsymbol{M}^{-1}\boldsymbol{f}](\boldsymbol{y}, \boldsymbol{v}, t) \end{pmatrix}. \tag{3.2}$$

3.2.1 Static Analysis

The computation of static equilibria is often the first step in the analysis of a multi-body system model. They define, for example, the working point for the linearization of (3.1) and provide initial values for the dynamical simulation. An equilibrium position $\boldsymbol{y}^*$ is determined by the equilibrium conditions $\dot{\boldsymbol{y}} = \ddot{\boldsymbol{y}} = \boldsymbol{0}$ at $t = t_0$:

$$\boldsymbol{0} = \boldsymbol{f}(\boldsymbol{y}^*, \boldsymbol{0}, t_0). \tag{3.3}$$

Equation (3.3) form a system of n_y nonlinear equations for the n_y unknowns $\boldsymbol{y}^*$ that is solved by Newton's method [14] being available as free software in a number of implementations that meet the demands on robustness and efficiency in engineering applications, see, for example, the results of the MINPACK project [15] at http://www.netlib.org/minpack.

Alternatively, the equilibrium position $\boldsymbol{y}^*$ of a stable system may also be obtained as limit $\boldsymbol{y}^* = \lim_{t\to\infty}\boldsymbol{y}(t)$ by a long-term time integration of the equations of motion (3.1) without external excitations. The time integration to the equilibrium position needs more computing time than Newton's method but in critical applications it is often the more robust approach.

Problems with the same mathematical structure as the equilibrium equations (3.3) result from the analysis of steady states. If a car runs with constant speed v_0 in a constant radius path, its position and velocity along this path are given by $s(t) = s_0 + v_0(t - t_0)$ and by v_0, respectively, and a force acts in normal direction to keep the radius constant. The remaining $n_y - 1$ components $\bar{\boldsymbol{f}}(\boldsymbol{y}, \dot{\boldsymbol{y}}, t)$ of the force vector $\boldsymbol{f}$ in (3.1) have to vanish and give the first $n_y - 1$ equations of the n_y steady-state conditions

$$\boldsymbol{0} = \bar{\boldsymbol{f}}(\boldsymbol{y}^*, \boldsymbol{v}^*, t_0), \quad s_0 = s(t_0) \tag{3.4}$$

that have to be solved w.r.t. $\boldsymbol{y}^* \in \mathbb{R}^{n_y}$. All components of the steady-state velocity vector $\boldsymbol{v}^*$ are equal to zero except the one that is tangential to the constant radius path ($v_0^* = v_0$). For steady-state problems (3.4), Newton's method (or, alternatively, the long-term time integration of a stable system into its steady state) is again the method of choice.

There are some other static analysis methods that are closely related to the equilibrium problem (3.3): the computation of nominal forces in vehicle dynamics [5] and the trimming of aircraft models in aeronautics [16]. In both applications, the actual values of some parameters $\boldsymbol{\theta} \in \mathbb{R}^{n_\theta}$ in the force elements are left undefined in the model setup: $\boldsymbol{f} = \boldsymbol{f}(\boldsymbol{y}, \dot{\boldsymbol{y}}, t; \boldsymbol{\theta})$. Later, these parameters are adjusted to meet equilibrium conditions

$$\boldsymbol{0} = \boldsymbol{f}(\boldsymbol{y}_0, \boldsymbol{0}, t_0; \boldsymbol{\theta}^*) \tag{3.5}$$

for a predefined position $\boldsymbol{y}_0$ of the multi-body system. The actual values $\boldsymbol{\theta}^*$ of nominal forces or trim parameters are important criteria for the evaluation of a vehicle or aircraft design.

Equation (3.5) has the same mathematical structure as the classical equilibrium problem (3.3) and could in principle be solved again by Newton's method. However, in practical

applications, the system (3.5) is often underdetermined. Following the approach of Levenberg and Marquardt, (3.5) may be substituted by

$$\| \boldsymbol{f}(\boldsymbol{y}_0, \boldsymbol{0}, t_0; \boldsymbol{\theta}^*) \|_2 + \alpha \, \|\boldsymbol{\theta}^*\|_2 \rightarrow \min$$

to guarantee uniqueness of $\boldsymbol{\theta}^*$. Here, $\alpha > 0$ denotes a small scalar regularization parameter [17].

3.2.2 Linearization

The linearization of the equations of motion (3.1) is the key to the linear stability analysis near an equilibrium (see Chapter 5) and to other methods of linear system analysis [2]. Writing the right-hand side of (3.1) as $\boldsymbol{f}(\boldsymbol{y}, \dot{\boldsymbol{y}}, \boldsymbol{u}(t))$ with system inputs $\boldsymbol{u}(t) \in \mathbb{R}^{n_u}$, the linearization at an equilibrium $\boldsymbol{y} = \boldsymbol{y}^*, \dot{\boldsymbol{y}} = \boldsymbol{0}, \boldsymbol{u} = \boldsymbol{0}$ yields

$$\boldsymbol{M}\ddot{\bar{\boldsymbol{y}}} = -\boldsymbol{D}\dot{\bar{\boldsymbol{y}}} - \boldsymbol{K}\bar{\boldsymbol{y}} + \boldsymbol{B}\boldsymbol{u}(t) \tag{3.6}$$

with

$$\boldsymbol{M} = \boldsymbol{M}(\boldsymbol{y}^*), \quad \boldsymbol{D} = -\frac{\partial \boldsymbol{f}}{\partial \dot{\boldsymbol{y}}}(\boldsymbol{y}^*, \boldsymbol{0}, \boldsymbol{0}), \quad \boldsymbol{K} = -\frac{\partial \boldsymbol{f}}{\partial \boldsymbol{y}}(\boldsymbol{y}^*, \boldsymbol{0}, \boldsymbol{0}), \quad \boldsymbol{B} = \frac{\partial \boldsymbol{f}}{\partial \boldsymbol{u}}(\boldsymbol{y}^*, \boldsymbol{0}, \boldsymbol{0}).$$

The Jacobians $\partial \boldsymbol{f}/\partial \boldsymbol{y}$, $\partial \boldsymbol{f}/\partial \dot{\boldsymbol{y}}$, and $\partial \boldsymbol{f}/\partial \boldsymbol{u}$ are approximated by classical finite differences [14]. We obtain for the ith column of $\partial \boldsymbol{f}/\partial \boldsymbol{y}$

$$\left(\frac{\partial \boldsymbol{f}}{\partial \boldsymbol{y}}(\boldsymbol{y}^*, \boldsymbol{0}, \boldsymbol{0}) \right)_{\bullet, i} \approx \frac{\boldsymbol{f}(\boldsymbol{y}^* + \Delta \cdot \boldsymbol{e}_i, \boldsymbol{0}, \boldsymbol{0}) - \boldsymbol{f}(\boldsymbol{y}^*, \boldsymbol{0}, \boldsymbol{0})}{\Delta} \tag{3.7}$$

with the ith unit vector $\boldsymbol{e}_i$ and a small scalar parameter Δ that satisfies $0 < |\Delta| \ll 1$.

The numerical effort for the linearization (3.6) is dominated by the difference approximations (3.7) with a total of $2n_y + n_u + 1$ evaluations of $\boldsymbol{f}$ that require $2n_y + n_u + 1$ evaluations of each force element in the multi-body system model. Substantial savings are achieved by the simultaneous difference approximation of several columns of $\partial \boldsymbol{f}/\partial \boldsymbol{y}$, $\partial \boldsymbol{f}/\partial \dot{\boldsymbol{y}}$, and $\partial \boldsymbol{f}/\partial \boldsymbol{u}$ that requires some graph theoretical preparations based on the topology of the multi-body system [18,19].

3.2.3 Time Integration

The state space form (3.2) of the equations of motion may be integrated by any standard ODE solver [20]. Explicit Runge–Kutta methods like the fifth-order method of Dormand and Prince (free FORTRAN code **DOPRI5** [21] and default ODE solver **ode45** in MATLAB®,* see [22]) and predictor–corrector methods of Adam's type (free FORTRAN code **LSODE** at http://www.netlib.org/odepack and MATLAB solver **ode113**) proved to be favorable in non-stiff applications.

More frequently, the model equations in vehicle system dynamics appear to be *stiff* [20,23] because of stiff springs and/or strongly damping force elements in most multi-body vehicle models (for additional information on both non-stiff and stiff problems, see Chapter 5). Backward differentiation formulae (BDF, also Gear's method) are the most often used time

* MATLAB is a trademark of The MathWorks, Inc., http://www.mathworks.com.

integration methods for stiff technical systems. Starting from initial values $\boldsymbol{x}_0 = \boldsymbol{x}(t_0)$, the numerical solution is obtained time step by time step solving

$$\frac{1}{h_n}\sum_{j=0}^{k_n}\alpha_{n,j}\boldsymbol{x}_{n+1-j} = \boldsymbol{\varphi}(\boldsymbol{x}_{n+1}, t_{n+1}) \tag{3.8}$$

w.r.t. $\boldsymbol{x}_{n+1} \approx \boldsymbol{x}(t_{n+1})$, $(n = 0, 1, \ldots)$.

In (3.8), the stepsize of time step $t_n \to t_{n+1}$ is denoted by $h_n := t_{n+1} - t_n$. The parameter k_n defines the order of the method, $1 \le k_n \le 6$, and $\alpha_{n,j}$ are the BDF coefficients that are determined by k_n and by the stepsizes $h_n, h_{n-1}, \ldots$ [20]. The well-known backward Euler method

$$\frac{1}{h_n}(\boldsymbol{x}_{n+1} - \boldsymbol{x}_n) = \boldsymbol{\varphi}(\boldsymbol{x}_{n+1}, t_{n+1})$$

is a special case of (3.8), $k_n = 1$.

For given state vectors $\boldsymbol{x}_{n+1-j} \approx \boldsymbol{x}(t_{n+1-j})$, $(j = 1, \ldots, k)$, the BDF equations (3.8) define $\boldsymbol{x}_{n+1}$ implicitly as solution of the system of n_x nonlinear equations

$$\boldsymbol{0} = \Phi(\boldsymbol{x}) := \frac{\alpha_{n,0}}{h_n}\boldsymbol{x} - \boldsymbol{\varphi}(\boldsymbol{x}, t_{n+1}) + \frac{1}{h_n}\sum_{j=1}^{k_n}\alpha_{n,j}\boldsymbol{x}_{n+1-j}. \tag{3.9}$$

The application of Newton's method to (3.9) yields

$$\boldsymbol{x}_{n+1}^{(l+1)} := \boldsymbol{x}_{n+1}^{(l)} - \boldsymbol{J}^{-1}\cdot\boldsymbol{\Phi}(\boldsymbol{x}_{n+1}^{(l)}), \quad (l \ge 0) \tag{3.10}$$

with an initial guess $\boldsymbol{x}_{n+1}^{(0)}$ that is obtained by polynomial extrapolation of $\boldsymbol{x}_n, \boldsymbol{x}_{n-1}, \ldots$. In (3.10), matrix $\boldsymbol{J}$ approximates the Jacobian of (3.9):

$$\boldsymbol{J} \approx \frac{\partial\boldsymbol{\Phi}}{\partial\boldsymbol{x}}\left(\boldsymbol{x}_{n+1}^{(l)}\right) = \frac{\alpha_{n,0}}{h_n}\boldsymbol{I}_{n_x} - \frac{\partial\boldsymbol{\varphi}}{\partial\boldsymbol{x}}\left(\boldsymbol{x}_{n+1}^{(l)}, t_{n+1}\right). \tag{3.11}$$

Typically, the approximation of $\partial\boldsymbol{\varphi}/\partial\boldsymbol{x}$ by finite differences according to (3.7) dominates the overall computing time in the dynamical simulation because of the large number of function evaluations of $\boldsymbol{\varphi}$ that require the evaluation of all force elements in the multi-body system and the computation of $[\boldsymbol{M}^{-1}\boldsymbol{f}](\boldsymbol{y}, \boldsymbol{v}, t)$ by the O(N) formalism (see 3.2). Therefore, these time-consuming reevaluations of the Jacobian $\boldsymbol{J}$ have to be avoided as far as possible [19,20].

In practical computations, stepsize h_n and order k_n are adapted automatically to meet the user-defined error tolerances. The combination of stepsize and order control with the algorithms for Newton's method (3.10) and for the Jacobian reevaluations results in a fairly complicated structure of state-of-the-art BDF solvers. Free FORTRAN codes are **LSODE** at http://www.netlib.org/odepack and **DASSL** at http://www.netlib.org/ode. The MATLAB BDF solver is **ode15s** (see [22]).

From the viewpoint of multi-body dynamics, the solver **DASSL** [24] is especially interesting because of its interface in residual form

$$\boldsymbol{0} = \boldsymbol{F}(\boldsymbol{x}, \dot{\boldsymbol{x}}, t) \tag{3.12}$$

that is a generalization of (3.2) with $\boldsymbol{F}(\boldsymbol{x}, \dot{\boldsymbol{x}}, t) = \dot{\boldsymbol{x}} - \boldsymbol{\varphi}(\boldsymbol{x}, t)$ and optionally allows also the use of very efficient residual formalisms [13]:

$$\boldsymbol{x}(t) := \begin{pmatrix}\boldsymbol{y}(t)\\ \boldsymbol{v}(t)\end{pmatrix}, \quad \boldsymbol{F}(\boldsymbol{x}, \dot{\boldsymbol{x}}, t) := \begin{pmatrix}\dot{\boldsymbol{y}} - \boldsymbol{v}\\ \boldsymbol{M}(\boldsymbol{y})\dot{\boldsymbol{v}} - \boldsymbol{f}(\boldsymbol{y}, \boldsymbol{v}, t)\end{pmatrix}.$$

Furthermore, **DASSL** may also be used in the time integration of closed-loop systems (see Section 3.4).

BDF for (3.12) have the form

$$\mathbf{0} = \boldsymbol{F}\left(\boldsymbol{x}_{n+1},\ \frac{1}{h_n}\sum_{j=0}^{k_n} \alpha_{n,j}\boldsymbol{x}_{n+1-j},\ t_{n+1} \right) \tag{3.13}$$

with the Jacobian

$$\boldsymbol{J} \approx \frac{\alpha_{n,0}}{h_n}\frac{\partial \boldsymbol{F}}{\partial \dot{\boldsymbol{x}}}(\boldsymbol{x}, \dot{\boldsymbol{x}}, t) + \frac{\partial \boldsymbol{F}}{\partial \boldsymbol{x}}(\boldsymbol{x}, \dot{\boldsymbol{x}}, t) \tag{3.14}$$

instead of (3.11). To keep the efficiency of classical BDF solvers in the application to multi-body systems, **DASSL**'s standard algorithm for Jacobian reevaluation has to be modified to exploit the special block structure of $\partial \boldsymbol{F}/\partial \dot{\boldsymbol{x}}$ (see [19]):

Explicit formalism: $\dfrac{\partial \boldsymbol{F}}{\partial \dot{\boldsymbol{x}}} = \begin{pmatrix} \boldsymbol{I}_{n_y} & \mathbf{0} \\ \mathbf{0} & \boldsymbol{I}_{n_y} \end{pmatrix}$, residual formalism: $\dfrac{\partial \boldsymbol{F}}{\partial \dot{\boldsymbol{x}}} = \begin{pmatrix} \boldsymbol{I}_{n_y} & \mathbf{0} \\ \mathbf{0} & \boldsymbol{M} \end{pmatrix}$.

3.3 GENERAL STRUCTURE OF MODEL EQUATIONS

The numerical methods that are discussed in Section 3.2 may be extended from the equations of motion (3.1) to more complex model equations that are typical of applications in vehicle system dynamics.

3.3.1 Flexible Multi-Body Systems

The elastic deformation of flexible bodies is not covered by the classical equations of motion (3.1) of rigid multi-body systems. In the moving frame of reference formulation [25–27], the configuration $\vec{u}^{(i)}(\vec{x}, t)$ of a flexible body $(.)^{(i)}$ in $\mathbb{R}^3$ is represented by the gross motion of a body fixed reference frame with coordinates $\boldsymbol{y}_r^{(i)}(t)$ and the (small) elastic deformation $\vec{w}^{(i)}(\vec{x}, t)$ w.r.t. this reference configuration:

$$\vec{u}^{(i)}(\vec{x}, t) = \vec{r}\left(\boldsymbol{y}_r^{(i)}(t) \right) + \vec{w}^{(i)}(\vec{x}, t). \tag{3.15}$$

Following a Rayleigh–Ritz approach, a low-dimensional modal approximation of $\vec{w}^{(i)}(\vec{x}, t)$ is used:

$$\vec{w}^{(i)}(\vec{x}, t) \approx \sum_{j=1}^{\sigma_i} q_j^{(i)}(t)\, \vec{w}_j^{(i)}(\vec{x}). \tag{3.16}$$

In general, the σ_i modes $\vec{w}_j^{(i)}$ are selected based on a finite element analysis of the flexible body $(.)^{(i)}$. Typical mode functions $\vec{w}_j^{(i)}$ are eigenmodes in the frequency range up to 50–100 Hz, static modes, or frequency response modes [27,28].

With (3.15) and (3.16), the equations of motion for flexible multi-body systems get the basic structure (3.1) with a coordinate vector $\boldsymbol{y}(t)$ that contains the generalized coordinates of rigid bodies and the elastic coordinates $\boldsymbol{y}_r^{(i)}(t)$ and $\left(q_1^{(i)}(t), \ldots, q_{\sigma_i}^{(i)}(t) \right)$ of flexible bodies. $\boldsymbol{M}(\boldsymbol{y})$ and $\boldsymbol{f}(\boldsymbol{y}, \dot{\boldsymbol{y}}, t)$ are extended by the modal mass, damping and stiffness matrices and by the coupling terms between gross motion and elastic deformation $\vec{w}^{(i)}$ (see [26,29]). In industrial applications, these data are generated automatically using standardized interfaces to finite element tools [30].

Today, the selection of an appropriate set of modes $\left\{ \vec{w}_1^{(i)}, \ldots, \vec{w}_{\sigma_i}^{(i)} \right\}$ still relies much on engineering intuition. Algorithms for (semi)automatic mode selection are a topic of active research (see [28]

for a criterion that is based on a linear error analysis, [29] for a more general approach that could be used in an adaptive mode selection strategy, and [31] for the use of *thermal response* modes in thermoelastic applications).

Recently, the moving frame of reference formulation has been extended to a modal multifield approach that considers elastic deformation as well as electrostatic fields in piezo elements and spatial temperature distributions in thermoelastic problems like the thermal deformation of disk brakes [31].

3.3.2 Inner State Variables

Frequently, force elements in multi-body system models describe engineering systems that have their own, internal dynamics (*dynamical* force elements [5]). Typical examples include hydraulic components, control devices (see Chapters 7 and 22), and advanced tire models (see Chapters 17 and 18). From the mathematical viewpoint, these force elements are characterized by *inner* state variables. Elements like hydraulic components have time continuous state variables $\boldsymbol{c}(t)$ with state equations

$$\dot{\boldsymbol{c}}(t) = \boldsymbol{d}(\boldsymbol{c}, \boldsymbol{y}, \dot{\boldsymbol{y}}, t). \tag{3.17}$$

The internal dynamics of discrete controllers is characterized by time discrete state variables $\boldsymbol{r}$ with $\boldsymbol{r} = \boldsymbol{r}_j$ in the sampling interval $[T_j, T_{j+1})$ and

$$\boldsymbol{r}_{j+1} = \boldsymbol{k}(\boldsymbol{r}_j, \boldsymbol{r}_{j-1}, \ldots, \boldsymbol{y}, \dot{\boldsymbol{y}}, T_{j+1}). \tag{3.18}$$

In most applications, the sampling points are equally spaced: $T_j = j \cdot \Delta_t$, typical sampling rates are in the range of Δ_t = 1–10 ms.

In the multi-body system, these force elements contribute to the force vector $\boldsymbol{f}$ in (3.1):

$$\boldsymbol{f} = \boldsymbol{f}(\boldsymbol{y}(t), \dot{\boldsymbol{y}}(t), \boldsymbol{c}(t), \boldsymbol{r}_j, t) \quad \text{if } t \in [T_j, T_{j+1}). \tag{3.19}$$

With (3.18) and (3.19), the equations of motion are not longer continuous in time but form a hybrid system with continuous and discrete components. In the dynamical simulation, the variable order, variable stepsize integrators of Section 3.2 may be used only within a single sampling interval $[T_j, T_{j+1}]$. At $t = T_{j+1}$, the integration has to be stopped, the discrete variables $\boldsymbol{r}$ are updated according to (3.18), and the time integration may be continued for $t \in [T_{j+1}, T_{j+2}]$.

The frequent re-initializations of the ODE solvers have a very negative effect on their performance that is compensated in part by an adapted algorithm for Jacobian reevaluations [4,19]. Alternatively, special Runge–Kutta type methods are proposed for a more efficient re-initialization after the sampling point T_{j+1} (see [32]).

3.3.3 Time Events

The discontinuous changes (3.18) of state variables are special *time events* [20]. The term "time event" refers to a discontinuity ("event") in state variables or model equations at an isolated time $t = T^*$ during simulation. For model equations (3.1) with $\boldsymbol{f} = \boldsymbol{f}(\boldsymbol{y}, \dot{\boldsymbol{y}}, \boldsymbol{c}, \boldsymbol{r}_j, \boldsymbol{u}(t); \boldsymbol{\theta})$, typical time events result from switching processes with jumping system inputs $\boldsymbol{u}(t)$ and from contact problems including stick-slip phenomena with force elements that change their force parameters $\boldsymbol{\theta}$ or even their internal structure during simulation (unilateral force elements, varying friction coefficients $\boldsymbol{\theta}$, etc. [5,33], see also Chapter 5).

For switching inputs $\boldsymbol{u}(t)$ the time T^* is known in advance but, in general, T^* has to be determined during simulation. State-of-the-art ODE solvers locate time events automatically using *switching functions* that have to be provided in addition to the model equations (3.1) (see [5,24]).

In case of a time event, the time integration is stopped at $t = T^*$, system variables $\boldsymbol{y}$, $\boldsymbol{c}$, $\boldsymbol{r}_j$ and system parameters $\boldsymbol{\theta}$ are updated (if necessary), and the simulation is continued after a re-initialization of the solver. Again, frequent time events may slow down the time integration substantially.

3.3.4 Kinematically Closed Loops

In the setup of multi-body system models, it is important to select an appropriate set of coordinates $\boldsymbol{y}$. For tree-structured systems, joint coordinates $\boldsymbol{y}$ that describe the degrees of freedom in the joints of the multi-body system form a minimum set of generalized coordinates resulting in equations of motion in ODE form (3.1).

If, however, the multi-body system has kinematically closed loops, then the joint coordinates $\boldsymbol{y}$ are no longer independent of each other. Loop closing joints restrict the system's configuration to joint coordinates $\boldsymbol{y}$ satisfying n_g *constraints*

$$\boldsymbol{0} = \boldsymbol{g}(\boldsymbol{y}, t). \tag{3.20}$$

Coordinate partitioning methods [7,34] locally select a subset of linearly independent joint coordinates and compute the remaining (dependent) joint coordinates solving the system of nonlinear equations (3.20). From the numerical viewpoint, it proved to be more favorable to keep *all* joint coordinates in the equations of motion that get the form

$$\boldsymbol{M}(\boldsymbol{y})\,\ddot{\boldsymbol{y}}(t) = \boldsymbol{f}(\boldsymbol{y},\,\dot{\boldsymbol{y}},\,t) - \boldsymbol{G}^{\top}(\boldsymbol{y},\,t)\lambda, \tag{3.21a}$$

$$\boldsymbol{0} = \boldsymbol{g}(\boldsymbol{y}, t) \tag{3.21b}$$

with constraint forces $-\boldsymbol{G}^{\top}(\boldsymbol{y},\,t)\boldsymbol{\lambda}$ that are determined by the constraint matrix $\boldsymbol{G}(\boldsymbol{y},\,t)$: = $(\partial \boldsymbol{g}/\partial \boldsymbol{y})$ $(\boldsymbol{y},\,t)$ and the Lagrange multipliers $\boldsymbol{\lambda}(t) \in \mathbb{R}^{n_g}$ (see [12]). The common assumption rank $\boldsymbol{G}(\boldsymbol{y},\,t) = n_g$ (*Grübler* condition) excludes redundant constraints (3.21b). Equations (3.21) form a second-order DAE, the *descriptor form* of the equations of motion [24].

The descriptor form is not restricted to joint coordinates $\boldsymbol{y}$. Using absolute (Cartesian) coordinates $\boldsymbol{y}$, *any* joint results in a constraint (3.21b). The resulting equations of motion (3.21) have a much larger dimension than in the joint coordinate case but $\boldsymbol{M}(\boldsymbol{y})$, $\partial \boldsymbol{f}/\partial \boldsymbol{y}$, $\partial \boldsymbol{f}/\partial \dot{\boldsymbol{y}}$, $\boldsymbol{G}^{\top}$ are sparse matrices with a structure that reflects the topology of the multi-body system [35]. The counterpart to O(N) formalisms that eliminate redundant coordinates in a joint coordinate formulation [11,12] are *topological solvers* for the absolute coordinate formulation that allow an efficient elimination of redundant coordinates in (3.10) (see [32,35]).

In DAE terminology, the descriptor form (3.21) is an index-3 system (see [23,24]). The constraints (3.21b) imply additional restrictions on the state variables $\boldsymbol{y}(t)$ and $\boldsymbol{\lambda}(t)$. These *hidden* constraints are obtained by differentiation of (3.21b):

$$\begin{aligned}\boldsymbol{0} &= \frac{\mathrm{d}}{\mathrm{d}t}\,\boldsymbol{g}(\boldsymbol{y}(t), t) = \frac{\partial \boldsymbol{g}}{\partial \boldsymbol{y}}(\boldsymbol{y}, t)\cdot\frac{\mathrm{d}\boldsymbol{y}}{\mathrm{d}t}(t) + \frac{\partial \boldsymbol{g}}{\partial t}(\boldsymbol{y}, t)\\ &= \boldsymbol{G}(\boldsymbol{y}, t)\,\dot{\boldsymbol{y}}(t) + \boldsymbol{g}^{(I)}(\boldsymbol{y}, t),\end{aligned} \tag{3.22a}$$

$$\boldsymbol{0} = \frac{\mathrm{d}^2}{\mathrm{d}t^2}\,\boldsymbol{g}(\boldsymbol{y}(t), t) = \boldsymbol{G}(\boldsymbol{y}, t)\,\ddot{\boldsymbol{y}}(t) + \boldsymbol{g}^{(II)}(\boldsymbol{y},\,\dot{\boldsymbol{y}},\,t) \tag{3.22b}$$

with functions $\boldsymbol{g}^{(I)}$ and $\boldsymbol{g}^{(II)}$ that summarize higher-order derivatives of $\boldsymbol{g}$ and the partial derivatives w.r.t. t. The solution of (3.21) has to satisfy the constraints (3.21b) on position level as well as the hidden constraints (3.22) on velocity and acceleration level.

Initial values $\boldsymbol{y}_0, \dot{\boldsymbol{y}}_0, \boldsymbol{\lambda}_0$ have to be *consistent* with all these constraints:

$$\begin{aligned} \mathbf{0} &= \boldsymbol{g}(\boldsymbol{y}_0, t_0), \quad \mathbf{0} = \boldsymbol{G}(\boldsymbol{y}_0, t_0)\,\dot{\boldsymbol{y}}_0 + \boldsymbol{g}^{(I)}(\boldsymbol{y}_0, t_0), \\ \mathbf{0} &= \boldsymbol{G}(\boldsymbol{y}_0, t_0)\,\ddot{\boldsymbol{y}}_0 + \boldsymbol{g}^{(II)}(\boldsymbol{y}_0, \dot{\boldsymbol{y}}_0, t_0) \end{aligned} \tag{3.23}$$

with $\boldsymbol{M}(\boldsymbol{y}_0)\,\ddot{\boldsymbol{y}}_0(t) = \boldsymbol{f}(\boldsymbol{y}_0, \dot{\boldsymbol{y}}_0, t_0) - \boldsymbol{G}^{\top}(\boldsymbol{y}_0, t_0)\boldsymbol{\lambda}_0$.

The computation of consistent initial values $\boldsymbol{y}_0, \dot{\boldsymbol{y}}_0, \boldsymbol{\lambda}_0$ is part of the initialization in the time integration of (3.21). If initial values $y_{0,ij}$ are given for $n_y - n_g$ independent position coordinates y_{ij}, $(j = 1, \ldots, n_y - n_g)$, the remaining initial values $y_{0,ij}$, $(j = n_y - n_g + 1, \ldots, n_y)$ are uniquely determined by (3.23) and may be computed by Newton's method. Furthermore, (3.23) defines systems of linear equations for the initial values $\dot{\boldsymbol{y}}_{0,ij}$, $(j = n_y - n_g + 1, \ldots, n_y)$ of n_g-dependent velocity components and for the initial values $\boldsymbol{\lambda}_0$.

3.3.5 Advanced DAE Models

The descriptor form (3.21) is linear w.r.t. $\boldsymbol{\lambda}$. This structural property is lost if the model has friction forces that depend on the constraint forces $-\boldsymbol{G}^{\top}\boldsymbol{\lambda}$. The resulting force vector $\boldsymbol{f} = \boldsymbol{f}(\boldsymbol{y}, \dot{\boldsymbol{y}}, \boldsymbol{\lambda}, t)$ has to satisfy the generalized Grübler condition

$$\operatorname{rank} \boldsymbol{G}(\boldsymbol{y}, t) = \operatorname{rank}\left(\boldsymbol{G}(\boldsymbol{y}, t)\,\boldsymbol{M}^{-1}(\boldsymbol{y})\left(\frac{\partial \boldsymbol{f}}{\partial \boldsymbol{\lambda}}(\boldsymbol{y}, \dot{\boldsymbol{y}}, \boldsymbol{\lambda}, t) - \boldsymbol{G}^{\top}(\boldsymbol{y}, t) \right) \right) = n_g \tag{3.24}$$

to guarantee the unique solvability of (3.21).

Another extension of (3.21) shows the large potential of DAE formulations in view of user-friendly algorithms for model setup. Consider rigid bodies $(.)^{(i)}$ and $(.)^{(j)}$ that are in contact. To formulate the contact conditions, parameterizations $\boldsymbol{s}^{(i)}, \boldsymbol{s}^{(j)} \in \mathbb{R}^2$ of the body surfaces are introduced. Then the position of the points $\vec{P}^{(i)}$ on the surface of body $(.)^{(i)}$ in $\mathbb{R}^3$ is determined by the position and orientation of this body, that is, by the multi-body system coordinates $\boldsymbol{y}$, and by the surface parameter $\boldsymbol{s}^{(i)}$: $\vec{P}^{(i)} = \vec{P}^{(i)}(\boldsymbol{y}, \boldsymbol{s}^{(i)})$ (see Figure 3.1).

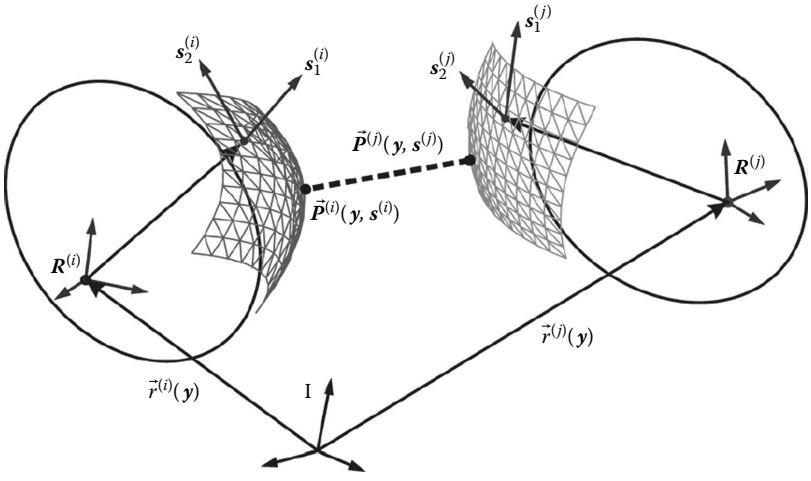

FIGURE 3.1 Formulation of contact conditions using surface parameters $\boldsymbol{s}$ as additional algebraic variables.

If both bodies are strictly convex, then there is a uniquely defined contact point $\vec{P}^{(i)}(\boldsymbol{y}, \boldsymbol{s}^{(i)}) = \vec{P}^{(j)}(\boldsymbol{y}, \boldsymbol{s}^{(j)})$ that belongs to the surfaces of both bodies. The contact point is characterized by the condition that the normal vector of body $(.)^{(i)}$ at $\vec{P}^{(i)}$ is parallel to the normal vector of body $(.)^{(j)}$ at $\vec{P}^{(j)}$ (see [12]). This geometrical condition defines implicitly the contact point coordinates $\boldsymbol{s} = (\boldsymbol{s}^{(i)}, \boldsymbol{s}^{(j)})$ as solution $\boldsymbol{s} = \boldsymbol{s}(\boldsymbol{y}, t)$ of a nonlinear system

$$\boldsymbol{0} = \boldsymbol{h}(\boldsymbol{y}, \boldsymbol{s}, t) \tag{3.25}$$

with non-singular Jacobian $\partial \boldsymbol{h}/\partial \boldsymbol{s}$ (see [5,6]).

Contact and friction forces act at the contact point. Furthermore, the contact point coordinates $\boldsymbol{s} = \boldsymbol{s}(\boldsymbol{y}, t)$ are used in the formulation of the contact condition

$$\boldsymbol{0} = \vec{P}^{(i)}(\boldsymbol{y}, \boldsymbol{s}^{(i)}) - \vec{P}^{(j)}(\boldsymbol{y}, \boldsymbol{s}^{(j)}) \tag{3.26}$$

that defines constraints $\boldsymbol{0} = \boldsymbol{g}(\boldsymbol{y}, t)$ in (3.21). In a classical implementation, each evaluation of $\boldsymbol{g}(\boldsymbol{y}, t)$ would require the solution of (3.25) to get the contact point coordinates $\boldsymbol{s} = \boldsymbol{s}(\boldsymbol{y}, t)$ that have to be inserted in the contact condition (3.26).

As an alternative, the DAE framework allows to add simply the nonlinear equations (3.25) to the equations of motion (3.21) and to append the contact conditions (3.26) directly to the constraints:

$$\boldsymbol{M}(\boldsymbol{y})\,\ddot{\boldsymbol{y}}(t) = \boldsymbol{f}(\boldsymbol{y}, \boldsymbol{s}, \dot{\boldsymbol{y}}, \lambda, t) - \boldsymbol{G}^{\top}(\boldsymbol{y}, \boldsymbol{s}, t)\boldsymbol{\lambda}, \tag{3.27a}$$

$$\boldsymbol{0} = \boldsymbol{h}(\boldsymbol{y}, \boldsymbol{s}, t), \tag{3.27b}$$

$$\boldsymbol{0} = \boldsymbol{g}(\boldsymbol{y}, \boldsymbol{s}, t). \tag{3.27c}$$

With this formulation, the solution of (3.25) w.r.t. $\boldsymbol{s} = \boldsymbol{s}(\boldsymbol{y}, t)$ is left to the DAE solver [4,6]. Note that the constraint matrix is now

$$\begin{aligned} \boldsymbol{G}(\boldsymbol{y}, \boldsymbol{s}, t) &= \frac{\mathrm{D}}{\mathrm{D}\boldsymbol{y}}\,\boldsymbol{g}(\boldsymbol{y}, \boldsymbol{s}(\boldsymbol{y}, t), t) = \left[\frac{\partial \boldsymbol{g}}{\partial \boldsymbol{y}} + \frac{\partial \boldsymbol{g}}{\partial \boldsymbol{s}}\frac{\partial \boldsymbol{s}}{\partial \boldsymbol{y}}\right](\boldsymbol{y}, \boldsymbol{s}, t) \\ &= \left[\frac{\partial \boldsymbol{g}}{\partial \boldsymbol{y}} - \frac{\partial \boldsymbol{g}}{\partial \boldsymbol{s}}\left(\frac{\partial \boldsymbol{h}}{\partial \boldsymbol{s}}\right)^{-1}\frac{\partial \boldsymbol{h}}{\partial \boldsymbol{y}}\right](\boldsymbol{y}, \boldsymbol{s}, t) \end{aligned} \tag{3.28}$$

because of

$$\boldsymbol{0} = \frac{\mathrm{D}}{\mathrm{D}\boldsymbol{y}}\,\boldsymbol{h}(\boldsymbol{y}, \boldsymbol{s}(\boldsymbol{y}, t), t) = \left[\frac{\partial \boldsymbol{h}}{\partial \boldsymbol{y}} + \frac{\partial \boldsymbol{h}}{\partial \boldsymbol{s}}\frac{\partial \boldsymbol{s}}{\partial \boldsymbol{y}}\right](\boldsymbol{y}, \boldsymbol{s}, t). \tag{3.29}$$

From the mathematical viewpoint, Equation (3.25) is just a special case of algebraic equations

$$\boldsymbol{0} = \boldsymbol{b}(\boldsymbol{w}, \boldsymbol{y}, \dot{\boldsymbol{y}}, \lambda, t) \tag{3.30}$$

with variables $\boldsymbol{w}(t) \in \mathbb{R}^{n_b}$ that are defined implicitly by (3.30) if $\partial \boldsymbol{b}/\partial \boldsymbol{w}$ is non-singular. The mathematical modeling of force elements may be simplified substantially using such auxiliary variables $\boldsymbol{w}$. A typical example is the modeling of joint friction (see [4] for a detailed discussion).

With variables $\boldsymbol{w}$ the force vector in (3.27) gets the general form $\boldsymbol{f} = \boldsymbol{f}(\boldsymbol{y}, \boldsymbol{s}, \dot{\boldsymbol{y}}, \boldsymbol{\lambda}, \boldsymbol{w}, t)$ and the Jacobian $\partial \boldsymbol{f}/\partial \boldsymbol{\lambda}$ in the generalized Grübler condition (3.24) has to be substituted by

$$\left[\frac{\partial \boldsymbol{f}}{\partial \boldsymbol{\lambda}} - \frac{\partial \boldsymbol{f}}{\partial \boldsymbol{w}} \left(\frac{\partial \boldsymbol{b}}{\partial \boldsymbol{w}} \right)^{-1} \frac{\partial \boldsymbol{b}}{\partial \lambda} \right] (\boldsymbol{y}, \boldsymbol{s}, \dot{\boldsymbol{y}}, \boldsymbol{\lambda}, \boldsymbol{w}, t).$$

3.3.6 Summary

Based on the multi-body system approach, the model equations in vehicle system dynamics are formulated as hybrid system of DAEs

$$\boldsymbol{M}(\boldsymbol{y})\, \ddot{\boldsymbol{y}}(t) = \boldsymbol{f}(\boldsymbol{y}, \boldsymbol{s}, \dot{\boldsymbol{y}}, \boldsymbol{c}, \boldsymbol{r}_j, \boldsymbol{\lambda}, \boldsymbol{w}, t) - \boldsymbol{G}^{\top}(\boldsymbol{y}, \boldsymbol{s}, t)\boldsymbol{\lambda}, \tag{3.31a}$$

$$\dot{\boldsymbol{c}}(t) = \boldsymbol{d}(\boldsymbol{c}, \boldsymbol{y}, \boldsymbol{s}, \dot{\boldsymbol{y}}, \boldsymbol{r}_j, \boldsymbol{\lambda}, \boldsymbol{w}, t). \tag{3.31b}$$

$$\boldsymbol{0} = \boldsymbol{b}(\boldsymbol{w}, \boldsymbol{y}, \boldsymbol{s}, \dot{\boldsymbol{y}}, \boldsymbol{c}, \boldsymbol{r}_j, \boldsymbol{\lambda}, t), \tag{3.31c}$$

$$\boldsymbol{0} = \boldsymbol{h}(\boldsymbol{y}, \boldsymbol{s}, \boldsymbol{r}_j, t), \tag{3.31d}$$

$$\boldsymbol{0} = \boldsymbol{g}(\boldsymbol{y}, \boldsymbol{s}, \boldsymbol{r}_j, t) \tag{3.31e}$$

with $t \in [T_j, T_{j+1})$ and discrete state equations

$$\boldsymbol{r}_{j+1} = \boldsymbol{k}(\boldsymbol{r}_j, \boldsymbol{r}_{j-1}, \ldots, \boldsymbol{y}, \boldsymbol{s}, \dot{\boldsymbol{y}}, \boldsymbol{c}, \boldsymbol{\lambda}, \boldsymbol{w}, T_{j+1}). \tag{3.32}$$

The continuous part (3.31) of the model equations forms an index-3 DAE with a complex but characteristic structure that will be exploited in the numerical solution (see Section 3.4).

It is important that the contact point coordinates $\boldsymbol{s}$ in the constraints (3.31e) are defined by an equation that is independent of $\dot{\boldsymbol{y}}$ and $\boldsymbol{\lambda}$ (see 3.31d). Otherwise, the model equations would not be solvable unless strong additional regularity conditions were satisfied.

3.4 DAE TIME INTEGRATION IN VEHICLE SYSTEM DYNAMICS

The time integration of DAE model equations (3.31) is based on classical ODE methods combined with *index reduction* and *projection* techniques. The time integration methods will be discussed in detail for DAEs (3.21) that are rewritten as first-order systems in residual form (3.12) with

$$\boldsymbol{x}(t) = \begin{pmatrix} \boldsymbol{y}(t) \\ \boldsymbol{v}(t) \\ \boldsymbol{\lambda}(t) \end{pmatrix}, \quad \boldsymbol{0} = \boldsymbol{F}(\boldsymbol{x}, \dot{\boldsymbol{x}}, t) = \begin{pmatrix} \dot{\boldsymbol{y}} - \boldsymbol{v} \\ \boldsymbol{M}(\boldsymbol{y})\dot{\boldsymbol{v}} - \boldsymbol{f}(\boldsymbol{y}, \boldsymbol{v}, t) + \boldsymbol{G}^{\top}(\boldsymbol{y}, t)\boldsymbol{\lambda} \\ \boldsymbol{g}(\boldsymbol{y}, t) \end{pmatrix}. \tag{3.33}$$

At the end of this section, we will come back to DAEs of the more general form (3.31).

The first generation of DAE time integration methods failed in the application to constrained mechanical systems (see [36]). Very similar numerical problems were observed in quite different practical applications like robotics, road vehicle simulation, and railway vehicle simulation. To discuss

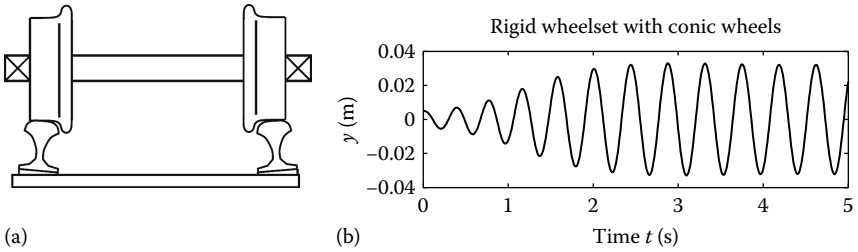

FIGURE 3.2 (a) Rigid wheelset performing a hunting motion, (b) Lateral displacement y.

these numerical effects in more detail, one of the best analyzed benchmark problems from the literature will be used throughout this section [6,37]. This multi-body system model comes from railway dynamics, but in time integration it shows all those numerical effects that are typical of any constrained systems (3.33) including the ones from road vehicle dynamics.

The benchmark describes a rigid wheelset with conic wheels moving with constant speed along a straight track. Starting with a small initial lateral displacement y, the wheelset oscillates in lateral direction (see Figure 3.2). This so-called hunting motion is a well-known phenomenon in railway vehicle dynamics.

The equations of motion are formulated in DAE form (3.27) with the position coordinates $\boldsymbol{y}(t) \in \mathbb{R}^6$ of the wheelset that correspond to its six degrees of freedom. Two constraints (3.27c) guarantee permanent contact between the two wheels and the rails [6]. Exploiting symmetries in the geometry of wheel and rail, the contact point between a single wheel and the rail may be described by a scalar position coordinate $s(t)$ resulting in two equations (3.27b) that determine implicitly $\boldsymbol{s} = (s_l, s_r)^\top \in \mathbb{R}^2$ for the contact point coordinates on left and right wheel [37].

3.4.1 DAE Time Integration by ODE Methods

Equation (3.33) suggests to apply BDF (3.13) and other ODE methods straightforwardly to the time integration of DAEs. Simple test problems like (3.33) with $\boldsymbol{M} = \boldsymbol{I}_{n_y}$, $\boldsymbol{f} = \boldsymbol{0}$, and linear constraints

$$\boldsymbol{0} = \boldsymbol{g}(\boldsymbol{y}, t) = \boldsymbol{C}\boldsymbol{y} - \boldsymbol{z}(t)$$

show that this approach fails, in general. According to (3.21a) and (3.22b), we get $\ddot{\boldsymbol{y}}(t) = -\boldsymbol{C}^\top \boldsymbol{\lambda}$ and $\boldsymbol{C}\ddot{\boldsymbol{y}}(t) = \ddot{\boldsymbol{z}}(t)$ resulting in Lagrange multipliers $\boldsymbol{\lambda}(t) = -(\boldsymbol{C}\boldsymbol{C}^\top)^{-1}\ddot{\boldsymbol{z}}(t)$. The BDF solution $\boldsymbol{x}_n = (\boldsymbol{y}_n, \boldsymbol{v}_n, \boldsymbol{\lambda}_n)^\top$ satisfies (3.13) and hence also

$$\boldsymbol{0} = \boldsymbol{g}(\boldsymbol{y}_n, t_n) = \boldsymbol{C}\boldsymbol{y}_n - \boldsymbol{z}(t_n), \ (n > 0)$$

since the constraints (3.21b) are part of the residual $\boldsymbol{F}$ in (3.33). A simple computation shows that the application of backward Euler method to (3.33), that is, BDF (3.13) with $k_n = 1$, yields

$$\boldsymbol{\lambda}_{n+1} = \frac{h_n + h_{n-1}}{2h_n}\boldsymbol{\lambda}(t_{n+1}) + \mathcal{O}(h_n) + \mathcal{O}\left(\frac{h_{n-1}^2}{h_n}\right).$$

For varying stepsizes, the numerical solution $\boldsymbol{\lambda}_{n+1}$ is completely wrong since it does not converge to the analytical solution $\boldsymbol{\lambda}(t_{n+1})$ if $h_n \to 0$ and h_{n-1} is fixed (see also [36]).

For some higher-order methods, convergence can still be guaranteed [23] but the errors in the numerical solution are typically substantially larger than in the ODE case. This is illustrated by simulation results for the hunting motion of the rigid wheelset in Figure 3.2. In this application, the BDF

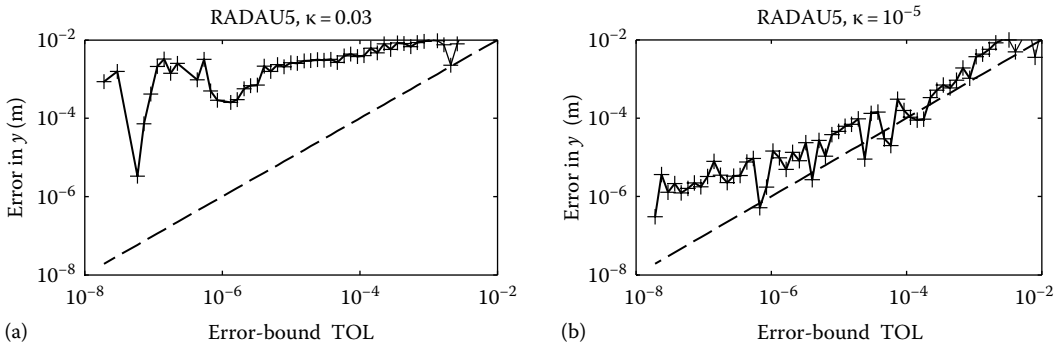

FIGURE 3.3 ODE solver **RADAU5** applied to the differential-algebraic equations of motion (3.21) of a rigid wheelset. (a) Solver parameter $\kappa = 0.03$, (b) Solver parameter $\kappa = 10^{-5}$.

integrator **DASSL** applied to (3.27) fails completely. As an alternative, the implicit Runge–Kutta solver **RADAU5** was used in the numerical tests [23]. For **RADAU5**, experience shows that the error of the numerical solution in ODE applications is usually kept well below the user-defined error tolerances TOL. But in the application to DAE (3.27), the relative error remains even for extremely small error bounds always in the size of 0.1%–1.0%. As a typical example, the left plot of Figure 3.3 shows the error in the lateral displacement y for various values of TOL.

To analyze these unsatisfactory results of **RADAU5,** we modify one of the internal parameters of the solver. BDF (3.13) and implicit Runge–Kutta methods define $\boldsymbol{x}_{n+1}$ as solution of a system of nonlinear equations. In the practical implementation, this system is solved iteratively by Newton's method that is stopped if the iteration error is less than $\kappa \cdot \mathrm{TOL}$. In this stopping criterion, the user-defined error tolerance for time integration (TOL) is scaled by a constant $\kappa \leq 1$ that is a free control parameter of the solver. Default values are $\kappa = 0.33$ in **DASSL** [24] and $\kappa = 0.03$ in **RADAU5** [23].

The right plot of Figure 3.3 shows that the error in time integration is reduced drastically and remains now roughly below the error bounds if κ is set to the very small value $\kappa = 10^{-5}$. The comparison of left and right plot in Figure 3.3 illustrates that the direct application of **RADAU5** to DAEs (3.27) makes the solver very sensitive w.r.t. (small) iteration errors in Newton's method.

An analytical perturbation analysis for (3.33) shows that the errors in $\boldsymbol{y}_n$, $\boldsymbol{v}_n$, and $\boldsymbol{\lambda}_n$ are of size $\mathcal{O}(\theta) + \mathcal{O}(\theta^2/h^2)$, $\mathcal{O}(\theta/h)$, and $\mathcal{O}(\theta/h^2)$, respectively, if the errors in the constraints (3.21b) are bounded by some small positive constant $\theta \ll 1$ (see [38]). Note that these error bounds *grow* unboundedly for decreasing time stepsize $h := \min_m h_m$.

This error amplification is typical of the direct application of ODE solvers to DAE (3.33). It may be considered as discrete analog of corresponding error bounds $\mathcal{O}(\max_t \|\boldsymbol{\theta}(t)\|) + \mathcal{O}(\max_t \|\dot{\boldsymbol{\theta}}(t)\|^2)$, $\mathcal{O}(\max_t \|\dot{\boldsymbol{\theta}}(t)\|)$, and $\mathcal{O}(\max_t \|\ddot{\boldsymbol{\theta}}(t)\|)$ for the analytical solution $\boldsymbol{y}(t)$, $\boldsymbol{v}(t)$, and $\boldsymbol{\lambda}(t)$ of (3.33) with perturbed constraints

$$\boldsymbol{\theta}(t) = \boldsymbol{g}(\boldsymbol{y}(t), t)$$

and $\max_t \left\|\boldsymbol{\theta}(t)\right\| \ll 1$ (see [38]).

For perturbations like $\boldsymbol{\theta}(t) = \varepsilon \sin \omega t$ that oscillate with small amplitude $\varepsilon \ll 1$ and high frequency $\omega \gg 1$, the errors in the solution $(\boldsymbol{y}(t), \boldsymbol{v}(t), \boldsymbol{\lambda}(t))$ are much larger than the perturbation itself since $\|\dot{\boldsymbol{\theta}}(t)\| = \mathcal{O}(\omega\varepsilon)$, $\|\ddot{\boldsymbol{\theta}}(t)\| = \mathcal{O}(\omega^2\varepsilon)$. A mechanical interpretation of these results is the well-known fact that high-frequency kinematic excitations $\boldsymbol{\theta}(t)$ in loop closing joints may cause large joint and constraint forces in a multi-body system.

3.4.2 Index Reduction and Projection

In the direct application of ODE methods to DAE (3.33), the robustness of the solvers may be improved substantially by small values of κ that result in (very) small iteration errors in Newton's method (see the right plot of Figure 3.3). On the other hand, values of κ that are less than 10^{-3} increase the number of Newton steps per time step substantially and may slow down the ODE solver dramatically.

Instead of applying ODE solvers directly to (3.33), it proved to be much more advantageous to transform the equations of motion *analytically* before time integration. These analytical transformations are guided by the perturbation analysis. In (3.21), the Lagrange multipliers $\boldsymbol{\lambda}(t)$ are defined implicitly by the constraints (3.21b). Differentiating these constraints $\mathbf{0} = \boldsymbol{g}(\boldsymbol{y}(t), t)$ twice, the acceleration constraints (3.22b) are obtained that define together with $\ddot{\boldsymbol{y}}(t) = \boldsymbol{M}^{-1}(\boldsymbol{y})(\boldsymbol{f} - \boldsymbol{G}^{\top}\boldsymbol{\lambda})$ (see 3.21a) the system of linear equations

$$\mathbf{0} = -[\boldsymbol{G}\boldsymbol{M}^{-1}\boldsymbol{G}^{\top}](\boldsymbol{y}, t)\boldsymbol{\lambda} + [\boldsymbol{G}\boldsymbol{M}^{-1}\boldsymbol{f}](\boldsymbol{y}, \dot{\boldsymbol{y}}, t) + \boldsymbol{g}^{(II)}(\boldsymbol{y}, \dot{\boldsymbol{y}}, t) \tag{3.34}$$

for the Lagrange multipliers $\boldsymbol{\lambda}(t)$. The $r = 2$ differentiation steps introduce the large error terms $\mathcal{O}(\|\ddot{\boldsymbol{\theta}}(t)\|)$ and $\mathcal{O}(\theta/h^2)$ in the analytical and numerical solution, respectively. In DAE terminology, the system (3.21) forms a DAE of index $r + 1 = 3$ that is called the *index-3 formulation* of the equations of motion [24].

For consistent initial values satisfying (3.23), the solution of the equations of motion (3.21) remains unchanged if the constraints (3.21b) on position level are substituted by the constraints (3.22a) on velocity level since

$$\boldsymbol{g}(\boldsymbol{y}(t), t) = \underbrace{\boldsymbol{g}(\boldsymbol{y}_0, t_0)}_{=0, \text{see (3.23)}} + \int_{t_0}^{t} \underbrace{\frac{\mathrm{d}}{\mathrm{d}t}\boldsymbol{g}(\boldsymbol{y}(\tau), \tau)}_{=0, \text{see (3.22a)}} \mathrm{d}\tau = \mathbf{0}. \tag{3.35}$$

From the numerical viewpoint, the *index-2 formulation* (3.21a/3.22a) of the equations of motion is attractive because only $r = 1$ differentiation of the velocity constraints (3.22a) is necessary to get the system (3.34) of linear equations defining $\boldsymbol{\lambda}(t)$.

With a perturbation $\boldsymbol{\theta}(t)$ in the velocity constraints (3.22a), the error terms for this index-2 DAE are of size $\mathcal{O}(\max_t \|\boldsymbol{\theta}(t)\| \, \|\dot{\boldsymbol{\theta}}(t)\|)$ for $\boldsymbol{y}(t)$, $\boldsymbol{v}(t)$ and of size $\mathcal{O}(\max_t \|\dot{\boldsymbol{\theta}}(t)\|)$ for $\boldsymbol{\lambda}(t)$. The error bounds for the numerical solution are $\mathcal{O}(\theta) + \mathcal{O}(\theta^2/h)$ for $\boldsymbol{y}_n$, $\boldsymbol{v}_n$ and $\mathcal{O}(\theta/h)$ for $\boldsymbol{\lambda}_n$. They are smaller by the (small) factor h than the corresponding error bounds for the original index-3 DAE (3.21) (see [38]). Applying **RADAU5** with the standard setting $\kappa = 0.03$ to the wheelset example of Figure 3.2 in index-2 formulation (3.21a/3.22a), the error of the numerical solution is kept well below the user-defined error tolerances TOL.

In the same way, the *index-1 formulation* (3.21a/3.22b) of the equations of motion is obtained substituting (3.21b) by the constraints (3.22b) on acceleration level. The error bounds for $\boldsymbol{\lambda}(t)$ and $\boldsymbol{\lambda}_n$ are slightly improved to $\mathcal{O}\|\max_t \|\boldsymbol{\theta}(t)\|)$ and $\mathcal{O}(\theta)$, respectively. BDF and implicit Runge–Kutta solvers applied to the index-1 formulation are as robust and efficient as in the classical ODE case.

In DAE terminology, the substitution of the constraints (3.21b) by one of its time derivatives is called *index reduction*. Index reduction by differentiation improves the solver's robustness substantially but suffers in long-term simulations from the *drift-off effect* that is illustrated by Figure 3.4.

Because of (3.35), the *analytical* solution of the index-2 formulation satisfies the original constraints (3.21b) exactly for all $t \geq t_0$. In the *numerical* solution, the integrand $(\mathrm{d}\boldsymbol{g}/\mathrm{d}t)(\boldsymbol{y}(\tau), \tau)$ in (3.35) is still bounded by a small constant $\varepsilon > 0$ but it does *not* vanish identically. Therefore, the error in (3.21b) may increase linearly in time t:

$$\|\boldsymbol{g}(\boldsymbol{y}_n, t_n)\| \leq \|\boldsymbol{g}(\boldsymbol{y}_0, t_0)\| + \int_{t_0}^{t_n} \epsilon \, \mathrm{d}t = \epsilon \cdot (t_n - t_0); \tag{3.36}$$

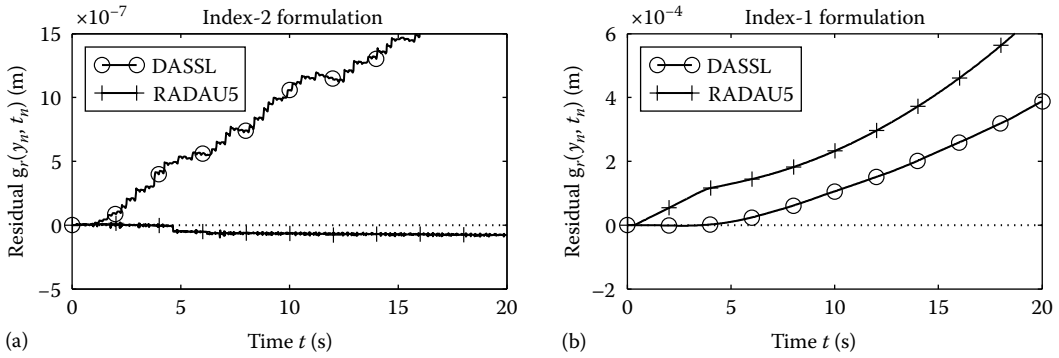

FIGURE 3.4 Drift-off effect in the dynamical simulation of the rigid wheelset of Figure 3.2 resulting in an increasing distance $g_r(\boldsymbol{y}, t)$ between the right wheel and the rail, i.e., in an increasing error in the constraints $\mathbf{0} = \boldsymbol{g} = (g_l, g_r)^\top$ that are defined by the contact conditions for left and right wheel. (a) Index-2 formulation, (b) Index-1 formulation.

the numerical solution $\boldsymbol{y}_n$ *drifts off* the manifold $\{(\boldsymbol{\eta}, t)\colon \boldsymbol{g}(\boldsymbol{\eta}, t) = \mathbf{0}\}$ that is defined by the constraints (3.21b) on position level. The error bound ε summarizes discretization and roundoff errors and the iteration errors of Newton's method.

For the index-1 formulation, a quadratic error growth $\|\boldsymbol{g}(\boldsymbol{y}_n, t_n)\| \leq \epsilon \cdot (t_n - t_0)^2$ has to be expected since the constraints (3.21b) on position level are substituted by their second derivatives (3.22b). Practical experience shows that ε depends on the solver and on the user-defined error tolerances TOL. In general, however, there is always a linear drift in the time integration of the index-2 formulation and a quadratic drift for the index-1 formulation (see Figure 3.4 for a typical example).

An early attempt to avoid both the numerical problems for the index-3 formulation (3.21) and the drift-off effect in the index-2 and index-1 formulation goes back to the work of Baumgarte [39] who substituted the constraints (3.21b) by a linear combination of all three constraints (3.21b, 3.22a, 3.22b). Because of the problems to select suitable coefficients for this linear combination (*Baumgarte coefficients*), the practical use of Baumgarte's approach is restricted to small-scale models (see also [40]).

Today, it is state of the art to avoid the drift-off effect by *projection* techniques [41,42]. During the time integration of the index-2 formulation, the residual $\|\boldsymbol{g}(\boldsymbol{y}_n, t_n)\|$ in the constraints (3.21b) is monitored. If the residual exceeds some user-defined small error bound $\epsilon > 0$, then $\boldsymbol{y}_n$ is projected onto the manifold $\{\boldsymbol{\eta}\colon \boldsymbol{g}(\boldsymbol{\eta}, t_n) = \mathbf{0}\}$ and the time integration is continued with the projected position coordinates $\hat{\boldsymbol{y}}_n$ instead of $\boldsymbol{y}_n$ (see Figure 3.5).

Mathematically, the projection defines a minimization problem

$$\|\boldsymbol{\eta} - \boldsymbol{y}_n\| \rightarrow \min_{\{\boldsymbol{\eta}\colon \boldsymbol{g}(\boldsymbol{\eta}, t_n) = \mathbf{0}\}} \tag{3.37}$$

that can be solved efficiently by simplified Newton iterations to get $\hat{\boldsymbol{y}}_n$ (see [42]).

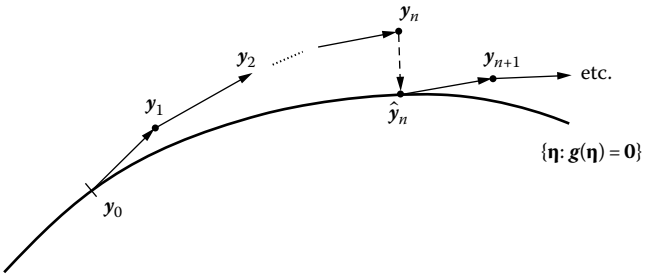

FIGURE 3.5 Time integration with projection steps for DAEs (3.21) with $\boldsymbol{g} = \boldsymbol{g}(\boldsymbol{y})$.

For the index-1 formulation, the projection of both $\boldsymbol{y}_n$ and $\boldsymbol{v}_n$ helps to avoid the drift in the constraints (3.21b) and (3.22a) on position and velocity level [41].

3.4.3 Gear–Gupta–Leimkuhler Formulation

In the complex applications of vehicle system dynamics, the use of classical explicit projection methods like (3.37) is restricted to Runge–Kutta and other one-step methods since the efficient implementation in advanced BDF solvers with order and stepsize control is nontrivial.

Instead of implementing explicit projection steps in the solver, the equations of motion (3.21) are reformulated in a way that contains implicitly the projection onto the constraint manifold $\{\boldsymbol{\eta}: \boldsymbol{g}(\boldsymbol{\eta}, t_n) = \boldsymbol{0}\}$. The *Gear–Gupta–Leimkuhler formulation* (or *stabilized index-2 formulation*) of the equations of motion considers the constraints (3.21b) and (3.22a) on position and velocity level simultaneously [43]:

$$\begin{aligned} \dot{\boldsymbol{y}}(t) &= \boldsymbol{v} - \boldsymbol{G}^{\top}(\boldsymbol{y}, t)\boldsymbol{\mu}, \\ \boldsymbol{M}(\boldsymbol{y})\dot{\boldsymbol{v}}(t) &= \boldsymbol{f}(\boldsymbol{y}, \boldsymbol{v}, t) - \boldsymbol{G}^{\top}(\boldsymbol{y}, t)\boldsymbol{\lambda}, \\ \boldsymbol{0} &= \boldsymbol{g}(\boldsymbol{y}, t), \\ \boldsymbol{0} &= \boldsymbol{G}(\boldsymbol{y}, t)\boldsymbol{v} + \boldsymbol{g}^{(I)}(\boldsymbol{y}, t). \end{aligned} \tag{3.38}$$

The increasing number of equations is compensated by a correction term $-\boldsymbol{G}^{\top}\boldsymbol{\mu}$ with auxiliary variables $\boldsymbol{\mu}(t) \in \mathbb{R}^{n_g}$. The correction term vanishes identically for the analytical solution ($\boldsymbol{\mu}(t) \equiv \boldsymbol{0}$) and remains in the size of the user-defined error tolerances TOL for the numerical solution.

Equation (3.38) forms an index-2 DAE that may be solved robustly and efficiently by BDF [43] and implicit Runge–Kutta methods [23]. However, the error estimates in classical ODE solvers tend to overestimate the local errors in the algebraic components $\boldsymbol{\lambda}$, $\boldsymbol{\mu}$ of DAE (3.38) (see [36]). Therefore, the components $\boldsymbol{\lambda}$ and $\boldsymbol{\mu}$ should not be considered in the automatic stepsize control of BDF solvers [44]. For implicit Runge–Kutta solvers, the error estimates for $\boldsymbol{\lambda}$ and $\boldsymbol{\mu}$ are scaled by the small factor h_n.

The efficient evaluation of the correction term $\boldsymbol{G}^{\top}(\boldsymbol{y}, t)\boldsymbol{\mu}$ for given $\boldsymbol{\mu}, \boldsymbol{y}, t$ is nontrivial since multibody formalisms evaluate matrix-vector products $\boldsymbol{G}^{\top}\boldsymbol{\lambda}$ and $\boldsymbol{G}\boldsymbol{v}$ with O(N) complexity but do not evaluate the matrix $\boldsymbol{G}(\boldsymbol{y}, t)$ itself.

The key to the efficient solution of (3.38) was found in the analysis of a special class of overdetermined DAEs [45] that are closely related to DAEs (3.38) (see [46]). BDF solvers and implicit Runge–Kutta solvers for DAEs (3.12) approximate the Jacobian $(\alpha_{n,0}/h_n)(\partial \boldsymbol{F}/\partial \dot{\boldsymbol{x}}) + (\partial \boldsymbol{F}/\partial \boldsymbol{x})$ to compute $\boldsymbol{x}_{n+1}$ iteratively by Newton's method (see (3.10) and (3.14)). In (3.38), this Jacobian has a 4×4 block structure reflecting the four equations in (3.38) and the partitioning $\boldsymbol{x} = (\boldsymbol{y}, \boldsymbol{v}, \boldsymbol{\lambda}, \boldsymbol{\mu})^{\top}$. Block (3,1) is an approximation of $(\partial \boldsymbol{g}/\partial \boldsymbol{y})(\boldsymbol{y}, t) = \boldsymbol{G}(\boldsymbol{y}, t)$, its transpose may be used to get the matrix-vector product $\boldsymbol{G}^{\top}\boldsymbol{\mu}$. This algorithm was implemented in the BDF solver **ODASSL** [45] that exploits furthermore the special structure of (3.38) to compute $\boldsymbol{\mu}_{n+1}$ more efficiently than in the standard **DASSL** implementation.

3.4.4 Advanced DAE Models

The numerical algorithms for DAE time integration that we discussed in detail for classical constrained mechanical systems with equations of motion (3.21) may be applied as well to the more complex hybrid DAEs (3.31/3.32) that are typical of vehicle system dynamics.

In the model equations in residual form (3.33), the vector $\boldsymbol{x}(t)$ is now given by $\boldsymbol{x} = (\boldsymbol{y}, \boldsymbol{s}, \boldsymbol{v}, \boldsymbol{c}, \boldsymbol{\lambda}, \boldsymbol{w})^{\top}$. Time events and the discrete state equations (3.32) are handled by the methods that are known from ODE theory (see Section 3.2).

The differential equations (3.31b) and the algebraic equations (3.31c) and (3.31d) are added to the residual $\boldsymbol{F}(\boldsymbol{x}, \dot{\boldsymbol{x}}, t)$. As a consequence, the BDF solution $\boldsymbol{x}_{n+1}$ of (3.31) satisfies the nonlinear equations (3.31d) exactly:

$$\boldsymbol{0} = \boldsymbol{h}(\boldsymbol{y}_{n+1}, \boldsymbol{s}_{n+1}, \boldsymbol{r}_j, t_{n+1}),$$

(see 3.13). The BDF solution $\boldsymbol{s}_{n+1}$ coincides with the function value $\boldsymbol{s}(\boldsymbol{y}_{n+1}, t_{n+1})$ of the function $\boldsymbol{s}(\boldsymbol{y}, t)$ that is implicitly defined by

$$\boldsymbol{0} = \boldsymbol{h}(\boldsymbol{y}, \boldsymbol{s}(\boldsymbol{y}, t), \boldsymbol{r}_j, t)$$

if $\partial \boldsymbol{h}/\partial \boldsymbol{s}$ is non-singular (see (3.25) and (3.31d)). BDF compute for a given geometric configuration $\boldsymbol{y}$ of the multi-body system the contact point coordinates $\boldsymbol{s}$ exactly up to the (small) iteration errors in Newton's method. The same result may be shown for the algebraic variables $\boldsymbol{w}$ in (3.31c).

With the regularity assumptions of Section 3.3, the model equations (3.31) form an index-3 DAE. Index reduction and projection techniques have to be applied. It is important to note that the nonlinear equations (3.31c) and (3.31d) may be solved directly w.r.t. the algebraic variables $\boldsymbol{w}$ and $\boldsymbol{s}$. In contrast to the constraints (3.31e), the nonlinear equations (3.31c) and (3.31d) do *not* imply hidden constraints on the state variables like (3.22).

The index reduction is based on time derivatives of the constraints $\boldsymbol{0} = \boldsymbol{g}(\boldsymbol{y}, \boldsymbol{s}, t)$. It does not involve any derivatives of the nonlinear equations $\boldsymbol{0} = \boldsymbol{b}(\boldsymbol{w}, \ldots)$ and $\boldsymbol{0} = \boldsymbol{h}(\boldsymbol{y}, \boldsymbol{s}, t)$. The hidden constraints on the level of velocity coordinates are

$$\boldsymbol{0} = \frac{\mathrm{d}}{\mathrm{d}t}\boldsymbol{g}(\boldsymbol{y}(t), \boldsymbol{s}(t), t) = \boldsymbol{G}(\boldsymbol{y}, \boldsymbol{s}, t)\boldsymbol{v} + \boldsymbol{g}^{(I)}(\boldsymbol{y}, \boldsymbol{s}, t)$$

with matrix $\boldsymbol{G}$ of (3.28) since $\dot{\boldsymbol{s}}(t)$ is a linear function of $\dot{\boldsymbol{y}}(t) = \boldsymbol{v}(t)$ that may be obtained differentiating $\boldsymbol{0} = \boldsymbol{h}(\boldsymbol{y}(t), \boldsymbol{s}(t), t)$ implicitly w.r.t. t (see also (3.29)).

Using a rather general concept of DAE index reduction [47], the Gear–Gupta–Leimkuhler formulation (3.38) is generalized to complex DAE models (3.31) (see [48,49]). Here, the Gear–Gupta–Leimkuhler formulation (3.38) is extended by (3.31b–d). To compensate the simultaneous consideration of the constraints on position level and the hidden constraints on velocity level, there is, as before, just one correction term. It has to be added to the kinematic equations $\dot{\boldsymbol{y}}(t) = \boldsymbol{v}$ that take the form

$$\dot{\boldsymbol{y}}(t) = \boldsymbol{v} - \boldsymbol{G}^{\top}(\boldsymbol{y}, \boldsymbol{s}, t)\boldsymbol{\mu}$$

with the constraint matrix $\boldsymbol{G}$ of (3.28) and auxiliary variables $\boldsymbol{\mu}(t) \in \mathbb{R}^{n_g}$. Again, the correction term vanishes identically for the analytical solution and remains in the size of the user-defined error tolerances TOL for the numerical solution.

For this extended system, the Jacobian $\boldsymbol{J}$ in (3.14) has a 7×7 block structure with $(\partial \boldsymbol{g}/\partial \boldsymbol{y})$, $(\partial \boldsymbol{g}/\partial \boldsymbol{s})$, $(\partial \boldsymbol{h}/\partial \boldsymbol{s})$, $(\partial \boldsymbol{h}/\partial \boldsymbol{y})$ as blocks (6,1), (6,2), (5,2), and (5,1), respectively. In a modified version of the BDF solver **ODASSL**, these blocks are used for the efficient evaluation of the correction term $\boldsymbol{G}^{\top}\boldsymbol{\mu}$ with matrix $\boldsymbol{G}$ of (3.28) (see [48]).

3.4.5 Summary

The robust and efficient dynamical simulation in vehicle system dynamics may be based on DAE time integration methods with **DASSL** like BDF solvers that are applied to the Gear–Gupta–Leimkuhler formulation of the model equations. The approach is used successfully in industrial multi-body system simulation packages [4].

3.5 ALGORITHMS AND TOOLS FOR THE SIMULATION OF MULTI-PHYSICAL PROBLEMS

Typical applications of vehicle system dynamics are far beyond the field of classical multi-body analysis. Nevertheless, the methods and software tools of multi-body dynamics have been used very successfully as integration platform for large, complex models in vehicle system dynamics including mechanical, hydraulic, and electronic components.

Alternatives are general purpose simulation tools like Simulink® and modeling languages for complex physical systems like ACSL or Modelica.* Furthermore, the coupling of two or more mono-disciplinary simulation tools from different fields of application has proved to be very useful in industrial applications (*simulator coupling* or *co-simulation*).

3.5.1 Extensions of Multi-Body System Simulation Packages

In the early days of industrial multi-body system simulation, the focus was on specialized force elements with or without inner state variables $\boldsymbol{c}$ and $\boldsymbol{r}_j$ (see Section 3.3) [3].

Today, it might be even more important to embed the dynamical simulation of the mechanical system components efficiently in process chains for the simulation of the overall behavior of engineering systems. Figure 3.6 shows typical bidirectional interfaces between specialized simulation tools. The interfaces are used for data exchange in the pre- and post-processing of dynamical simulation.

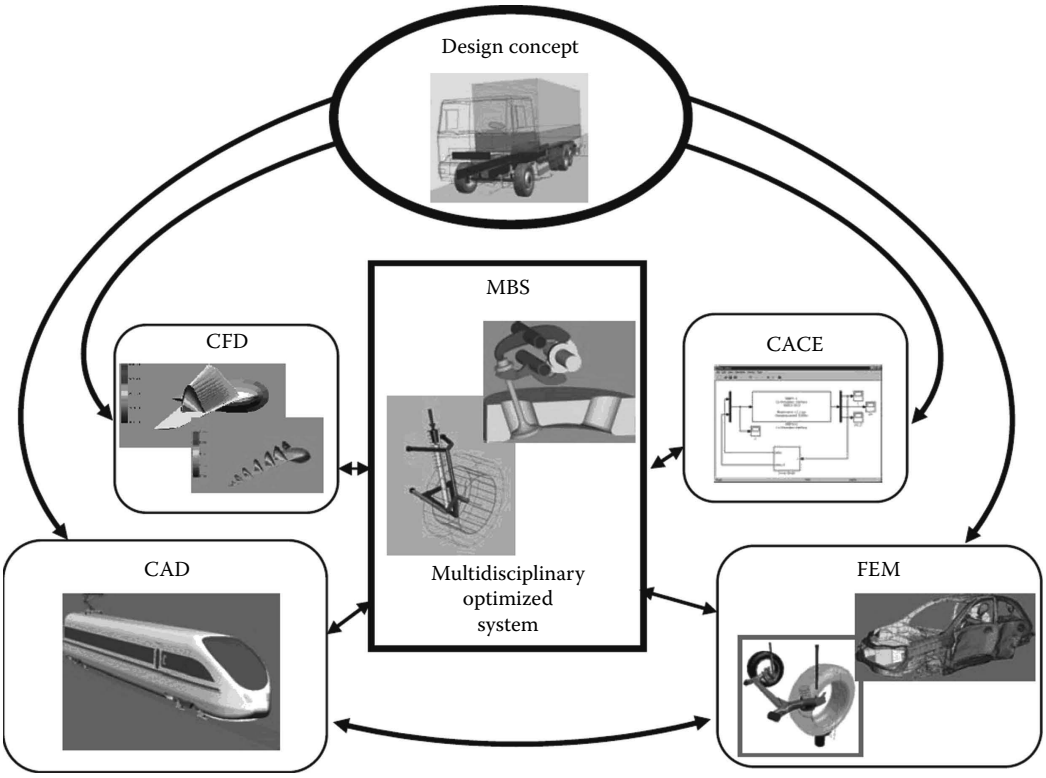

FIGURE 3.6 Integrated virtual design using multi-body system simulation software and its bidirectional interfaces. (From Veitl, A., *Integrierter Entwurf innovativer Stromabnehmer*, Fortschritt-Berichte VDI Reihe 12, Nr. 449, VDI-Verlag, Düsseldorf, Germany, 2001.)

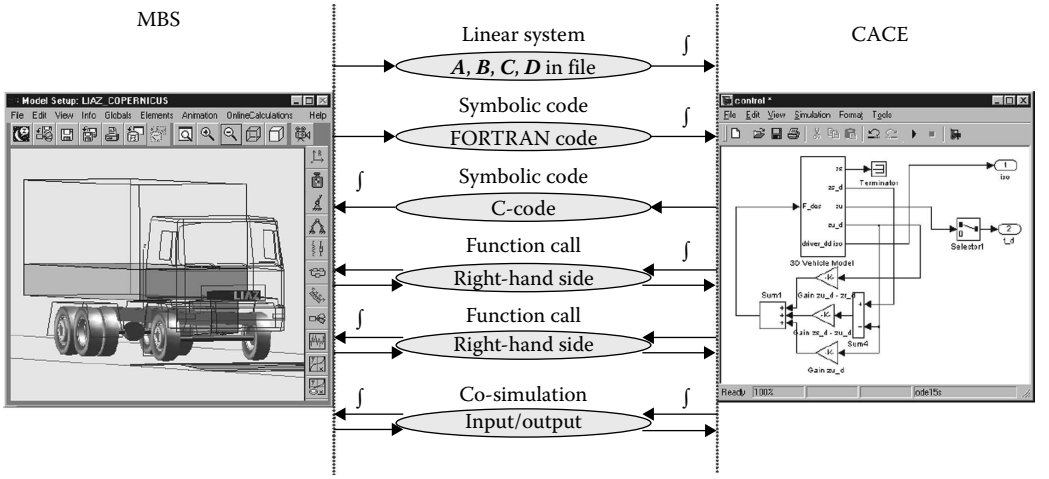

FIGURE 3.7 Typical interfaces between multi-body system tools and CACE tools. (From Vaculín, O. et al., *Vehicle Syst. Dyn*., 41:415–429, 2004.)

The simulation of flexible multi-body systems relies on the interfaces to finite element (FE) tools of structural dynamics. The interface from FE tool to multi-body system tool provides mass, damping, and stiffness data for the pre-processing of modes $\vec{w}^{(i)}$ in the Rayleigh–Ritz approach (3.16) (see [30]). The interface from multi-body system tool to FE tool supports the post-processing of multi-body system simulation data. Load vectors are transferred to the fatigue analysis in standard FE tools [51].

Modal reduction techniques are also used successfully in the analysis of certain aerodynamic effects. For this *close coupling* of computational fluid dynamics (CFD) and (flexible) multi-body dynamics, the classical interfaces between FE tools and multi-body system tools have been extended by an interface to CFD tools [16].

The interfaces between CAD and multi-body system tools support an efficient and fail-safe model setup using the geometrical data of CAD models. The opposite interface transfers all relevant geometrical modifications of the multi-body system model automatically back to the CAD model [52].

Controller synthesis is a central problem in many applications of vehicle system dynamics. Close links between the methods and tools for the dynamical simulation of mechanical components and the tools of computer-aided control engineering (CACE) are therefore essential. Figure 3.7 summarizes a number of typical interfaces between multi-body system software and CACE tools.

Already in the early 1990s, the increasing complexity of controllers in mechatronic system components motivated the integration of multi-body system models in CACE tools starting with the export of the system matrices $\boldsymbol{A}$, $\boldsymbol{B}$, $\boldsymbol{C}$, and $\boldsymbol{D}$ describing the linearized equations of motion (see 3.6). Later, this interface was extended by the export of FORTRAN source code for nonlinear equations of motion (3.2). In both cases, the time integration for the full system including multi-body system model and controller is performed in the CACE tool.

Since the solvers of CACE tools are not tailored to the DAE model (3.31), it is often more attractive to perform the time integration of the full system including the controller in the multi-body system tool. State-of-the-art CACE tools support this approach by a code export interface. A typical example is the Real-Time Workshop®* of The MathWorks, Inc., that generates and executes standalone C code for developing and testing algorithms modeled in Simulink [53].

As an alternative to code export the tools of multi-body system analysis and CACE may be coupled as well by a function call interface that evaluates during time integration repeatedly the right-hand sides of the model equations for various given input data (see [53] for a more detailed discussion). The last row of Figure 3.7 refers to the co-simulation interface, which will be discussed later.

* Real-Time Workshop is a trademark of The MathWorks, Inc.

3.5.2 General Purpose Simulation Tools and Modeling Languages

Using interfaces between well-developed mono-disciplinary simulation tools, the experienced engineer may study multi-physical problems without leaving his usual software environment. Latest new developments of the powerful specialized tools are immediately available and the access to highly developed specialized solvers is straightforward.

Alternative approaches resolutely focus on the multi-domain aspect of complex multi-physical applications. The most widespread general purpose simulation tool from system theory is Simulink that has been developed as platform for multi-domain simulation and model-based design of dynamic systems. It has a block diagram user interface for model setup and a number of toolboxes for special fields of application like SimMechanics and SimDriveline.

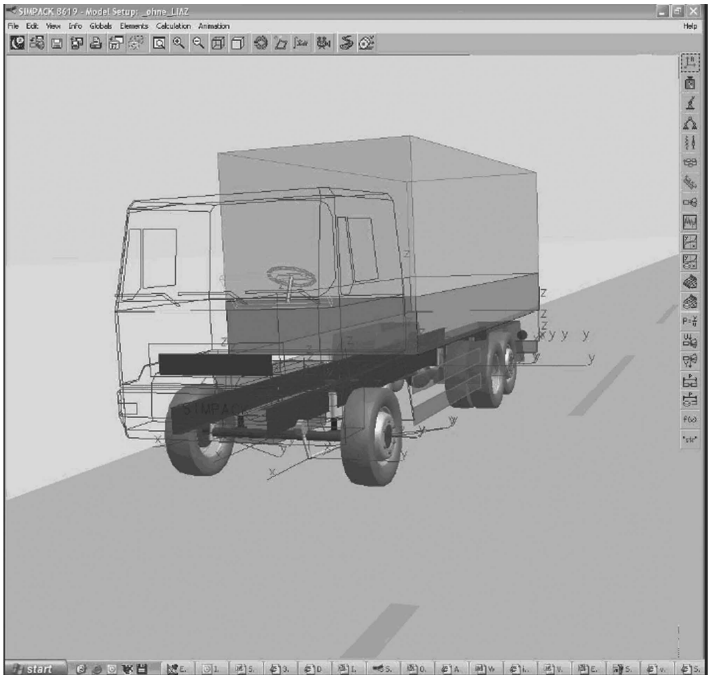
The different concept behind specialized multi-body system tools on the one hand and general purpose simulation tools from system theory on the other is illustrated by the screenshots of user interfaces in Figure 3.7.

The increasing complexity of industrial multi-physical applications results in a revival of modeling languages that are designed to bundle the experience of specialists from various engineering domains. Modern modeling languages like Modelica [54] are object-oriented and do not follow the classical input–output scheme of traditional block-oriented tools (*noncausal* modeling).

Instead of classical ODE model equations, the model equations get the form of DAEs. Modelica is a rapidly developing nonproprietary modeling language that covers a wide range of applications like electrical circuits, vehicle dynamics, hydraulic and pneumatic systems, and automotive power trains (see [8] and the up-to-date material at the Modelica website [54] for more details of this ongoing development).

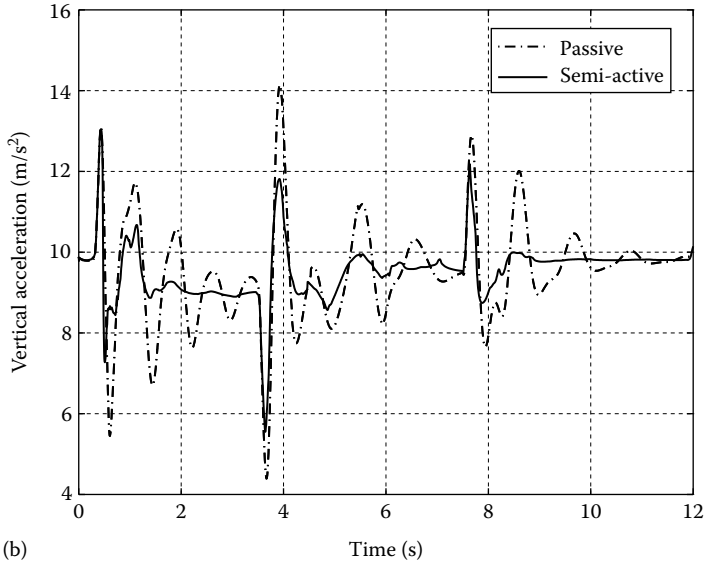
3.5.3 Simulator Coupling

Specialized mono-disciplinary tools and general purpose tools follow completely different strategies for the setup of multi-physical models and for the formulation of model equations. They have, however, in common that the full set of model equations is solved numerically in *one* simulation tool by *one* solver.



The modular structure of coupled multi-physical problems may also be exploited explicitly by coupling two or more well-established mono-disciplinary tools for model setup *and* for time integration (*simulator coupling* or *co-simulation*). In this way, the subsystems are handled by *different* solvers and each solver is tailored to the corresponding subsystem.

The communication between subsystems is restricted to discrete synchronization points T_j. For each subsystem, all necessary information from other subsystems has to be provided by interpolation or—if data for interpolation have not yet been computed—by extrapolation from $t \le T_j$ to the current *macro step* $T_j \to T_{j+1}$.



From the viewpoint of a multi-body system tool, the coupling variables to other simulation tools may be considered as a special type of discrete variables $\boldsymbol{r}_j$ in (3.32). In the multi-body system tool, the values of the coupling variables $\boldsymbol{r}_j$ are kept constant during the whole macro step $T_j \to T_{j+1}$. For all other simulation tools in the co-simulation environment, the update formula (3.32) involves the time integration from the synchronization point $t = T_j$ to the synchronization point $t = T_{j+1}$ to get $\boldsymbol{r}_{j+1} = \boldsymbol{k}(\ldots)$.

As a typical example of simulator coupling, Figure 3.8 shows simulation results for a heavy duty truck with semi-active suspensions [55]. The truck is modeled as a multi-body system with 41 bodies and 64 (mechanical) degrees of freedom. There are semi-active dampers in the axle suspension and in the cabin suspension that are controlled by an extended groundhook concept and by the skyhook law, respectively. Both controllers are modeled in Simulink and should be optimized to minimize dynamic road–tire forces and to maximize comfort.

In this application, the code export interfaces (see Figure 3.7) are not attractive since the multi-body system model contains closed loops resulting in constraints (3.31e) that cannot be handled by the standard solvers of Simulink. On the other hand, structure and parameters of the

(a)

(b)

FIGURE 3.8 Semi-active truck suspensions: vertical acceleration of the cabin (ISO filtered). (a): Multi-body system model, (b) Simulation data. (From Vaculín, O. et al., H. True, (ed.), *Proceedings of the 17th IAVSD Symposium on the Dynamics of Vehicles on Roads and on Tracks*, pp. 432–440. Supplement to *Vehicle Sys. Dyn.*, Vol. 37, Swets & Zeitlinger B.V., 2003.)

controllers are modified during the optimization process. It is therefore much more convenient to keep the controllers in Simulink instead of exporting their C code.

In [55], the problem was solved successfully by co-simulation of Simulink and the multi-body system tool SIMPACK [4]. The SIMPACK solver numerically integrates the mechanical part of the model, the control part is integrated in Simulink. The co-simulation sampling frequency is set to 200 Hz resulting in a constant *macro stepsize* $H = T_{j+1} - T_j = 5.0$ ms.

SIMPACK and Simulink run in two parallel processes. At the synchronization points, T_j the controller outputs, that is, the electrical signals defining the damper characteristics, are sent from Simulink to SIMPACK using inter-process communication (IPC). By the same IPC interface, Simulink gets the current vertical position, velocity and acceleration of truck chassis and cabin as controller input from SIMPACK. When the data exchange is completed, the solvers of Simulink and SIMPACK perform separately the macro step $T_j \rightarrow T_{j+1}$. Co-simulation continues with the data exchange at synchronization point T_{j+1} and so on.

The robust and reliable co-simulation contributed to the successful optimization of the controller design. A comparison of a truck with passive dampers and a truck with optimized semi-active dampers shows that the ride comfort is improved substantially (see the right plot of Figure 3.8 for the simulation of a typical driving maneuver [55]).

This case study illustrates that co-simulation techniques allow the convenient simulation and optimization of coupled problems in a classical software environment. Practical experience shows, however, that the coupling of different solvers may occasionally result in numerical instability. Furthermore, interpolation and extrapolation introduce additional discretization errors. The macro stepsize H has to be selected carefully. In typical standard applications, stability and accuracy may be guaranteed if H is in the range between 0.1 and 10 ms.

For certain classes of coupled problems, the instability phenomenon has been analyzed in great detail. Several modifications of the co-simulation techniques help to improve their stability, accuracy, and robustness also for larger macro stepsizes [56,57].

3.5.4 Summary

Complex multi-physical applications in vehicle system dynamics are beyond the field of multi-body dynamics. Successful simulation strategies use data interfaces or co-simulation interfaces between mono-disciplinary tools or models that are generated by general purpose simulation tools or modeling languages.

4.1 INTRODUCTION

A brief introduction to the finite element method in nonlinear mechanics is presented. The discussion focuses on purely mechanical problems excluding thermal processes. In view of finite element discretization, nonlinear theories of mechanics can be formulated in different ways, characterized by various advantages and difficulties. All such ways are here introduced and discussed.

The spatial discretization of the partial differential equations governing nonlinear problems leads to a system of nonlinear algebraic (for statics) or ordinary differential equations (for dynamics). Common problems in mechanics require to adopt nonlinear models. Nonlinearities are mainly due to the behavior of materials or to the magnitude of the displacements, or to the presence of unilateral constraints. Examples of such problems in the normal functioning of vehicles are the contact of the human subject with the vehicle, the mechanics of the tire, the mechanics of the bushings and of any rubber part in the vehicle, press fits, breaks pads, disks and calipers, and body structure. Examples of exceptional or pathological behaviors, that nevertheless have to be considered in the automotive design, are the mechanics of crash, the deployment of airbags, and the behavior of highly deformable parts designed to adsorb energy. The analysis of such problems can be pursued only with a nonlinear finite element approach.

The solution of a nonlinear system may be not unique, and the selection of a solver rather than another may privilege a particular solution and hide alternative solutions. Only the experience can help the analyst in selecting the most advantageous formulation and solver for a specific problem.

The following notes provide the indications on the basic tools necessary to analyze numerically the stress state of a generic mechanical model.

4.2 LINEAR PROBLEMS

The linearized theory of finite elements is based on several simplifying hypotheses concerning the behavior of solids and structures. In the literature, statics and dynamics problems able to satisfy such restrictive hypotheses are referred to as linear elasticity problems.

The linear elasticity assumptions are

1. The displacements are small. Under the action of external loads, bodies change their shape and their position in space. The small displacement hypothesis refers to a kinematics sufficiently small, such that
   a. The relative displacement between two close points is small. Thus, the displacement in a point neighborhood can be expressed as a linear function of the displacement of the point. The hypothesis does no exclude a priori the presence of large displacements or large rotations, but restricts the magnitude of the deformations. Thus, it allows writing the compatibility equations in linearized form. The linearized displacement field acquires the structure of a velocity field applied to the undeformed configuration (see Figure 4.1a).

      The expression of the derived small strains tensor ε_{ij} is

$$\varepsilon_{ij} = \frac{1}{2}\left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i}\right),$$

      where

      x_i is the coordinate of the particles of the solid

      $u_i = u_i(x_j)$ is the component of the displacement vector

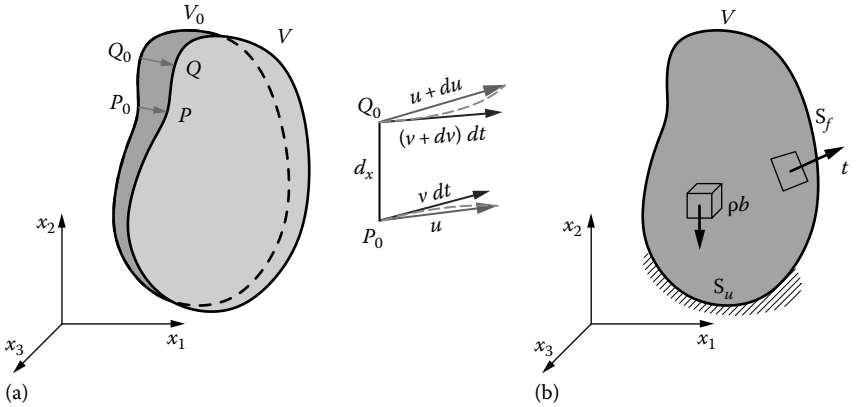

FIGURE 4.1 (a) Small displacement hypothesis. The displacements are equivalent to a velocity field applied to the undeformed configuration. (b) Static problem in small displacements. The equilibrium configuration reached under the external loads coincides with the undeformed configuration.

b. The displacements are small enough, so as not to alter the undeformed configuration of the body. In statics, the equilibrium condition is reached in the undeformed configuration (see Figure 4.1b). The hypothesis allows to write the equilibrium equations without accounting for the superposed kinematics and to decouple statics and kinematics:

$$\frac{\partial \sigma_{ij}}{\partial x_j} + \rho b_i = 0 \text{ in } V, \quad \sigma_{ij} n_i = t_j \text{ on } S_f,$$

where
σ_{ij} is the Cauchy stress tensor
ρ is the material density
b_i is the body forces per unit of mass
t_j is the surface tractions
n_i is the outward normal to the body external surface

2. The relationship between stress and strain is hyper-elastic and linear (Figure 4.2a). In an elastic material, the stress components are functions of the strain components. In a hyper-elastic material, a strain energy function acting as a potential for the stress is present. Hyper-elasticity induces reversibility, that is, a hyper-elastic material stores a certain amount of strain energy when loaded, and fully releases it when the load is removed. A linear constitutive law is characterized by linear relations between stress and strains. Linear elasticity automatically implies reversibility; therefore, the Hooke law is hyper-elastic.

   In linear hyper-elasticity, the relationship between Cauchy stress tensor σ_{ij} and small strain tensor ε_{ij} reads

$$\sigma_{ij} = C_{ijhk}\,\varepsilon_{hk}, \quad C_{ijhk} = \lambda \delta_{ij}\delta_{hk} + \mu(\delta_{ih}\delta_{jk} + \delta_{ik}\delta_{jh}), \tag{4.1}$$

where
δ_{ij} is the Kronecker delta
C_{ijhk} is the material stiffness tensor

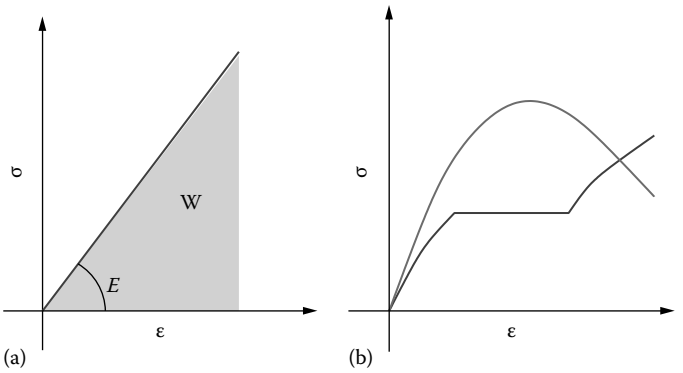

FIGURE 4.2 Material behaviors: (a) linear elasticity, implying reversibility and one-to-one correspondence and (b) nonlinear behavior, plasticity, softening, and in general nonreversibility.

The coefficients λ and μ are the Lamé constants:

$$\lambda = \frac{\nu E}{(1+\nu)(1-2\nu)}, \quad \mu = G = \frac{E}{2(1+\nu)}.$$

The statement of a static or of a dynamic problem in linear elasticity is straightforward, because irreversible and time-dependent effects are ruled out and the solution is unique.

3. The boundary conditions do not change during the loading. The constrained part of the boundary remains constrained, and unilateral constraints are excluded.

Under a finite element discretization, an elastostatic problem reduces to a linear system of algebraic equations:

$$\boldsymbol{KU} = \boldsymbol{R} \tag{4.2}$$

where

U is the nodal displacement array
R is the external load array
K is the stiffness matrix

As a consequence of small strain and linear elasticity hypotheses, the stiffness matrix and the nodal force arrays are independent of the nodal displacements. Therefore, ***U*** is a linear function of ***R***. Obviously, Equation 4.2 holds only when the constraints on the displacement components do not change for any value of the external loads.

4.3 NONLINEAR PROBLEMS

When one of the previous assumptions is not satisfied, the problem is called nonlinear. Nonlinear problems can be classified according to the kind of nonlinearities considered. Table 4.1 collects the different types of nonlinear analyses [1].

When small displacements, small rotations, and infinitesimal strains are considered (SD-SR-SS), but the material behavior is nonlinear, the analysis is called materially nonlinear (MN). Stress and strain measures are the Cauchy tensor σ_{ij} and the small strain tensor ε_{ij}, respectively. The only nonlinearities accounted for are due to the stress–strain relationship (Figure 4.2b).

When finite displacements, finite rotations, small strains are considered (LD-LR-SS), and no special hypotheses are made on the nature of the material, it is assumed that the material undergoes

TABLE 4.1
Classification of Nonlinear Analyses

Analysis	Formulation	Stress Measure	Strain Measure
SD-SR-SS	MN	σ_{ij}	ε_{ij}
LD-LR-SS	TL	S_{ij}	E_{ij}
	UL	σ_{ij}	A_{ij}
LD-LR-LS	TL	S_{ij}	E_{ij}
	UL	σ_{ij}	ε_{ij}

small deformations in a reference system in motion with the body. In that case, it is possible to adopt two alternative formulations, both Lagrangian (i.e., the deformation process is described from a reference configuration).

The formulation is said Updated Lagrangian (UL) when the reference configuration is updated at every step of the evolution analysis. The stress and strain measures adopted are the Cauchy tensor σ_{ij} and the Almansi tensor A_{ij}, respectively.

The formulation is said Total Lagrangian (TL) when the reference configuration is always the same and coincides with the undeformed configuration. The stress and strain measures are the second Piola–Kirchhoff tensor S_{ij} and the right Green–Lagrange tensor E_{ij}, respectively.

The two formulations (UL and TL) can also be used in the large deformation, large rotation, and large displacement case (LD-LR-LS). In UL, the stress measure is the Cauchy tensor σ_{ij} and the strain measure is the Hencky tensor ε_{ij}. In TL, the stress measure is the second Piola–Kirchhoff tensor S_{ij} and the strain measure is the right Green–Lagrange tensor E_{ij}.

A totally different problem that may induce nonlinearities in the formulation is the change in the boundary conditions, as it happens in contact.

It is important to observe that the choice of a formulation is suggested by the problem at the hand. A preliminary accurate evaluation of the problem permits to select the correct formulation, avoiding painful fix-ups for pending ends or algorithmic inconsistencies. The most general formulation (TU) is always correct, but it can be expensive. Simplified formulations (MN, UL) may reduce the computational effort and provide a better understanding of the underling mechanics but they are not always accurate enough for the problem in consideration.

4.3.1 Solution Strategy

To solve a nonlinear mechanical problem, the equilibrium configurations of a deformable body under the action of external loads have to be found. A finite element discretization transforms the equilibrium condition in a nonlinear system of algebraic or ordinary differential equations, in the general form:

$$\boldsymbol{R}(t) - \boldsymbol{F}^{\text{int}}(t) = \boldsymbol{0}, \tag{4.3}$$

where

the array $\boldsymbol{R}(t)$ contains the external forces applied to the nodes

the array $\boldsymbol{F}^{\text{int}}(t)$ contains the internal forces, that is, the integral of the element stresses

Equation 4.3 includes all the nonlinearities of the problem. The external forces $\boldsymbol{R}(t)$ can be decomposed in the contributions of volume forces $\boldsymbol{R}_B(t)$, surface forces $\boldsymbol{R}_S(t)$, and contact forces $\boldsymbol{R}_C(t)$:

$$\boldsymbol{R}(t) = \boldsymbol{R}_B(t) + \boldsymbol{R}_S(t) + \boldsymbol{R}_C(t).$$

In a dynamical analysis, $\boldsymbol{R}(t)$ also includes inertia and damping forces.

The general expression for the internal forces $\boldsymbol{F}^{\text{int}}(t)$ is

$$\boldsymbol{F}^{\text{int}}(t) = \sum_{e} \int_{V^{(e)}(t)} \boldsymbol{B}^{(e)T} \boldsymbol{\sigma}^{(e)}(t)\, dV^{(e)},$$

where

$\boldsymbol{B}$ is the matrix that collects the strain-displacement functions
the index e runs over the element number

In general, the stress $\sigma^{(e)}(t)$ and the element volume $V^{(e)}(t)$ at time t are unknown.

Equation 4.3 has to be satisfied at every t time of the entire loading history, that is, for $0 \le t \le T$. In a static analysis with no viscous effects, the load level is the only relevant parameter; therefore, the time has the meaning of an ordering parameter. If time is used only to describe the sequence of load application, a dynamical analysis becomes equivalent to a static analysis, where the inertia effects are included.

In some cases, only the stress and the displacement fields in particular equilibrium configurations are of interest. Ad hoc methods exist able to identify such equilibrium configurations, avoiding the calculation of transient configurations. Of course, this can be done only if time-dependent behaviors are not important, and path-dependent geometrical and material nonlinearities are excluded.

In general cases, though, it is necessary to carry out an incremental step-by-step analysis. In an incremental step-by-step analysis, the event duration (or pseudo-duration) T is subdivided into time steps $\Delta t = t - t_0$ suitably chosen. The solution at time t_0 is known, while the solution at the time t has to be computed.

The nodal forces $\boldsymbol{F}^{\text{int}}(t)$ can be expressed as the sum of the previous step solution and of the increment $\Delta \boldsymbol{F}$, which accounts for the displacement and stress changes in the interval Δt:

$$\boldsymbol{F}^{\text{int}}(t) = \boldsymbol{F}^{\text{int}}(t_0) + \Delta \boldsymbol{F}. \tag{4.4}$$

The array $\Delta \boldsymbol{F}$ can be rendered in approximate form through a linearization, which introduces the stiffness matrix $\boldsymbol{K}(t_0)$ at time t_0:

$$\Delta \boldsymbol{F} = \boldsymbol{K}(t_0)\, \Delta \boldsymbol{U}, \quad \boldsymbol{K}(t_0) = \left. \frac{\partial \boldsymbol{F}^{\text{int}}}{\partial \boldsymbol{U}} \right|_{t=t_0}. \tag{4.5}$$

$\boldsymbol{K}(t_0)$ is the derivative of the nodal forces $\boldsymbol{F}^{\text{int}}$ with respect to the nodal displacements $\boldsymbol{U}$ at time t_0. The combination of 4.4, 4.5, and 4.3 gives

$$\boldsymbol{K}(t_0)\, \Delta \boldsymbol{U} = \boldsymbol{R}(t) - \boldsymbol{F}^{\text{int}}(t_0), \quad \Delta \boldsymbol{U} = \boldsymbol{K}(t_0)^{-1} [\boldsymbol{R}(t) - \boldsymbol{F}^{\text{int}}(t_0)]. \tag{4.6}$$

The solution of 4.6 is an approximation of the incremental nodal displacements in the interval Δt:

$$\boldsymbol{U}(t) = \boldsymbol{U}(t_0) + \Delta \boldsymbol{U}. \tag{4.7}$$

For an accurate evaluation of stresses and forces, the nonlinear system (4.3) requires an iterative procedure. A rough approximation of the solution may lead to numerical instabilities.

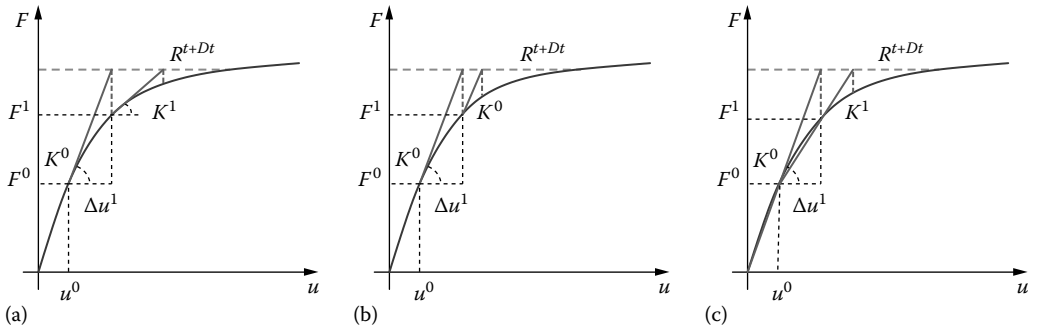

FIGURE 4.3 Schematic of (a) Newton–Raphson iterative procedure. (b) Modified Newton–Raphson iterative procedure. (c) Secant iterative procedure.

4.3.2 Solution Methods

The most widely used algorithm for the solution of nonlinear system is the Newton–Raphson method (Figure 4.3a). Equations 4.6 and 4.7 are applied iteratively. The solution of iteration k is used as the starting point for the next iteration $(k + 1)$:

$$\begin{aligned} \Delta \boldsymbol{U}^{k+1} &= \boldsymbol{K}^{k-1}[\boldsymbol{R}(t) - \boldsymbol{F}^k] \\ \boldsymbol{U}^{k+1} &= \boldsymbol{U}^k + \Delta \boldsymbol{U}^{k+1}. \end{aligned} \tag{4.8}$$

Stresses, nodal forces $\boldsymbol{F}^{k+1}$, and tangent stiffness $\boldsymbol{K}^{k+1}$ at iteration $(k + 1)$ are computed through the computed displacements (4.8). The error $\boldsymbol{R}(t) - \boldsymbol{F}^{\text{int}}(t)^k$ is called "residual." The residual is an array of out-of-balance forces that requires a further increment of the displacements to be equilibrated. The Newton–Raphson method is very efficient, but it may be excessively demanding in terms of computational cost. In fact, at each iteration it requires the evaluation of the nodal forces array and of the tangent stiffness matrix.

Alternative methods can be used to reduce the computational effort. In the modified Newton (or quasi-Newton) method, the tangent stiffness is computed only at the beginning of the load step, and is considered constant during the iterative procedure (see Figure 4.3b). In the secant method, the tangent stiffness is approximated with the secant stiffness. Its calculation requires the knowledge of the nodal forces and displacements at two sequential iterations, but it does not need the derivation of the analytical expression of the stiffness matrix (see Figure 4.3c).

The iterative procedure terminates under the satisfaction of a convergence test. In general, the convergence test is based on the norm of the arrays involved in the solution, such as the residual norm (or the incremental displacement norm). The solution is considered correct when the global array norm is smaller than a small percentage of the norm of the residuals at the iteration zero (or of the norm or the total displacement):

$$|\boldsymbol{R}^{k+1}| \leq \epsilon\, |\boldsymbol{F}^{\text{ext}}|, \quad |\Delta \boldsymbol{U}^{k+1}| \leq \epsilon\, |\boldsymbol{U}|,$$

where the small constant ε (e.g., 10^{-12}) is the desired tolerance.

4.4 CONTINUUM MECHANICS

The description of the nonlinear finite element approaches requires a brief overview of the continuum mechanics variables and equations.

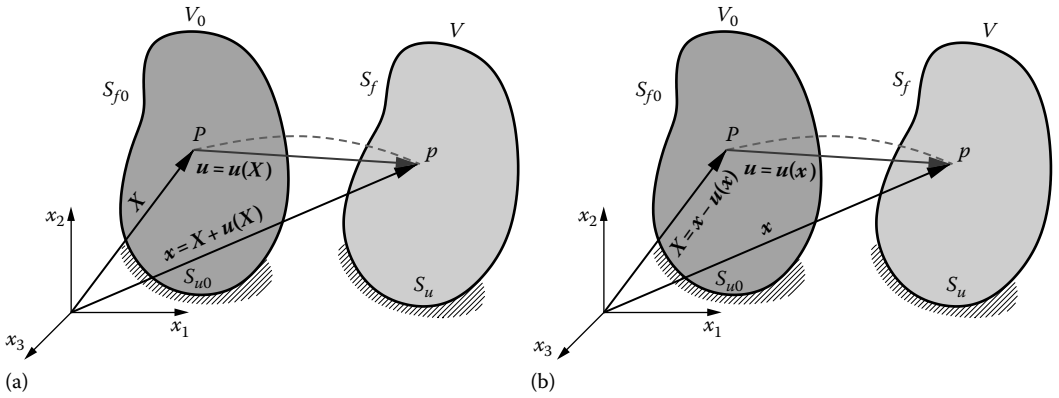

FIGURE 4.4 A continuum in the initial and deformed configuration, definition of the variables. (a) Lagrangian approach. (b) Eulerian approach.

A body, subject to constraints, surface tractions, and body forces (all variables in time), undergoes a motion described by a regular mapping φ. The position of the body is identified by a fixed Cartesian reference system. The equilibrium configurations of the body at regular time intervals Δt have to be determined.

The motion of a continuum without restrictions on the magnitude of displacements can be studied with two alternative point of views:

- In a Lagrangian or "material" formulation, one tracks the evolution of all the body particles from the initial configuration to the final configuration (Figure 4.4a).
- In an Eulerian or "spatial" formulation, one follows the motion of the material through a reference volume (Figure 4.4b). The Eulerian formulation is used widely in fluid mechanics.

In the following, only the Lagrangian description will be considered. A detailed derivation of the equations that govern a continuum mechanics problem in both descriptions can be found in several well-known books, for example, [2–4].

The reference variables are identified with a capital symbol, while the current configuration variables are identified with lowercase symbols. When an uppercase symbol is necessary for both configurations, a superscript 0 index will distinguish the reference configuration from the current, see, for example, the volume V^0 and V, respectively.

4.4.1 Strong and Weak Forms of Equilibrium

As in the linear case, the equilibrium of the continuum at time t is expressed in weak form through the virtual work theorem:

$$\int_V \sigma_{ij}\delta e_{ij}\, dV = W(t), \quad \delta e_{ij} = \frac{1}{2}\left(\frac{\partial \delta u_i}{\partial x_j} + \frac{\partial \delta u_j}{\partial x_i}\right), \tag{4.9}$$

where

x_i is the spatial coordinate of a point at time t

δu is the component of a virtual (i.e., compatible) displacement field added to the deformed configuration at time t

σ_{ij} is the Cauchy stress tensor, expressing the forces per unit of area in the current configuration

δe_{ij} is the symmetric part of the displacement gradient, derived from the virtual displacements

V is the body volume at time t

The right-side member of Equation 4.9_1 represents the virtual external work:

$$W(t) = \int_V \rho b_i \delta u_i \, dV + \int_{S_f} t_i \delta u_i \, dS, \tag{4.10}$$

where

ρb_i is the body force per unit of volume at time t
t_i is the surface traction at time t
S_f defines the part of the external boundary where tractions are applied

Equation 4.9_1 is derived by considering an infinitesimal variation of the current equilibrium configuration. It corresponds to the strong equilibrium equations in the volume V:

$$\frac{\partial \sigma_{ij}}{\partial x_j} + \rho b_i = 0 \tag{4.11}$$

and on the boundary S_f

$$\sigma_{ij} n_i = t_j, \tag{4.12}$$

where n_i defines the outward normal on S_f at time t.

It is important to observe that

1. The virtual work equation is obtained from the equilibrium equations (4.11 and 4.12), transformed from vectorial equation to a scalar through a virtual displacement field, and integrated over continuum volume and surface.
2. The components of the virtual deformation tensor in $(4.9)_2$ are obtained, like in the small strain case, by differentiation of the displacement field with respect to the current coordinates x_i at time t. The expression of the virtual deformation does not depend on the magnitude of the actual displacements.
3. The virtual displacements δu_i are a compatible first variation of the true displacements u_i. Compatibility implies satisfaction of the displacement conditions on the constrained boundary and of the internal compatibility constraints.
4. Formally, the virtual displacement equation is identical to the one used in linear analyses, except that it is written in the current configuration. Therefore, all the results obtained for the linear virtual work equation hold also for Equation 4.9_1.
5. The substantial difference with respect to linear analyses is that the current configuration at time t is unknown. This has strong implications on solution procedures. For example, it is not possible to apply the principle of the superposition of effects; also, in the evaluation of the Cauchy stress, it is necessary to account for the presence of rigid rotations.
6. To follow the configuration changes of a body in finite deformations, it is necessary to use work conjugate stress and strain measures, related through constitutive equations.

4.4.2 Deformation Gradient

A deformation mapping φ modifies the configuration of a continuum. In a fixed reference system, the position of a particle P in the initial or undeformed configuration is identified by the coordinates $\boldsymbol{X} = \{X_i\}$. The position of the same particle in the current or deformed configuration, at time t,

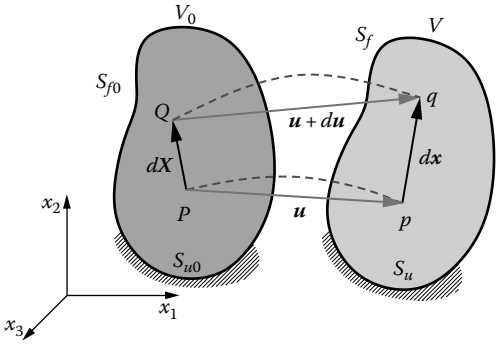

FIGURE 4.5 Configuration change in a continuum undergoing a mapping φ. The segment $d\boldsymbol{X}$ transforms into $d\boldsymbol{x} = \boldsymbol{F}d\boldsymbol{X}$.

is identified with $\boldsymbol{x} = \{x_i\}$. The current position is obtained by the initial position by adding the displacements to the initial position, $\boldsymbol{x} = \boldsymbol{X} + \boldsymbol{u}$ (or in components $x_i = X_i + u_i$). For particles sufficiently close, the configuration change is described completely by the deformation gradient $\boldsymbol{F}$:

$$\boldsymbol{F} = \frac{d\boldsymbol{x}}{d\boldsymbol{X}} = \boldsymbol{I} + \frac{d\boldsymbol{u}}{d\boldsymbol{X}}, \quad F_{ij} = \frac{dx_i}{dX_j} = \delta_{ij} + \frac{du_i}{dX_j}.$$

$\boldsymbol{F}$ is the Jacobian matrix of the mapping φ and is a real value nonsymmetric tensor. The determinant $J = \det(\boldsymbol{F})$ is called the Jacobian of the transformation. Figure 4.5 shows that, under the mapping φ, the deformation gradient transforms the segment $d\boldsymbol{X}$ into the segment $d\boldsymbol{x} = \boldsymbol{F}d\boldsymbol{X}$.

If the deformation mapping is continuum and regular, J is nonzero and $\boldsymbol{F}$ is invertible:

$$\boldsymbol{F}^{-1} = \frac{d\boldsymbol{X}}{d\boldsymbol{x}} = \boldsymbol{I} - \frac{d\boldsymbol{u}}{d\boldsymbol{x}}, \quad F_{ij}^{-1} = \frac{dX_i}{dx_j} = \delta_{ij} - \frac{du_i}{dx_j}.$$

It is possible to prove that J measures the ratio between the local initial density ρ^0 and the local current density ρ:

$$J = \frac{\rho^0}{\rho} > 0.$$

Clearly, for physical reasons, negative values of J are not acceptable.

The deformation gradient $\boldsymbol{F}$ contains all the information about the configuration change in the neighborhood of a point, including deformations and rigid rotations. Theoretically, $\boldsymbol{F}$ could be used in the constitutive relations, although the rigid rotation part has to be removed. For practical reasons, however, it is more convenient to introduce measures of deformations that exclude rigid rotations.

4.4.3 Deformation Tensors

To eliminate rigid rotations from $\boldsymbol{F}$, it is possible to define symmetric measures of deformation.

By pre- or post-multiplication of $\boldsymbol{F}$ with the transpose $\boldsymbol{F}^T$, the right Cauchy–Green stretch tensor $\boldsymbol{C}$ and left Cauchy–Green stretch tensor $\boldsymbol{B}$, respectively, are obtained:

$$\boldsymbol{C} = \boldsymbol{F}^T\boldsymbol{F}, \quad \boldsymbol{B} = \boldsymbol{F}\boldsymbol{F}^T.$$

$\boldsymbol{C}$ is a symmetric real-value tensor, with three real eigenvalues, C_α, and three orthogonal eigenvectors, $\boldsymbol{N}_\alpha$. The eigenvectors define the three principal directions of stretch in the undeformed (or material) reference configuration. Also, $\boldsymbol{B}$ is a symmetric real-value tensor, and possesses three real eigenvalues B_α, and three orthogonal eigenvectors, $\boldsymbol{n}_\alpha$. The eigenvectors define three principal directions of stretch in the deformed or spatial reference configuration.

The right stretch tensor $\boldsymbol{U}$ and the left stretch tensor $\boldsymbol{V}$ (related to pure deformations) are defined as

$$\boldsymbol{C} = \boldsymbol{U}^2, \quad \boldsymbol{U} = \boldsymbol{C}^{1/2}, \quad \boldsymbol{B} = \boldsymbol{V}^2, \quad \boldsymbol{V} = \boldsymbol{B}^{1/2}.$$

$\boldsymbol{C}$ and $\boldsymbol{B}$ are definite positive tensors, and their eigenvalues C_α and B_α are positive. The three real numbers $\lambda_\alpha = \sqrt{C_\alpha}$ are called principal stretches. The tensors $\boldsymbol{C}$ and $\boldsymbol{B}$ admit the spectral decomposition:

$$\boldsymbol{C} = \sum_{\alpha=1}^{3} C_\alpha \boldsymbol{N}_\alpha \otimes \boldsymbol{N}_\alpha, \quad \boldsymbol{B} = \sum_{\alpha=1}^{3} B_\alpha \boldsymbol{n}_\alpha \otimes \boldsymbol{n}_\alpha.$$

Clearly, $\boldsymbol{U}$ and $\boldsymbol{V}$ also admit a spectral decomposition:

$$\boldsymbol{U} = \sum_{\alpha=1}^{3} \lambda_\alpha \boldsymbol{N}_\alpha \otimes \boldsymbol{N}_\alpha, \quad \boldsymbol{V} = \sum_{\alpha=1}^{3} \sqrt{B_\alpha}\, \boldsymbol{n}_\alpha \otimes \boldsymbol{n}_\alpha. \tag{4.13}$$

Alternative deformation tensors are obtained by decomposing the deformation gradient into the product of a deformation tensors and a rotation matrix $\boldsymbol{R}$, in the two alternative forms:

$$\boldsymbol{F} = \boldsymbol{R}\boldsymbol{U}, \quad \boldsymbol{F} = \boldsymbol{V}\boldsymbol{R}, \quad \boldsymbol{V} = \boldsymbol{R}\boldsymbol{U}\boldsymbol{R}^T. \tag{4.14}$$

Equation 4.14_1 defines the right polar decomposition of the deformation gradient, while Equation 4.14_2 defines the left polar decomposition. The rotation matrix $\boldsymbol{R}$ describes the rigid rotation of the deformed configuration with respect to the undeformed.

The meaning of the polar decomposition is that any deformation may be thought as the application of a pure deformation (right stretch) $\boldsymbol{U}$, described in the principal directions of the undeformed reference configuration, followed by a rigid rotation $\boldsymbol{R}$ $(4.14)_1$; or, alternatively, as the application of a rigid rotation followed $\boldsymbol{R}$ by a pure deformation (left stretch) $\boldsymbol{V}$ in the principal directions of the deformed configuration $(4.14)_2$. The two polar decompositions are visualized in Figure 4.6 in the case of a plane pure shear deformation. The components of the matrix $\boldsymbol{R}$ are defined by the rigid rotation angle β.

If $\boldsymbol{\Lambda}$ denotes the diagonal tensor that contains the principal stretches λ_α, and $\boldsymbol{R}_L$ the matrix that lists the three eigenvectors $\boldsymbol{N}_\alpha$, Equation 4.13_1 may be written as

$$\boldsymbol{U} = \boldsymbol{R}_L \boldsymbol{\Lambda} \boldsymbol{R}_L^T. \tag{4.15}$$

The components of the matrix $\boldsymbol{R}_L$ are defined by the angle φ illustrated in Figure 4.6, which identifies the position of the principal stretch angles before the application of the rigid rotation.

From $(4.14)_3$ and (4.15), one obtains

$$\boldsymbol{V} = \boldsymbol{R}_E \boldsymbol{\Lambda} \boldsymbol{R}_E^T, \quad \boldsymbol{R}_E = \boldsymbol{R}\boldsymbol{R}_L, \tag{4.16}$$

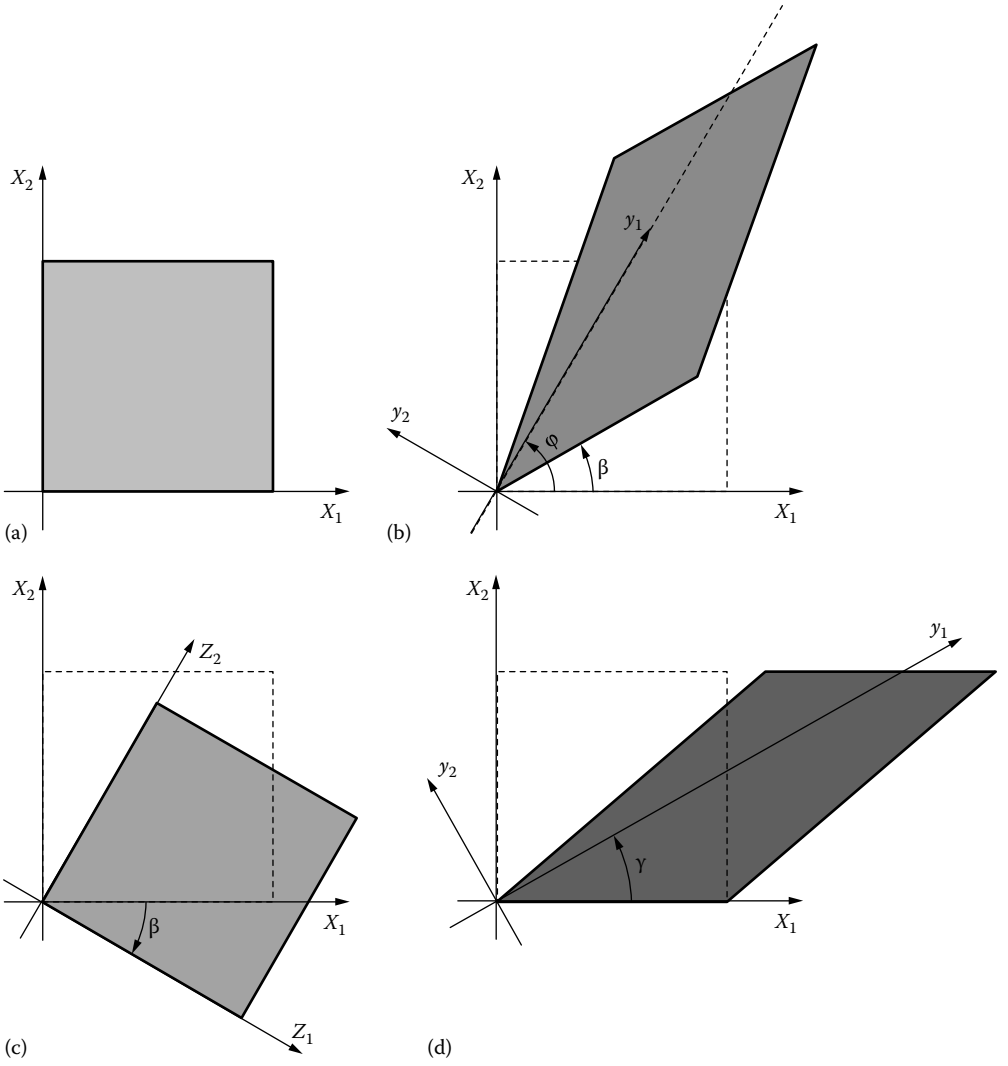

FIGURE 4.6 Visualization of the polar decomposition in the pure shear case. (a)→(b)→(d) right decomposition, (a)→(c)→(d) left decomposition.

where $\boldsymbol{R}_E$ collects the eigenvectors of $\boldsymbol{B}$. The components of the matrix $\boldsymbol{R}_E$ are defined by the angle γ, illustrated in Figure 4.6, as the angle that identifies the position of the principal stretch axes. By comparing $(4.13)_2$ and (4.16), it is clear that

$$\sqrt{B_\alpha} = \lambda_\alpha, \quad \boldsymbol{n}_\alpha = \boldsymbol{R}\boldsymbol{N}_\alpha,$$

that is, the eigenvectors of $\boldsymbol{C}$ and $\boldsymbol{B}$ are equal, while their eigenvectors are rotated by the angle $\boldsymbol{R}$. For the shear example in Figure 4.6, this means that $\varphi = \beta + \gamma$.

4.4.4 Strain Rates

In the description of the motion of a material particle, it is necessary to define the rates of the deformation measures previously mentioned [5,6]. A few definitions are introduced in the following.

The rotation rate $\dot{\boldsymbol{R}}$ is given by

$$\dot{\boldsymbol{R}} = \boldsymbol{\Omega}_R \boldsymbol{R}, \tag{4.17}$$

where $\boldsymbol{\Omega}_R$ is the skew-symmetric spin tensor. It is evident that at the initial time (when deformed and undeformed configurations coincide) $\boldsymbol{R} = \boldsymbol{I}$, and this helps in understanding the meaning of $\boldsymbol{\Omega}_R$. The rotations of the principal reference systems referred as the undeformed and deformed configuration, respectively, are expressed by analogous relations:

$$\dot{\boldsymbol{R}}_L = \boldsymbol{R}_L \boldsymbol{\Omega}_L, \quad \dot{\boldsymbol{R}}_E = \boldsymbol{R}_E \boldsymbol{\Omega}_E$$

The tensors $\boldsymbol{\Omega}_L$ and $\boldsymbol{\Omega}_E$ are called spin of the principal reference systems in the undeformed and deformed configuration.

The velocity gradient $\boldsymbol{L}$ is defined as

$$\boldsymbol{L} = \frac{d\boldsymbol{v}}{d\boldsymbol{x}}, \quad \boldsymbol{v} = \frac{d\boldsymbol{x}}{dt} = \frac{d\boldsymbol{u}}{dt},$$

where $\boldsymbol{v}$ is the velocity of a particle in the deformed configuration (Figure 4.7). The tensor $\boldsymbol{L}$ has the typical linear structure of a velocity field, and decomposes into the sum of two tensors (Figure 4.8): the symmetric deformation rate tensor $\boldsymbol{D}$ and the skew-symmetric spin tensor $\boldsymbol{W}$:

$$\boldsymbol{L} = \boldsymbol{D} + \boldsymbol{W}, \quad \boldsymbol{D} = \frac{1}{2}(\boldsymbol{L} + \boldsymbol{L}^T), \quad \boldsymbol{W} = \frac{1}{2}(\boldsymbol{L} - \boldsymbol{L}^T).$$

The physical interpretation of $\boldsymbol{D}$ and $\boldsymbol{W}$ is very simple. In terms of velocities, they correspond to the small strain tensor $\boldsymbol{\varepsilon}$ and small rotation tensor $\boldsymbol{\omega}$, respectively. Under the small displacement assumption, the kinematics can be considered as an incipient motion from the undeformed configuration.

The rate of the deformation gradient is computed as

$$\dot{\boldsymbol{F}} = \frac{d\boldsymbol{F}}{dt} = \frac{d}{dt}\left(\frac{d\boldsymbol{x}}{d\boldsymbol{X}}\right) = \frac{d}{d\boldsymbol{X}}\left(\frac{d\boldsymbol{x}}{dt}\right) = \frac{d\boldsymbol{v}}{d\boldsymbol{x}}\frac{d\boldsymbol{x}}{d\boldsymbol{X}} = \boldsymbol{L}\boldsymbol{F}. \tag{4.18}$$

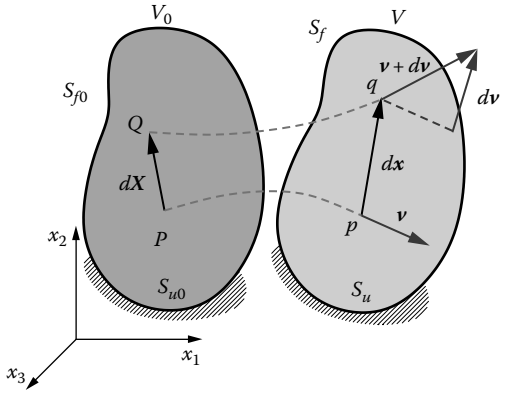

FIGURE 4.7 Meaning of the quantities $d\boldsymbol{v}$ and $d\boldsymbol{x}$ appearing in the velocity gradient $\boldsymbol{L}$.

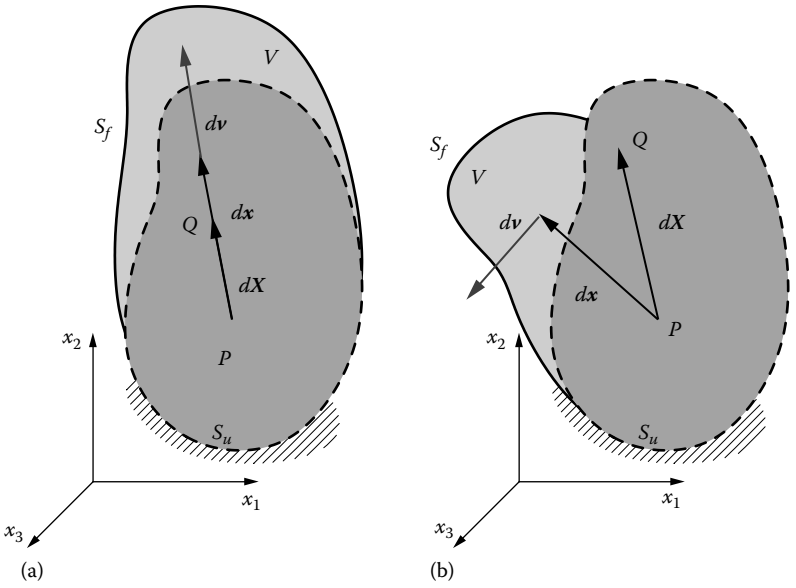

FIGURE 4.8 Examples of velocity vectors, leading to (a) deformation rate and (b) spin.

By using $(4.14)_1$ through (4.17) and (4.18), $\boldsymbol{D}$ and $\boldsymbol{W}$ are expressed as functions of the stretch tensor $\boldsymbol{U}$:

$$\boldsymbol{D} = \frac{1}{2}\boldsymbol{R}(\dot{\boldsymbol{U}}\boldsymbol{U}^{-1} + \boldsymbol{U}^{-1}\dot{\boldsymbol{U}})\boldsymbol{R}^T,$$

$$\boldsymbol{W} = \boldsymbol{\Omega}_{\boldsymbol{R}} + \frac{1}{2}\boldsymbol{R}(\dot{\boldsymbol{U}}\boldsymbol{U}^{-1} - \boldsymbol{U}^{-1}\dot{\boldsymbol{U}})\boldsymbol{R}^T$$

and, by using Equation 4.15, become

$$\begin{aligned} &\boldsymbol{D} = \boldsymbol{R}_E\boldsymbol{D}_E\boldsymbol{R}_E^T, \quad \boldsymbol{D}_E = \dot{\Lambda}\Lambda^{-1} + \frac{1}{2}\left(\Lambda^{-1}\boldsymbol{\Omega}_{\boldsymbol{L}}\Lambda - \Lambda\boldsymbol{\Omega}_{\boldsymbol{L}}\Lambda^{-1}\right), \\ &\boldsymbol{W} = \boldsymbol{R}_E\boldsymbol{W}_E\boldsymbol{R}_E^T, \quad \boldsymbol{W}_E = \boldsymbol{\Omega}_{\boldsymbol{E}} - \frac{1}{2}\left(\Lambda^{-1}\boldsymbol{\Omega}_{\boldsymbol{L}}\Lambda + \Lambda\boldsymbol{\Omega}_{\boldsymbol{L}}\Lambda^{-1}\right). \end{aligned} \tag{4.19}$$

$\boldsymbol{D}_E$ and $\boldsymbol{W}_E$ are the deformation rate and the spin tensors referred to the principal deformation axes at time t.

The diagonal elements of $(4.19)_2$ include only the first contribution of the left-side member. The second contribution is the difference between two transpose matrices and its diagonal terms are null. Therefore, the elements of $\dot{\boldsymbol{\Lambda}}$ are

$$[\dot{\Lambda}]_{\alpha\alpha} = \lambda_\alpha[\boldsymbol{D}_E]_{\alpha\alpha}.$$

For $\lambda_\alpha \neq \lambda_\beta$, the extra-diagonal elements of $\boldsymbol{\Omega}_L$ and $\boldsymbol{\Omega}_E$ are

$$[\boldsymbol{\Omega}_L]_{\alpha\beta} = \frac{2\lambda_\alpha\lambda_\beta}{\lambda_\beta^2 - \lambda_\alpha^2}[\boldsymbol{D}_E]_{\alpha\beta},$$

$$[\boldsymbol{\Omega}_E]_{\alpha\beta} = [\boldsymbol{W}_E]_{\alpha\beta} - \frac{\lambda_\alpha^2 + \lambda_\beta^2}{\lambda_\beta^2 - \lambda_\alpha^2}[\boldsymbol{D}_E]_{\alpha\beta}.$$

If $\boldsymbol{D}$ and $\boldsymbol{W}$ are described in the basis of the principal deformation system in the deformed configuration, where $\boldsymbol{R}_E = \boldsymbol{I}$, they define directly $\boldsymbol{\Omega}_L$ and $\boldsymbol{\Omega}_E$. Thus, $\dot{\boldsymbol{\Lambda}}$ is derived directly.

4.4.5 Strain Measures

Stretches measure the magnitude of deformations. They express the ratio between the length of a deformed segment and the length of the same segment undeformed. Thus, in the absence of deformation, they are equal to the unit. For small deformations, the stretch values differ slightly from the unit, say at the fourth or fifth digit. In engineering applications, it is more significant to adopt strain measures that are null in the case of null deformations, and assume nonzero values only when a deformation is present.

Different strain measures are available in finite kinematics. A general expression includes the definition of several strain tensors:

$$\boldsymbol{E}_G = \boldsymbol{R}_L g(\boldsymbol{\Lambda}) \boldsymbol{R}_L^T, \quad g(\boldsymbol{\Lambda}) = \mathrm{diag}[g(\lambda_i)],$$

where λ_i denotes the principal stretches. The corresponding strain rate tensor $\dot{\boldsymbol{E}}_G$ is given by

$$\dot{\boldsymbol{E}}_G = \boldsymbol{R}_L \dot{\boldsymbol{E}}_L \boldsymbol{R}_L^T, \quad \dot{\boldsymbol{E}}_L = \dot{\boldsymbol{\Lambda}} g'(\boldsymbol{\Lambda}) + \boldsymbol{\Omega}_L g(\boldsymbol{\Lambda}) - g(\boldsymbol{\Lambda}) \boldsymbol{\Omega}_L. \tag{4.20}$$

The earlier definition may be expanded in order to relate the components of $\dot{\boldsymbol{E}}_G$ with the components of $\boldsymbol{D}_E$, in the general form:

$$[\dot{\boldsymbol{E}}_G]_{\alpha\beta} = \gamma_{\alpha\beta} [\boldsymbol{D}_E]_{\alpha\beta}. \tag{4.21}$$

The explicit expression of $\gamma_{\alpha\beta}$ can be obtained only once $g(\boldsymbol{\Lambda})$ has been defined.

The most used strain measures in engineering applications are

1. Small strain tensor $\boldsymbol{\varepsilon}$:

$$\boldsymbol{\varepsilon} = \boldsymbol{R}_L (\boldsymbol{\Lambda} - \boldsymbol{I}) \boldsymbol{R}_L^T.$$

In Cartesian components, and introducing explicitly the displacements

$$\varepsilon_{ij} = \frac{1}{2}(u_{i,j} + u_{j,i}).$$

2. Green–Lagrange strain tensor $\boldsymbol{E}$:

$$\boldsymbol{E} = \boldsymbol{R}_L \frac{1}{2}(\boldsymbol{\Lambda}^2 - \boldsymbol{I}) \boldsymbol{R}_L^T = \frac{1}{2}(\boldsymbol{C} - \boldsymbol{I}).$$

In Cartesian components, and introducing explicitly the displacements

$$E_{ij} = \frac{1}{2}(u_{i,j} + u_{j,i} + u_{k,i} u_{k,j}).$$

The components of $\boldsymbol{E}$ do not change if the body undergoes a rigid rotation $\boldsymbol{R}$. In fact, the rigid rotation part $\boldsymbol{R}$ of $\boldsymbol{F}$ does not enter in the definition of $\boldsymbol{E}$.

The expression of $\gamma_{\alpha\beta}$ is

$$\gamma_{\alpha\beta} = \lambda_\alpha \lambda_\beta. \tag{4.22}$$

By combining Equations 4.19_1 through 4.22, the following relation is obtained:

$$\dot{\boldsymbol{E}} = \boldsymbol{F}^T \boldsymbol{D} \boldsymbol{F}, \quad \boldsymbol{D} = \boldsymbol{F}^{-T} \dot{\boldsymbol{E}} \boldsymbol{F}^{-1}, \tag{4.23}$$

also obtained by differentiating $\boldsymbol{E}$ with respect to time.

3. Hencky or logarithmic strain tensor ϵ:

$$\boldsymbol{\epsilon} = \boldsymbol{R}_L \log \boldsymbol{\Lambda} \boldsymbol{R}_L^T = \frac{1}{2} \log \boldsymbol{C}.$$

The expression of $\gamma_{\alpha\beta}$ is

$$\gamma_{\alpha\beta} = \begin{cases} 1 & \text{if } \lambda_\alpha = \lambda_\beta \\ \dfrac{2\lambda_\alpha \lambda_\beta}{\lambda_\alpha^2 - \lambda_\beta^2} \log \dfrac{\lambda_\beta}{\lambda_\alpha} & \text{otherwise} \end{cases}. \tag{4.24}$$

Because of the complexity of 4.24, it is not possible to find an explicit relation between ϵ and $\boldsymbol{D}$. The Hencky strain is used often in inelastic analyses. In that case, the correct incremental relation for ϵ is defined in terms of conjugate work.

Figure 4.9 compares the three strain measures ε_{ij}, ϵ_{ij}, and E_{ij} in the uniaxial case. In small strain condition (i.e., when the stretch is close to one), the three measures coincide.

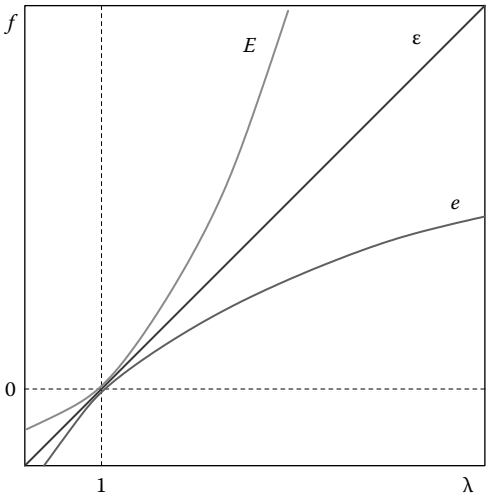

FIGURE 4.9 Comparison of the deformation measures in the uniaxial case. The lowest curve corresponds to the logarithmic deformation. The straight curve corresponds to the engineering deformation (small strain). The upper curve corresponds to Green–Lagrange.

An example of Eulerian strain measure is the Almansi strain tensor. It relates with the Green–Lagrange strain tensor as follows:

$$\boldsymbol{A} = \frac{1}{2}[\boldsymbol{I} - \boldsymbol{B}^{-1}] = \frac{1}{2}[\boldsymbol{I} - \boldsymbol{F}^{-T} \cdot \boldsymbol{F}^{-1}] = \boldsymbol{F}^{-T} \cdot \boldsymbol{E} \cdot \boldsymbol{F}^{-1}.$$

In Cartesian components, it reads

$$A_{ij} = \frac{1}{2}\left[u_{i,j} + u_{j,i} - u_{k,i}u_{k,j}\right].$$

Unlike Green–Lagrange strain tensor, the Almansi strain tensor components are not invariant under rigid rotations.

4.4.6 Stress Measures

The stress measures for finite deformations are dependent on the choice of the strain measures. The Cauchy stress $\boldsymbol{\sigma}$ is defined in the current configuration and is suitable for Eulerian formulations. In a Lagrangian formulation, the most used stress measures are the first $\boldsymbol{P}$ and the second $\boldsymbol{S}$ Piola–Kirchhoff tensors. The two Piola–Kirchhoff tensors do not have a precise physical meaning. They are introduced in order to provide a traction, that is, a force per unit of undeformed surface. Therefore, the only physically meaningful stress measure also in large strains is the Cauchy stress.

Figure 4.10 shows two traction vectors. The surface traction $d\boldsymbol{t}$ is applied to the elementary deformed surface dS, while the surface traction $d\boldsymbol{T}$ is applied to the elementary undeformed surface dS^0. The first Piola–Kirchhoff tensor $\boldsymbol{P}$ refers the current surface traction $d\boldsymbol{t}$ to the undeformed surface dS^0. Thus, the traction $d\boldsymbol{t}$ is linked unnaturally to the normal $\boldsymbol{N}$ to dS^0 in the undeformed reference system. By extending the definition of Cauchy stress to the undeformed surface, one obtains

$$d\boldsymbol{t} = (\boldsymbol{n}\boldsymbol{\sigma})dS = (\boldsymbol{N}\boldsymbol{P})dS^0.$$

The second Piola–Kirchhoff stress tensor $\boldsymbol{S}$ uses the surface traction $d\boldsymbol{T}$, related to $d\boldsymbol{t}$ by the same relation that links $d\boldsymbol{X}$ and $d\boldsymbol{x}$, that is, the inverse of the deformation gradient $\boldsymbol{F}^{-1}$. It also refers it to the undeformed surface dS^0:

$$d\boldsymbol{T} = \boldsymbol{F}^{-1}d\boldsymbol{t} = \boldsymbol{F}^{-1}(\boldsymbol{n}\boldsymbol{\sigma})dS = (\boldsymbol{N}\boldsymbol{S})dS^0.$$

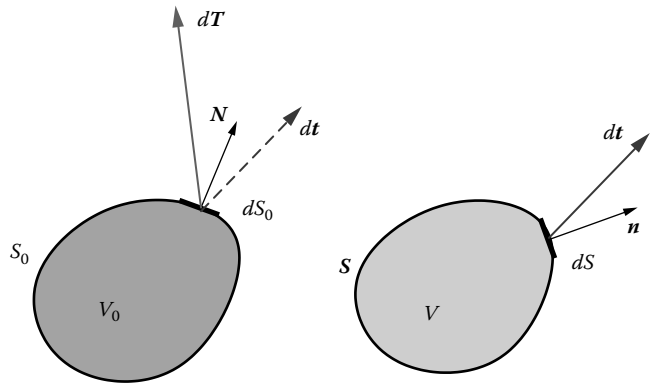

FIGURE 4.10 Traction vectors for the definition of the Piola–Kirchhoff stress tensors.

To find the relations between $\boldsymbol{\sigma}$, $\boldsymbol{P}$, and $\boldsymbol{S}$, it is necessary to express the deformed area dS as a function of the undeformed one dS^0 through the Nanson's formula [2]:

$$\boldsymbol{n}\, dS = \boldsymbol{JNF}^{-1}\, dS^0,$$

obtaining

$$\boldsymbol{\sigma} = J^{-1}\boldsymbol{FSF}^T = J^{-1}\boldsymbol{FP}. \tag{4.25}$$

Unlike $\boldsymbol{\sigma}$ and $\boldsymbol{S}$, $\boldsymbol{P}$ is nonsymmetric.

A strain tensor and a stress tensor are said to be work conjugated if the sum of the product of their equal-index components is a physical work or energy per unit of volume. In a constitutive relationship, only work-conjugated tensors can be used. The second Piola–Kirchhoff stress tensor $\boldsymbol{S}$ is work conjugated to the Green–Lagrange strain tensor $\boldsymbol{E}$, while the first Piola–Kirchhoff stress tensor $\boldsymbol{P}$ is work conjugated to the deformation gradient $\boldsymbol{F}$.

$\boldsymbol{S}$ and $\boldsymbol{E}$ are the most widely used pair of tensors in finite deformation analyses. Both $\boldsymbol{S}$ and $\boldsymbol{E}$ do not change under rigid rotations, since a rigid rotation does not affect the Cauchy–Green strain tensor $\boldsymbol{C}$. As a consequence of their definition, the components of $\boldsymbol{S}$ and $\boldsymbol{E}$ do not change if a rigid rotation is applied [1]. Such property, called material frame indifference, does not hold for the stress rates.

4.5 NONLINEAR FORMULATIONS OF THE VIRTUAL WORK EQUATION

For a generic time t, $0 \le t \le T$, of a loading process, the internal virtual work in Equation 4.9_1 can be written in terms of 4.25 and 4.23, accounting for $\rho dV = \rho^0 dV^0$:

$$\int_V \sigma_{ij}\,\delta e_{ij}\, dV = \int_V \left(\frac{\rho}{\rho^0} F_{ih} S_{hk} F_{jk}\right)\left(F_{il}^{-1}\delta E_{lm} F_{jm}^{-1}\right) dV = \int_{V^0} S_{hk}\delta E_{hk}\, dV^0. \tag{4.26}$$

A similar treatment is needed for the external work W, whose expression has to be derived according to the particular case in examination.

Closed form solutions of 4.9 or 4.26, referred to the unknown configuration at time t, cannot be derived. Solutions are obtained in approximate form. In general, the solution is evaluated at predefined times, separated by constant intervals Δt (e.g., $t = t_0 + \Delta t$). The approximation is based on the linearization of the equations, and needs to know the solutions at previous times. Then, the accuracy is improved by iterative procedures. In practice, two formulations have become more popular than others, that is, the TL formulation and the UL formulation:

- The TL formulation refers the static and kinematic quantities to the initial configuration at time $t = 0$:

$$\int_{V^0} S_{hk}(t)\,\delta E_{hk}(t)\, dV^0 = W^0(t). \tag{4.27}$$

- The UL formulation refers the static and kinematic quantities to the configuration at time $t = t_0$, and the deformation is expressed as increment $\delta\Delta E_{hk}$ between t_0 and t:

$$\int_{V^t} S_{hk}(t)\delta\Delta E_{hk}\, dV^t = W^t(t).$$

Both formulations include all the effects of finite kinematics, that is, large displacements, large rotations, and large deformations, but the correctness of the approach depends on the adopted constitutive relations. The choice of the formulation is motivated by the computational efficiency.

The formulations are based on the consistent linearization of governing equations, stresses, and strains.

4.5.1 TL Formulation

The TL formulation of the virtual work equation is based on the following steps:

1. The stress $S_{hk}(t)$ is expressed in terms of the initial configuration variables at time $t = 0$:

$$S_{hk}(t) = \frac{\rho^0}{\rho} F_{ih}^{-1} \sigma_{ij}(t) F_{jk}^{-1}, \quad F_{ih}^{-1} = \frac{dX_i}{dx_h(t)}.$$

2. Also, the deformation $E_{hk}(t)$ is expressed as a function of the initial configuration variables at time $t = 0$:

$$E_{hk}(t) = \frac{1}{2}(u_{h,k}(t) + u_{k,h}(t) + u_{j,h}(t)u_{j,k}(t)), \quad u_h(t) = x_h(t) - X_h.$$

3. The stress is written as the sum of the value at the previous step and of an increment ΔS_{hk} referred to the initial configuration:

$$S_{hk}(t) = S_{hk}(t_0) + \Delta S_{hk}.$$

4. The displacement is written as the sum of the value at the previous step and of an increment Δu_h referred to the initial configuration:

$$u_h(t) = u_h(t_0) + \Delta u_h. \tag{4.28}$$

The consistent deformation is written as the sum of three contributions:

$$E_{hk}(t) = E_{hk}(t_0) + \Delta E_{hk} = E_{hk}(t_0) + \Delta e_{hk} + \Delta \eta_{hk}. \tag{4.29}$$

a. A known term (with null variation):

$$E_{hk}(t_0) = \frac{1}{2}(u_{h,k}(t_0) + u_{k,h}(t_0) + u_{j,h}(t_0)u_{j,k}(t_0)).$$

b. A term linear in the increment $\Delta u_{h,k}$ (accounts for the initial displacement):

$$\Delta e_{hk} = \frac{1}{2}(\Delta u_{h,k} + \Delta u_{k,h} + \Delta u_{j,h}u_{j,k}(t_0) + u_{j,h}(t_0)\Delta u_{j,k}).$$

c. A term quadratic in the increment $\Delta u_{h,k}$:

$$\Delta \eta_{hk} = \frac{1}{2}\Delta u_{j,h}\,\Delta u_{j,k}.$$

5. The variation of the deformation (4.29) is inserted in the virtual work equation:

$$\delta E_{hk} = \delta \Delta E_{hk} = \delta \Delta e_{hk} + \delta \Delta \eta_{hk},$$

Obtaining

$$\int_{V^0} \Delta S_{hk} \delta \Delta E_{hk} \, dV^0 + \int_{V^0} S_{hk}(t_0) \delta \Delta \eta_{hk} \, dV^0 = W^0(t) - \int_{V^0} S_{hk}(t_0) \delta \Delta e_{hk} \, dV^0. \tag{4.30}$$

The left side of 4.30 is strongly nonlinear in the displacement increments. The right side of 4.30 contains all the known terms, the integral being known when the current displacement is known.

6. The second integral in the right side is a linear function of $\Delta u_{h,k}$ and does not need changes. The first integral instead is linearized by Taylor's expansion of the stress S_{hk} and by using 4.29:

$$\Delta S_{hk} \approx \left. \frac{\partial S_{hk}}{\partial E_{ij}} \right|_t \Delta E_{ij} = C^t_{hkij} (\Delta e_{ij} + \Delta \eta_{ij}).$$

The material tangent stiffness C^t_{hkij} at time t is referred to the configuration at time t_0. Finally, the increment of the deformation is linearized:

$$\Delta E_{ij} \approx \Delta e_{ij}.$$

At this point, the first integral in 4.30 is a linear function of the displacement increment $\Delta u_{h,k}$. This gives the virtual work equation in the TL formulation:

$$\int_{V^0} C^t_{hkij} \Delta e_{ij} \delta \Delta e_{hk} \, dV^0 + \int_{V^0} S_{hk}(t_0) \delta \Delta \eta_{hk} \, dV^0 = W^0(t) - \int_{V^0} S_{hk}(t_0) \delta \Delta e_{hk} \, dV^0. \tag{4.31}$$

4.5.2 UL Formulation

The UL formulation of the virtual work theorem is based on the following steps:

1. The stress $S_{hk}(t)$ is expressed as function of the configuration variables at the reference time t_0:

$$S_{hk}(t) = \frac{\rho^{t_0}}{\rho} F^{-1}_{ih} \sigma_{ij}(t) F^{-1}_{jk}, \quad F^{-1}_{ih} = \frac{dx_i(t_0)}{dx_h(t)}.$$

2. Since the deformation is referred to the previous step, its value coincides with the increment of the deformation ΔE_{hk}. The deformation is expressed as a function of the displacement $u_h(t) = \Delta u_h$ referred to the previous step:

$$\Delta E_{hk} = \frac{1}{2}(\Delta u_{h,k} + \Delta u_{k,h} + \Delta u_{j,h}\Delta u_{j,k}), \quad \Delta u_h = u_h(t) - u_h(t_0).$$

3. The stress is decomposed into the sum of two terms. The first is the stress at the end of the previous step, referred to the previous step itself. It corresponds to the Cauchy stress σ_{hk} at the previous time. The second term is the increment from the previous time step:

$$S_{hk}(t) = \sigma_{hk}(t_0) + \Delta S_{hk}.$$

4. Following the same decomposition as in TL, the strain is expressed now as the sum of two contributions:

$$\Delta E_{hk} = \Delta e_{hk} + \Delta \eta_{hk}. \tag{4.32}$$

   a. A term linear in the displacement increment $\Delta u_{h,k}$:

$$\Delta e_{hk} = \frac{1}{2}(\Delta u_{h,k} + \Delta u_{k,h}).$$

   b. A term quadratic in the displacement increment $\Delta u_{j,h}$:

$$\Delta \eta_{hk} = \frac{1}{2}\Delta u_{j,h}\,\Delta u_{j,k}.$$

5. The virtual work equation is written in terms of variation of the incremental strain:

$$\int_{V^t} \Delta S_{hk}\delta\Delta E_{hk}\, dV^t + \int_{V^t} \sigma_{hk}(t_0)\,\delta\Delta\eta_{hk}\, dV^t = W^t(t) - \int_{V^t} \sigma_{hk}(t_0)\,\delta\Delta e_{hk}\, dV^t. \tag{4.33}$$

   The left side of 4.33 is strongly nonlinear in the displacement increment. The right-hand side contains all the known terms, since the integral is known when the displacement is known.

6. By linearizing the constitutive relations, the incremental stress is written as $\Delta S_{hk} = C^t_{hkij}\Delta e_{ij}$ (where the material tangent stiffness C^t_{hkij} at time t is referred to the configuration at time t) and the strains are written as $\delta\Delta E_{hk} = \delta\Delta e_{hk}$. The virtual work equation in the UL formulation is

$$\int_{V^t} C^t_{hkij}\Delta e_{ij}\,\delta\Delta e_{hk}\, dV^t + \int_{V^t} \sigma_{hk}(t_0)\,\delta\Delta\eta_{hk}\, dV^t = W^t(t) - \int_{V^t} \sigma_{hk}(t_0)\,\delta\Delta e_{hk}\, dV^t. \tag{4.34}$$

The formulations 4.31 and 4.34 are very similar. The only difference is conceptual and is the choice of the reference system, where the static and kinematics variables are expressed. The results obtained from the two formulations have to be identical, if the correct stress and strain measures are used. The choice of TL or UL is matter of computational efficiency. In general, the TL formulation provides a more complex stiffness matrix, due to the presence of an initial displacement.

Note that in the case that the nonlinearities can be confined to the material (i.e., small displacements), a less demanding approach can be followed. The virtual work equation can be written in the undeformed configuration (neglecting the geometry changes) and the strain accounts only for the linear components. In that case, TL and UL reduce to the same expression:

$$\int_V C_{hkij}^{t(k-1)} \Delta e_{ij}^{(k)} \delta \Delta e_{hk} \, dV = W(t) - \int_V \sigma_{hk}^{(k-1)} \delta \Delta e_{hk} \, dV.$$

In particular, for a linear elastic material it coincides with the classic virtual work theorem.

In conclusion, Equations 4.31 and 4.34 are used for the computation of the incremental displacements at time t. The total displacements are approximated through 4.28; strains are evaluated through 4.29 or 4.32, and stresses through the constitutive equations, described in the next section.

4.6 CONSTITUTIVE LAWS

For finite displacement formulations, it is necessary to use the proper constitutive relationships. If the finite deformation behavior is described through a TL approach, the constitutive law has to be expressed in terms of finite strains.

Table 4.2 summarizes the different models of behavior to be used in finite deformations. The internal variables q_h are scalar, vector, or tensor variables that have to be introduced in the constitutive behavior of nonlinear materials to keep track of the loading history.

The nonlinear analysis is conducted in incremental form, and direct approaches are excluded. At each time increment Δt, a nonlinear analysis requires the iteration of a sequence of steps, until the convergence test is satisfied. Clearly, the solution at the end of the previous step, that is, $S_{ij}(t_0)$, $E_{ij}(t_0)$, and $q_h(t_0)$, is known:

1. From the known nodal displacements $\boldsymbol{U}(t)^{(k-1)}$, the corresponding strains $\boldsymbol{E}(t)^{(k-1)}$ are computed.
2. Compute in sequence:

TABLE 4.2
Models of Material Behaviors

Material Model	Features	Materials
Linear elastic	$\sigma_{ij} = C_{ijhk}\varepsilon_{hk}$	Steel, $\sigma_{ij} < \sigma_y$
Nonlinear elastic	$\sigma_{ij} = C_{ijhk}(\varepsilon_{hk})\varepsilon_{hk}$	Aluminum
Hyper-elastic	$S_{ij} = \partial W/\partial E_{ij}$	Rubber
Hypo-elastic	$d\sigma_{ij} = C_{ijhk} d\epsilon_{hk}$	Concrete
Elastoplastic	$dS_{ij} = C_{ijhk}^{t}(E_{hk}, q_h) dE_{hk}$	Steel, $\sigma_{ij} \leq \sigma_y$
Creep	$S_{ij} = C_{ijhk}(E_{hk}, t)E_{hk}$	High-temperature metals
Visco-plastic	$dS_{ij} = C_{ijhk}(E_{hk}, \dot{E}_{hk}, q_h) dE_{hk}$	Polymers

- The stresses $\boldsymbol{S}(t)^{(k-1)}$. In elastic analysis, the stresses are computed directly from the strains $\boldsymbol{E}(t)^{(k-1)}$, at the end of the iteration $(k-1)$. In inelastic analysis, strains are computed from the integration of the equation:

$$\boldsymbol{S}(t)^{(k-1)} = \boldsymbol{S}(t_0) + \int_{t_0}^{t^{(k-1)}} d\boldsymbol{S}. \tag{4.35}$$

- The tangent stiffness of the material $\boldsymbol{C}^{(k-1)}$. In elastic analysis, it is obtained directly from the strains $\boldsymbol{E}(t)^{(k-1)}$, at the end of the iteration $(k-1)$. In inelastic analysis, the stiffness matrix refers to the state t, at the end of the iteration $(k-1)$. It has to be computed consistently to the integration process (4.35). If isoparametric finite elements are used, strains and stresses have to be computed in all the integration points of the mesh, in order to define the equations used in step 3.
- The internal variables $\boldsymbol{q}(t)^{(k-1)}$ (only for inelastic analyses).

3. The stresses and the material stiffness matrix are numerically integrated over each elements, building the local nodal force array $\boldsymbol{F}^{\text{int}}(t)^{(k-1)}$ and the local element stiffness matrix $\boldsymbol{K}(t)^{(k-1)}$.
4. The increments of the nodal displacements $\Delta\boldsymbol{U}^{(k)}$ at the (k) iteration are computed as

$$\boldsymbol{K}(t)^{(k-1)}\Delta\boldsymbol{U}^{k} = \boldsymbol{R}(t) - \boldsymbol{F}^{\text{int}}(t)^{(k-1)}$$

$$\boldsymbol{U}(t)^{k} = \boldsymbol{U}(t)^{(k-1)} + \Delta\boldsymbol{U}^{k}.$$

Steps 1 to 4 are repeated to convergence.

The procedure works if all the variables (strains, stresses, and internal variables) at the end of the previous iteration are known. The variables have to be updated at all the integration points and at each iteration; therefore, it is incumbent to adopt the most efficient computational procedure.

The main difference between a nonlinear elastic analysis and an inelastic analysis is that in the former the total variables can be used, and an incremental formulation is not necessary.

4.6.1 Linear Elastic Behavior

Although not realistic, the simplest material model in finite deformations is the Hooke law. In a TL approach, it reads

$$S_{ij} = C_{ijhk}E_{hk}, \tag{4.36}$$

where, with respect to the linear approach, the Green–Lagrange strain tensor $\boldsymbol{E}$ replaces the small strain tensor $\boldsymbol{\varepsilon}$ and the second Piola–Kirchhoff stress tensor $\boldsymbol{S}$ replaces the Cauchy stress tensor $\boldsymbol{\sigma}$. Formally, 4.36 coincides with 4.1 except for the stress and strain measures.

In a large displacements, large rotations, and small strain formulation, relation 4.36 is a natural material (Lagrangian) description. In fact, the components of the Green–Lagrange strain tensor $\boldsymbol{E}$ and the second Piola–Kirchhoff stress tensor $\boldsymbol{S}$ measured in a fixed reference system do not change when the body undergoes rigid rotations and translations. Therefore, only stretches induce stress increments.

The earlier remark is important not only for the linear elastic behavior. In fact, any constitutive law developed in the material description for small displacement analysis (i.e., expressed in terms of small strain tensor $\boldsymbol{\varepsilon}$ and the Cauchy stress tensor $\boldsymbol{\sigma}$) can be used directly for large displacement,

large rotations, and small strains analyses, if the Green–Lagrange strain tensor $\boldsymbol{E}$ replaces $\boldsymbol{\varepsilon}$ and the second Piola–Kirchhoff stress tensor $\boldsymbol{S}$ replaces $\boldsymbol{\sigma}$.

Such consideration is of great practical interest, since many engineering problems imply large displacements and large rotations but can be treated in small strains. This is, for example, the case of buckling in slender beams and thin shells.

In order to use 4.36 in the UL formulation, the virtual work equation (4.27) has to be written as

$$\int_{V^0} C_{ijhk}(t_0)E_{hk}(t_0)\delta E_{ij}(t_0)\,dV^0 = W^0(t_0). \tag{4.37}$$

A new constitutive tensor, C_{mnrs}, referred to the current configuration, is then introduced:

$$C_{mnrs} = \frac{\rho(t_0)}{\rho^0} F_{mi}F_{nj}C_{ijhk}(t_0)F_{rh}F_{sk}, \quad C_{ijhk}(t_0) = \frac{\rho^0}{\rho(t_0)} F_{im}^{-1}F_{jn}^{-1}C_{mnrs}F_{hr}^{-1}F_{ks}^{-1}. \tag{4.38}$$

It is easy to prove that the variation of the small strain tensor in the current configuration is expressed as [1]:

$$\delta\varepsilon_{mn} = F_{im}^{-1}F_{jn}^{-1}\delta E_{ij}. \tag{4.39}$$

Replacing 4.38 and 4.39 in 4.37, and converting the integral over the initial volume into the integral over the current volume, one obtains

$$\int_{V^t} C_{mnrs}A_{rs}\delta\varepsilon_{mn}(t_0)\,dV^t = W(t_0),$$

where A_{rs} denotes the components of the Almansi strain tensor and

$$\sigma_{mn} = C_{mnrs}A_{rs} \tag{4.40}$$

is the Hooke law written in the UL approach. Practically, the same result can be obtained by transforming $\boldsymbol{S}$ in $\boldsymbol{\sigma}$, and using the relation (4.9). This avoids the calculation of C_{mnrs} and is computationally more efficient.

The equivalence between TL and UL formulations holds for any stress level, although the Hooke law is rigorously valid only in the small strain range.

It is important to observe that if the same constants are used to define 4.36 in TL and 4.40 in UL, no relevant differences in the results are observed for small strains. If the strains are large, instead, the two approaches give quite different results. But, if Equation 4.38 is used to switch from the material constants of one formulation to the material constants of the other formulation, the same response is obtained.

4.6.2 Nonlinear Elastic Behavior

Materials exhibiting large strains in their standard applications (see, e.g., rubber) and a nonlinear reversible behavior (hyper-elastic) can be characterized by a strain energy density function W such that

$$S_{ij} = \frac{\partial W}{\partial E_{ij}}, \quad C_{ijhk} = \frac{\partial^2 W}{\partial E_{ij}\partial E_{hk}}.$$

If the material is isotropic, W can be expressed as a function of the eigenvalues of $\boldsymbol{C}$, λ_i^2, or, alternatively, of the $\boldsymbol{C}$'s invariants I_1, I_2, and I_3 [5,6]:

$$I_1 = \lambda_1^2 + \lambda_2^2 + \lambda_3^2, \quad I_2 = \lambda_1^2\lambda_2^2 + \lambda_2^2\lambda_3^2 + \lambda_3^2\lambda_1^2, \quad I_3 = \lambda_1^2\lambda_2^2\lambda_3^2 = J^2.$$

Thus, an isotropic material strain energy function can be written as

$$W = W(\lambda_1^2, \lambda_2^2, \lambda_3^2) = W(I_1, I_2, I_3).$$

Assuming that W is continuum, smooth, and differentiable, it can be expressed through a power series:

$$W(I_1, I_2, I_3) = \sum_{p,q,r=0}^{\infty} c_{pqr}(I_1 - 3)^p (I_2 - 3)^q (I_3 - 1)^r, \tag{4.41}$$

where the coefficients c_{pqr} are independent of the strains. In particular, the condition $W = 0$ in the undeformed configuration implies that $c_{000} = 0$ and $c_{100} + 2c_{010} + c_{001} = 0$.

A special class of materials is obtained by excluding the dependence on the invariant I_2:

$$W(I_1, I_3) = c_1(I_1 - 3) + g(I_3).$$

The class of materials is known as neo-Hookean extended to the compressible range. An example of strain energy density with a particularly satisfying choice of $g(I_3)$ is

$$W(I_1) = \frac{1}{2}\mu(I_1 - 3 - 2\log J) + \frac{1}{2}K(J-1)^2,$$

where K is a coefficient related to the bulk modulus of the material.

4.6.2.1 Incompressible Materials

Rubberlike materials exhibit a quasi-incompressible behavior [5,6]. The incompressibility constraint (no volume change) is expressed by the condition:

$$I_3 = \lambda_1^2\lambda_2^2\lambda_3^2 = 1, \quad \lambda_3^2 = \lambda_1^{-2}\lambda_2^{-2}.$$

For such materials, Equation 4.41 can be written as

$$W(I_1, I_2) = \sum_{p,q=0}^{\infty} c_{pq}(I_1 - 3)^p (I_2 - 3)^q.$$

Among the most diffused material models for rubber, it is worth to mention the following:

- Mooney–Rivlin model:

$$W(I_1, I_2) = \frac{1}{2}\mu_1(I_1 - 3) - \frac{1}{2}\mu_2(I_2 - 3), \quad \mu = \mu_1 - \mu_2,$$

also written as

$$W(\lambda_1^2, \lambda_2^2) = \frac{1}{2}\mu_1(\lambda_1^2 + \lambda_2^2 + \lambda_1^{-2}\lambda_2^{-2} - 3) - \frac{1}{2}\mu_2(\lambda_1^{-2} + \lambda_2^{-2} + \lambda_1^2\lambda_2^2 - 3),$$

where μ is the shear elastic modulus G and $E = 6(\mu_1 + \mu_2)$.

- Neo-Hookean model:

$$W(I_1) = \frac{1}{2}\mu(I_1 - 3),$$

also written as

$$W(\lambda_1^2, \lambda_2^2) = \frac{1}{2}\mu(\lambda_1^2 + \lambda_2^2 + \lambda_1^{-2}\lambda_2^{-2} - 3).$$

- Odgen model:

$$W(\lambda_1, \lambda_2) = \sum_{n=1}^{3} \frac{\mu_n}{\alpha_n}(\lambda_1^{\alpha_n} + \lambda_2^{\alpha_n} + \lambda_1^{-\alpha_n}\lambda_2^{-\alpha_n} - 3),$$

where μ_n and α_n are material constants, and the following relation holds

$$2\mu = \sum_{n=1}^{3} \alpha_n \mu_n.$$

A comparison between the material response and an uniaxial loading for different rubber material model is reported in Figure 4.11.

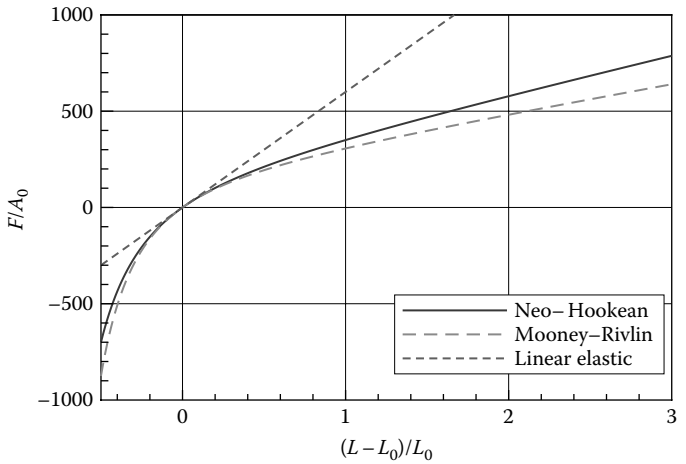

FIGURE 4.11 Uniaxial response of a rubber, compared to the linear response of the Hooke law.

The use of incompressible material models introduces numerical complications. Such phenomena are known as volumetric locking. To avoid the difficulties linked to such formulations, mixed approaches are used. Mixed approaches discretize as primary variables both the displacement field and a static field, for example, the isotropic pressure [1].

4.6.3 Inelastic Behavior

A material behavior is said inelastic when the value of the stress does not depend only on the strain but also on the loading history. Examples of inelastic behaviors are elastoplasticity, creep, viscoplasticity. The dependence on the loading history requires the adoption of an incremental analysis able to follow the loading history.

As already mentioned, there are three possible kinematic formulations:

- SD-SR-SS, small displacements and rotations, and small strains. A MN formulation is used, where the nonlinearities are related only to the material behavior.
- LD-LR-SS, large displacements and rotations, and small strains. The TL formulation, which can be used also for large strain problems, is employed successfully. If small strains are assumed, the same material model developed for MN formulations can be used, by simply replacing the strain and stress engineering measures with Green–Lagrange and second Piola–Kirchhoff tensors, respectively.
- LD-LR-LS, large displacements and large deformations. The TL formulation or the UL formulation can be used without substantial difference. It is important to observe that in this case the constitutive equations are more complicated, and numerous operative difficulties are encountered.

Since the first two kinematic formulations adopt the same constitutive relationships, in the following, only the MN formulation is discussed. The large strain for the TL formulations is discussed next.

The complete and accurate solution, in terms of displacements, strains, stresses, and internal variables, has been obtained at time t. All the iterative schemes are based on two subsequent steps:

1. Computation of the tangent stiffness of the material at time t, written as

$$C^t_{ijhk} = \left.\frac{\partial \sigma_{ij}}{\partial \varepsilon_{hk}}\right|_t . \tag{4.42}$$

   The tangent stiffness of the material is used in the evaluation of the global tangent stiffness matrix of the system. If the calculation of the tangent stiffness is not accurate, the displacement increments obtained in the iteration are not accurate, and the convergence rate of the algorithm is reduced.
2. Computation of stresses, inelastic strains, internal variables at time t. If the calculation of stresses is not accurate, the numeric error, in general, cannot be recovered in the next iterations. In practice, any error introduced in the evaluation of $\sigma_{ij}(t)$, or inelastic strains, or internal variables, contributes to spoil the accuracy of the method. Therefore, it compromises the ability of the algorithm to predict the mechanical response of the system.

   During the equilibrium iteration, the tangent stiffness and the stresses have to be computed in a consistent way at the current stress state. Consistency, formally expressed by Equation 4.42, defines the tangent stiffness as the partial derivative of the stresses with respect to the strains. Partial differentiation requires to consider all the dependencies, explicit and implicit, on the strains. The consistency concept is very important for the efficiency of the numerical approaches, and it will be recalled later.

4.6.3.1 Small Strain Elastoplasticity (von Mises)

Elastoplasticity theories in small strains, for example, Prandtl–Reuss equations [2,7], are based on the assumption of the additive decomposition of the incremental strains into en elastic $d\varepsilon_{ij}^{e}$ part and a plastic $d\varepsilon_{ij}^{p}$ part:

$$d\varepsilon_{ij} = d\varepsilon_{ij}^{e} + d\varepsilon_{ij}^{p}.$$

Only the elastic part of the strains contributes to the stresses through the elasticity tensor C_{ijhk}^{e}:

$$d\sigma_{ij} = C_{ijhk}^{e}(d\varepsilon_{ij} - d\varepsilon_{ij}^{p}). \tag{4.43}$$

The incremental total strains in general are known data of the problem. To compute the irreversible or inelastic part of the strains, the material model has to be completed with the inelastic constitutive relations:

1. A plasticity stress-dependent function, to define the combination of multiaxial stress states leading to the development of plastic strains. The plasticity function is written as

$$f_y(\sigma_{ij}, \varepsilon_{ij}^{p}, q_\alpha) \le 0.$$

   The material response is assumed to be elastic if $f_y < 0$. The response is either elastic or plastic, according to the sign of the incremental strains, if $f_y = 0$. The latter condition is called plasticity condition, and identifies the states where plastic strains can develop.
2. A flow rule, to define the increment of the plastic strains, function of the stresses and of the stress increments. The flow rule describes the evolution of the plastic strains. The material may exhibit an associate plastic behavior. In this case, the plastic strains are directed as the gradient of f_y, that is, they are parallel to the normal to the plasticity function. An associate plastic flow rule reads

$$d\varepsilon_{ij}^{p} = \frac{\partial f_y(\sigma_{ij}, \varepsilon_{ij}^{p})}{\partial \sigma_{ij}}\lambda,$$

   where λ is a scalar that measures the plastic strain magnitude.
3. A hardening or softening rule, to describe the evolution of the plasticity function with the plastic strains or with more general inelastic phenomena (e.g., fracture, damage, etc.). The hardening/softening rule modifies the value of the internal variables q_α used in f_y and the plasticity condition.

   In the standard von Mises plasticity, the volumetric plastic deformations are zero. In order to exploit this feature, it is convenient to split the elastic constitutive relation (4.43) into deviatoric and volumetric parts:

$$\boldsymbol{s}(t) = 2\mu[\boldsymbol{e}(t) - \boldsymbol{e}^{p}(t)], \quad \mu = \frac{E}{2(1+\nu)}, \tag{4.44}$$

$$\sigma_m(t) = 3K\varepsilon_m(t), \quad K = \frac{E}{3(1-2\nu)}, \tag{4.45}$$

   where
   $\boldsymbol{s}$ is the deviatoric stress
   σ_m is the mean stress (or isotropic pressure):

$$s_{ij} = \sigma_{ij} - \sigma_m \delta_{ij}, \quad \sigma_m = \frac{\sigma_{kk}}{3},$$

$\boldsymbol{e}$ is the deviatoric strain
ε_m is one third of the volumetric deformation:

$$e_{ij} = \varepsilon_{ij} - \varepsilon_m \delta_{ij}, \quad \varepsilon_m = \frac{\varepsilon_{kk}}{3}.$$

The deviatoric stress (4.44) is a function of the plastic strains, which in turn are dependent on the loading history. The mean stress is purely elastic. The only unknowns of the problem are the plastic strains $\boldsymbol{e}^p$ and the deviatoric stresses $\boldsymbol{s}$.

The total plastic strains can be written as the sum of a known term $\boldsymbol{e}^p(t_0)$ and of an unknown incremental term $\Delta\boldsymbol{e}^p$:

$$\boldsymbol{e}^p(t) = \boldsymbol{e}^p(t_0) + \Delta\boldsymbol{e}^p.$$

Thus, the elastic part of the deviatoric relationship is written as

$$\boldsymbol{s}(t) = 2\mu[\boldsymbol{e}''(t) - \Delta\boldsymbol{e}^p] \quad \boldsymbol{e}'' = \boldsymbol{e}(t) - \boldsymbol{e}^p(t_0). \tag{4.46}$$

Both $\Delta\boldsymbol{e}^p$ and $\boldsymbol{s}$ have to satisfy the plasticity condition, the flow rule, and the hardening rule. The von Mises plasticity function reads

$$f_y^M(t) = \frac{1}{2}\boldsymbol{s}(t)\cdot\boldsymbol{s}(t) - \frac{1}{3}\sigma_y^2(t), \tag{4.47}$$

where
$\boldsymbol{s}(t)\cdot\boldsymbol{s}(t) = s_{ij}s_{ij}$
$\sigma_y(t)$ is the current yield stress, function of the hardening of the material:

$$\sigma_y(t) = g(\bar{e}^p), \quad \bar{e}^p = \int_0^t \sqrt{\frac{2}{3} d\boldsymbol{e}^p \cdot d\boldsymbol{e}^p}\, dt.$$

During the evolution of the plastic strains, the stresses have to satisfy the plasticity condition $f_y^M = 0$ (see Figure 4.12). The associated flow rule states that the increment of the plastic strains has to be parallel to the final deviatoric stresses $\boldsymbol{s}(t)$, while the volumetric plastic strains are zero:

$$\Delta\boldsymbol{e}^p = \lambda \frac{\partial f_y^M(t)}{\partial\sigma} = \lambda\boldsymbol{s}(t). \tag{4.48}$$

The plastic multiplier λ is obtained by taking the tensor product of both the sides of 4.48:

$$\Delta\bar{e}^p = \frac{2}{3}\lambda\bar{\sigma}(t), \quad \Delta\bar{e}^p = \sqrt{\frac{2}{3}\Delta\boldsymbol{e}^p\cdot\Delta\boldsymbol{e}^p}, \quad \bar{\sigma}(t) = \sqrt{\frac{3}{2}\boldsymbol{s}\cdot\boldsymbol{s}}. \tag{4.49}$$

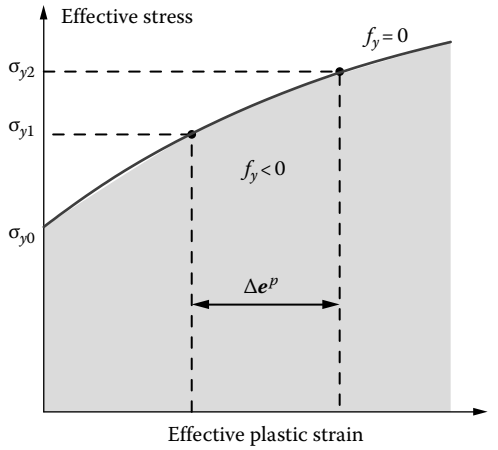

FIGURE 4.12 Generic plasticity function. The plastic strains can increase, but they appear only if $f_y = \sigma - \sigma_y = 0$. The material response has to satisfy the conditions $f_y \le 0$, $\varepsilon^p \ge 0$, $f_y \varepsilon^p = 0$.

Replacing 4.48 in 4.46 also shows that $\boldsymbol{e}''$ is oriented as $\boldsymbol{s}$:

$$\boldsymbol{s}(t) = \frac{2\mu}{1+2\mu\lambda}\boldsymbol{e}''(t). \tag{4.50}$$

The plastic multiplier λ is computed from 4.50 by using the tensor product:

$$a^2\bar{\sigma}^2(t) - d^2 = 0, \quad a = \frac{1}{2\mu} + \lambda, \quad d^2 = \frac{3}{2}\boldsymbol{e}''(t)\cdot\boldsymbol{e}''(t). \tag{4.51}$$

In general, the coefficient a in $(4.51)_1$ is a function of λ and of $\boldsymbol{s}$. Equation 4.51_1 can be written as

$$f(\bar{\sigma}^*) = a^2(\bar{\sigma}^*) - d^2 = 0 \tag{4.52}$$

and can be called effective stress function. When $f(\bar{\sigma}^*) = 0$, the effective stress $\bar{\sigma}^*$ coincides with $\bar{\sigma}(t)$. The evaluation of the final stress is reduced to the calculation of the solution of a scalar function, easily obtained with standard numerical approaches. This technique is very appealing especially for complex constitutive laws, including thermal or viscous effects. In fact, a simple bisection procedure may be used to solve the problem. For a bilinear material (see Figure 4.13a),

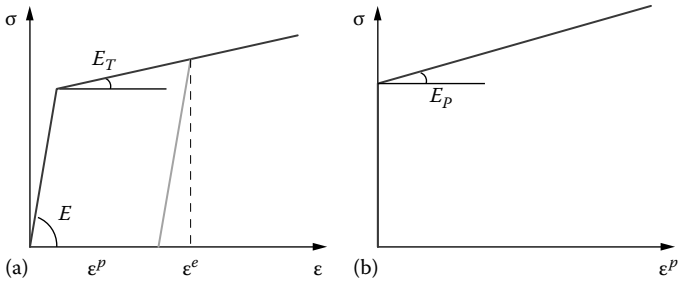

FIGURE 4.13 Bilinear elastoplastic material model. (a) Uniaxial constitutive law. (b) Rigid-plastic relationship.

Equation 4.52 becomes a linear relation, represented by the straight line of the rigid-plastic relationship $\bar{\sigma} - \bar{\varepsilon}^p$ in Figure 4.13b:

$$\Delta \bar{e}^{\,p} = \frac{\bar{\sigma}(t) - \sigma_y}{E_p}, \tag{4.53}$$

where E_P denotes the slope of the elastoplastic law:

$$E_P = \frac{EE_T}{E - E_T}$$

and E_T is the tangent modulus. From 4.53 and 4.49, one obtains

$$\bar{\sigma}(t) = \frac{2E_P d + 3\sigma_y}{E_P/\mu + 3}.$$

For simple plasticity, $E_P = 0$ and $\bar{\sigma}(t) = \sigma_y$, thus $(4.51)_1$ provides

$$\lambda = \frac{d}{\sigma_y} - \frac{1}{2\mu}.$$

The elastoplastic calculation is activated only when the material is in the condition to develop plastic strains in the time interval Δt. Therefore, the following preliminary condition has to be satisfied:

$$\bar{\sigma}^e = 2\mu\, d > \sigma_y(t_0).$$

In Figure 4.14, the solution algorithm known as elastic predictor-radial return is visualized in the deviatoric plane. The point A is the deviatoric stress at the beginning of the step, and it is assumed

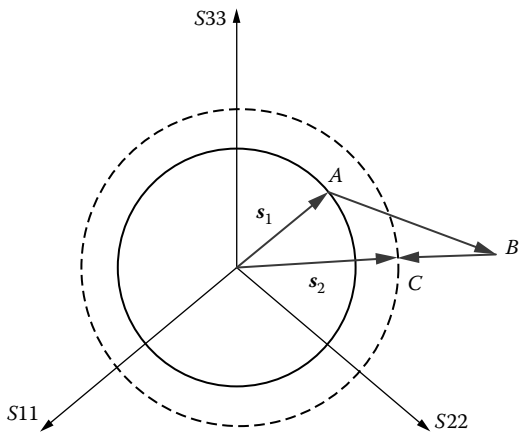

FIGURE 4.14 Geometric interpretation of the stress determination with the elastic predictor-radial return algorithm.

to lie on the plasticity surface. The position of A can be determined by sub-increments of the load step. The point B is the elastic predictor stress:

$$\boldsymbol{s}^{e}(t) = 2\mu \boldsymbol{e}''(t).$$

The corrector stress is represented by the vector CB and it is given by

$$\boldsymbol{s}^{C}(t) = 2\mu(-\Delta \boldsymbol{e}^{p}).$$

The final stress is the vector sum of the prediction stress and the corrector stress:

$$\boldsymbol{s}(t) = \boldsymbol{s}_{E}(t) + \boldsymbol{s}^{C}(t).$$

The final stress lies on the plasticity surface, hardened for the action of the plastic strains. Figure 4.14 shows that the prediction stress and the final stress are aligned in the direction of the normal to the plasticity surface $\boldsymbol{n}(t)$. This justifies the name of radial return. The plastic strain $\Delta \boldsymbol{e}^{p}$ can be written as

$$\Delta \boldsymbol{e}^{p} = \sqrt{\frac{3}{2}}\, \Delta e^{p} \boldsymbol{n}(t). \tag{4.54}$$

The interpretation of the solution algorithm gives some indication on the error of the method. The plasticity surface and the hardening rule are satisfied exactly, obviously at discrete times. Approximation is introduced only during the integration of the flow rule, where the plastic strains are estimated with a backward difference algorithm. The method is correct if the direction of the deviatoric stress $\boldsymbol{s}$ does not change during the loading step. If the normal direction $\boldsymbol{n}$ changes, though, the procedure introduces a numerical error.

One of the more restrictive requirements for the efficiency of the method is the accuracy in the calculation of the tangent stiffness matrix. To guarantee the maximum convergence rate of the Newton–Raphson algorithm, the tangent stiffness has to be consistent with the numerical scheme used to compute the stresses. This means that in terms of total stresses and strains

$$\boldsymbol{C}^{EP} = \left.\frac{\partial \boldsymbol{\sigma}}{\partial \boldsymbol{\varepsilon}}\right|_{t}, \tag{4.55}$$

that is, the stiffness matrix is the derivative of the stresses with respect to the strains. To include all the variables involved in the problem, the calculation of 4.55 must be done with the chain rule. For the bilinear elastoplastic law, the response depends only on the effective stress, and the chain rule imposes

$$\boldsymbol{C}^{EP} = \frac{\partial \boldsymbol{\sigma}(t)}{\partial \bar{\sigma}(t)} \frac{\partial \bar{\sigma}(t)}{\partial \boldsymbol{\varepsilon}(t)}.$$

All the differentiations have to be done in an accurate way. The final expression of the tangent stiffness matrix may result very complicated.

The previous algorithm refers to isotropic hardening, but it can be easily extended to the case of kinematic hardening, or mixed hardening, or to alternative constitutive laws (e.g., Drucker–Prager).

In such cases, more than one internal variable can be present and the consistent tangent calculation becomes more difficult.

4.6.3.2 Thermo-Elastoplasticity and Creep

The algorithm based on the effective stress function may be easily modified in order to include thermal and viscous effects, such as creep and relaxation. Temperature changes induce inelastic volumetric strains and may alter the mechanical properties of the materials.

A material model where the thermal effects modify the elastic properties, but do not modify the plastic behavior of the material, is described in the following by way of example. The material obeys isotropic hardening and von Mises plasticity condition.

The presence of creep may induce additional inelastic time-dependent strains. Following [1], Equations 4.44 and 4.45 are generalized as

$$\boldsymbol{s}(t) = 2\mu(t)[\boldsymbol{e}(t) - \boldsymbol{e}^{p}(t) - \boldsymbol{e}^{C}(t)],$$

$$\sigma_m(t) = 3K(t)[\varepsilon_m(t) - \varepsilon^{TH}(t)], \quad \varepsilon^{TH} = \alpha_m(t)[\theta(t) - \theta_{ref}],$$

where

ε^{TH} is the thermal volumetric strain

$\boldsymbol{e}^{C}$ is the deviatoric strain due to creep

The elastic constants G and K are functions of the temperature θ. Assuming that temperature is assigned during the loading history, the dependency on the temperature can be expressed as dependency on time. Thus, Equation 4.46 is written as

$$\boldsymbol{s}(t) = 2\mu(t)[\boldsymbol{e}''(t) - \Delta\boldsymbol{e}^{p} - \Delta\boldsymbol{e}^{C}].$$

All the known stresses are contained in $\boldsymbol{e}''(t)$. The incremental plastic strains $\Delta\boldsymbol{e}^{p}$ are computed as in the previous case, with the difference that $(4.51)_1$ is a function of the temperature. Two different procedures can be followed.

4.6.3.2.1 Time Hardening Procedure

The creep strains $\Delta\boldsymbol{e}^{C}$ are computed with a relation similar to the one used for the plastic strains, but using a more general procedure:

$$\Delta\boldsymbol{e}^{C} = \gamma(\tau)\boldsymbol{s}(\tau)\Delta t, \quad \boldsymbol{s}(\tau) = (1-\alpha)\,\boldsymbol{s}(t_0) + \alpha\boldsymbol{s}(t),$$

where the parameter α is chosen in the interval 0–1. The time τ falls in the interval Δt, that is, $\tau = t_0 + \alpha\Delta t$. The function $\gamma(\tau)$ is given by

$$\gamma(\tau) = \frac{3}{2}\frac{\dot{\bar{e}}^{C}(\tau)}{\bar{\sigma}(\tau)}, \tag{4.56}$$

while the effective "weighted" stress is

$$\bar{\sigma}(\tau) = (1-\alpha)\,\bar{\sigma}(t_0) + \alpha\bar{\sigma}(t). \tag{4.57}$$

The scalar function (4.56) is based on the definition of a creep law that describes the creep strain evolutions as functions of time, stresses, and temperature. A general relation, which includes several creep laws is

$$\bar{e}^{C}(t) = f_1[\bar{\sigma}(t)]\, f_2(t)\, f_3[\theta(t)] \tag{4.58}$$

and its incremental expression—which satisfies the experimental evidence and corresponds to the differentiation of the sole function f_2 with respect to time—can be reduced to

$$\Delta\bar{e}^{C}(\tau) = \Delta t f_1[\bar{\sigma}(\tau)]\, \dot{f}_2(t)\, f_3[\theta(\tau)], \quad \theta(\tau) = (1-\alpha)\theta(t_0) + \alpha\theta(t). \tag{4.59}$$

Thus, Equation 4.56 is evaluated through the expressions (4.57) and (4.59). This approach is known as "time hardening procedure."

4.6.3.2.2 Strain Hardening Procedure

When the stress is variable, it is physically more significant to express the creep strains as a function of the effective creep strain $\bar{e}^{C}$ than as a function of the time τ. From 4.58 to 4.59 with $\Delta\bar{e}^{C} = 0$, the pseudo-time τ_p is computed. The pseudo-time is defined as so as the effective creep strains equal the current strains but at a different level of the effective stress:

$$\bar{e}^{C}(t) + f_1[\bar{\sigma}(\tau)]\, f_3[\bar{\theta}(\tau)][\alpha\Delta t\dot{f}_2(\tau_p) - f_2(\tau_p)] = 0. \tag{4.60}$$

In general, Equation 4.60 has to be solved numerically. Once τ_p is known, from 4.59 the strain increment is computed. The method is called "strain hardening procedure." The difference between the time hardening method and the strain hardening method is visualized in Figure 4.15. Under cycling load, it is incumbent to account for load reversals, which renders the model more complicated.

4.6.4 Large Strain Elastoplasticity

Several formulations have been introduced in order to extend the inelastic response to finite deformations. Among them, the proposals by Green and Naghdi [8,9], Lubliner [10], Lee [11,12], Simó and Ortiz [13,14], and Ortiz and coworkers [15–17] must be quoted. In the following, an example of large strain elastoplasticity, based on the Cauchy stress $\boldsymbol{\sigma}$ and logarithmic strains $\boldsymbol{\epsilon}$, is described.

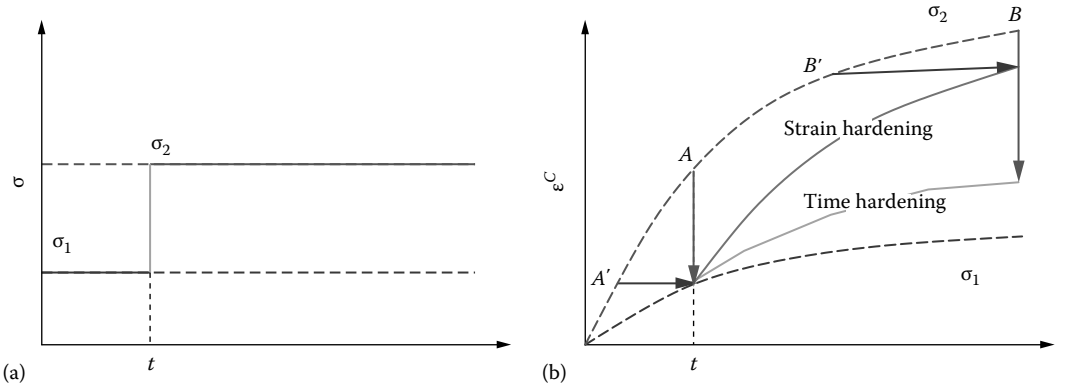

FIGURE 4.15 Creep strains in time hardening and strain hardening. (a) Stress history and (b) material response. After the stress increment in time hardening, the evolution of the creep strains follows the trend of the strains in the constant stress curve σ_2, and it is constant since the time t, curve AB. In strain hardening, the evolution of the creep strains follows the trend of the curves at constant stress σ_2 starting from the strain $\bar{e}^{C}$ at time t, curve $A'B'$.

The description of the formulation follows a few introductive remarks.

1. For any formulations, a few basic choices have to be done:
   a. The stress and strain measures (work conjugate)
   b. The characterization of the elastic behavior
   c. The flow rule
2. When the configuration changes are sufficiently small, the finite strain formulation must reduce to the infinitesimal strain formulations.
3. The previous nonlinear formulations (MN and LD-LR-SS) are expressed in terms of total stresses. This means that the equilibrium equations are written at time t and the strains are computed at time t. The numerical integration is used exclusively to compute the inelastic strain increment $\Delta\boldsymbol{\varepsilon}^p$ during the time interval Δt. The same approach can also be used in finite strain formulations, and it is especially suitable in UL formulation.
4. Alternative incremental formulations do exist. They are expressed in terms of stress rates (e.g., Jaumann tensor), strain rates, and rotation rates. All the incremental quantities (not only the inelastic strain increment) have to be integrated in the time interval Δt leading to bigger numerical errors. Thus, the accuracy of the solution is guaranteed only for small time steps. Some rate formulations bring to nonphysical mechanical responses. Recent works in the group of Bruhns and coworkers [18–20] show that incremental formulations are correct only when expressed in terms of logarithmic increments.
5. A natural approach, based on micromechanical observations of the plastic phenomena in finite strains, assumes a "hyperelastic" material description where the total deformation gradient is multiplicatively decomposed into an elastic and an inelastic part (Lee's decomposition) [11]. Such approach leads to a formulation in terms of total stresses, which can be seen as a natural extension of the small strain formulation.
6. The uniaxial constitutive law used to characterize the response is given by the uniaxial curve logarithmic strain ϵ–Cauchy stress $\boldsymbol{\sigma}$ (Figure 4.16). The plasticity condition, the flow rule, and the hardening rule have to be expressed always in terms of Cauchy stress $\boldsymbol{\sigma}$.

4.6.4.1 Governing Equations

The deformation gradient is decomposed in the product of two terms (Lee's decomposition):

$$\boldsymbol{F} = \boldsymbol{F}^e \boldsymbol{F}^p, \tag{4.61}$$

where

$\boldsymbol{F}^e$ represents the elastic part

$\boldsymbol{F}^p$ is the inelastic part

Relation (4.61) holds for any time of the deformation process.

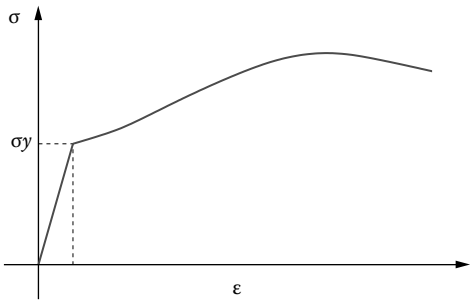

FIGURE 4.16 Uniaxial response example for elastoplasticity in finite strains.

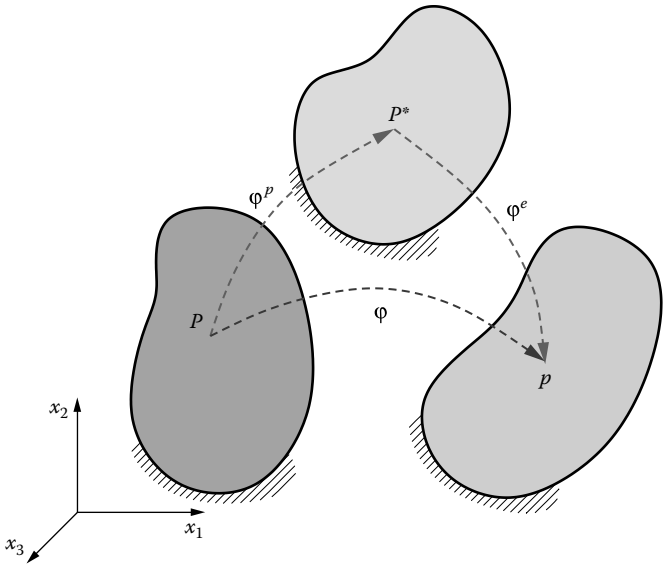

FIGURE 4.17 Multiplicative decomposition of the deformation gradient into an inelastic part $\boldsymbol{F}^p$ and into an elastic part $\boldsymbol{F}^e$.

It is convenient to think of 4.61 as two subsequent transformations (see Figure 4.17). The first transformation brings the initial configuration into a "relaxed" intermediate configuration, at the hypothetic time τ, where it is assumed that all the inelastic phenomena have already happened and the material is in a stress-free state. The fully inelastic deformation is described by the gradient $\boldsymbol{F}^p$. The second transformation, fully elastic, brings the material from the relaxed configuration to the final one. The deformation in the second step is measured by the gradient $\boldsymbol{F}^e$.

According to the experimental evidence, it makes sense to assume that the plastic deformations happen at constant volume. Therefore, the plastic Jacobian J^p can be assumed to be equal to the unit:

$$J^p = \det(\boldsymbol{F}^p) = 1, \quad J = \det(\boldsymbol{F}) = J^p J^e = \det(\boldsymbol{F}^e) = \frac{\rho}{\rho^0} > 0.$$

Equation 4.61 can be written as

$$\boldsymbol{F}^e = \boldsymbol{F}\,(\boldsymbol{F}^p)^{-1}.$$

The velocity gradient $\boldsymbol{L}$ decomposes into the sum of two terms:

$$\boldsymbol{L} = \dot{\boldsymbol{F}}(\boldsymbol{F})^{-1} = \dot{\boldsymbol{F}}^e(\boldsymbol{F}^e)^{-1} + \boldsymbol{F}^e\dot{\boldsymbol{F}}^p(\boldsymbol{F}^p)^{-1}(\boldsymbol{F}^e)^{-1} = \boldsymbol{L}^e + \boldsymbol{L}^p. \tag{4.62}$$

In order to characterize the response, it is necessary to know $\boldsymbol{F}$, $\boldsymbol{F}^p$, $\boldsymbol{\sigma}$, and the yield stress $\boldsymbol{\sigma}_y$. The Cauchy stress $\boldsymbol{\sigma}$ depends on the evolutive law of the plastic strains (or plastic deformation gradient $\boldsymbol{F}^p$) and on the hardening rule, from where σ_y is evaluated.

4.6.4.1.1 Conjugate Strain and Stress Measures

The elastic part of the deformation gradient admits the polar decomposition:

$$\boldsymbol{F}^e = \boldsymbol{R}^e \boldsymbol{U}^e, \quad \boldsymbol{C}^e = \boldsymbol{F}^{eT} \boldsymbol{F}^e = (\boldsymbol{U}^e)^2 \tag{4.63}$$

and it is spontaneous to introduce the logarithmic elastic strains (Hencky tensor) $\boldsymbol{\epsilon}^e$:

$$\boldsymbol{\epsilon}^e = \log(\boldsymbol{U}^e) = \frac{1}{2} \log \boldsymbol{C}^e.$$

The logarithmic strains refer to an intermediate configuration and $(4.63)_1$ defines the rigid rotation $\boldsymbol{R}^e$. A stress measure $\bar{\boldsymbol{\sigma}}$ corresponding to such configuration is defined as

$$\bar{\sigma} = J \boldsymbol{R}^{eT} \sigma \boldsymbol{R}^e.$$

The two stress and strain measures are conjugate, that is, their power equals to the power of $\boldsymbol{\sigma}$ and $\boldsymbol{D}^e$:

$$\bar{\sigma} \cdot \boldsymbol{\epsilon}^e = J \sigma \cdot \boldsymbol{D}^e, \quad \boldsymbol{D}^e = \frac{1}{2} (\boldsymbol{L}^e + \boldsymbol{L}^{eT}).$$

The corresponding plastic velocity gradient $\bar{\boldsymbol{L}}^p$ is obtained from 4.62:

$$\bar{\boldsymbol{L}}^p = (\boldsymbol{F}^e)^{-1} \boldsymbol{L}^p \boldsymbol{F}^e = \dot{\boldsymbol{F}}^p (\boldsymbol{F}^p)^{-1}. \tag{4.64}$$

4.6.4.1.2 Elastic Stress–Strain Relationship

The stresses $\bar{\boldsymbol{\sigma}}$ are linked to the elastic logarithmic strains $\boldsymbol{\epsilon}^e$ through a linear elastic isotropic relationship. By splitting $\boldsymbol{\epsilon}^e$ into deviatoric part $\boldsymbol{e}^e$ and isotropic part ϵ_m^e, the elastic constitutive relationship reads

$$\bar{\boldsymbol{s}} = 2\mu \boldsymbol{e}^e, \quad \bar{\sigma}_m = 3K\epsilon_m^e,$$

where $\bar{\boldsymbol{s}}$ is the deviatoric part of $\bar{\boldsymbol{\sigma}}$. The hyper-elastic law is written in terms of total stresses, and this allows for the accurate description of the stress also for moderate strains.

4.6.4.1.3 Plasticity Condition

The von Mises plasticity condition (4.47) is written in terms of deviatoric stresses $\boldsymbol{s}$. The effective stress $\bar{\sigma}$ is written as a function of the stresses in the intermediate configuration $\bar{\boldsymbol{s}}$:

$$\bar{\sigma} = \sqrt{\frac{3}{2} \boldsymbol{s} \cdot \boldsymbol{s}} = J^{-1} \sqrt{\frac{3}{2} \bar{\boldsymbol{s}} \cdot \bar{\boldsymbol{s}}}, \quad \bar{\boldsymbol{s}} = J \boldsymbol{R}^{eT} \boldsymbol{s} \boldsymbol{R}^e.$$

4.6.4.1.4 Plastic Strain Evolution Rule

The normal $\bar{\boldsymbol{n}}$ to the yield function in the intermediate configuration is given by

$$\bar{\boldsymbol{n}} = \sqrt{\frac{3}{2}} \frac{\bar{\boldsymbol{s}}}{J \bar{\sigma}}.$$

The evolutive equation for the plastic strains is obtained by generalizing the corresponding equation in small strains. The plastic strain rate is defined from the plastic velocity gradient, assuming a zero plastic spin:

$$\bar{\boldsymbol{D}}^p = \frac{1}{2}\left(\bar{\boldsymbol{L}}^p + \overline{\boldsymbol{L}^p}^T\right) = \bar{\boldsymbol{L}}^p, \quad \overline{\boldsymbol{W}}^p = \frac{1}{2}\left(\bar{\boldsymbol{L}}^p - \overline{\boldsymbol{L}^p}^T\right) = \boldsymbol{0}.$$

The flow rule (4.54) is written as

$$\bar{\boldsymbol{D}}^p = \bar{\boldsymbol{L}}^p = \sqrt{\frac{3}{2}}\,\dot{\bar{e}}^p\,\bar{\boldsymbol{n}} = \lambda\,\bar{\boldsymbol{s}}, \quad \dot{\bar{e}}^p = \sqrt{\frac{2}{3}\bar{\boldsymbol{D}}^p \cdot \bar{\boldsymbol{D}}^p}.$$

This corresponds to the maximum plastic dissipation principle [10].

4.6.4.2 Solution Procedure

The differences between the quantities used in MNL and UL are

- In the hyper-elastic law, $\bar{\boldsymbol{\sigma}}$ instead of $\boldsymbol{\sigma}$
- In the hyper-elastic law, $\boldsymbol{e}^e$ instead of $\boldsymbol{\varepsilon}^e$
- In the flow rule, $\bar{\boldsymbol{D}}^p$ instead of $\boldsymbol{\varepsilon}^p$

Assuming that at each time step the final value of the deformation gradient $\boldsymbol{F}(t)$ is assigned, the solution algorithm consists in the following steps:

1. Assignment of the trial elastic step
   Trial elastic deformation gradient:

$$\boldsymbol{F}^e(\tau) = \boldsymbol{F}(t)(\boldsymbol{F}^p(t_0))^{-1}.$$

   Elastic polar decomposition:

$$\boldsymbol{F}^e(\tau) = \boldsymbol{R}^e(\tau)\boldsymbol{U}^e(\tau).$$

   Trial elastic logarithmic strains:

$$\boldsymbol{\epsilon}^e(\tau) = \log(\boldsymbol{U}^e(\tau)).$$

   Trial Cauchy stresses (deviatoric and mean):

$$\bar{\boldsymbol{s}}(\tau) = 2\mu\boldsymbol{e}^e(\tau), \quad \bar{\sigma}_m(\tau) = 3K\epsilon^e_m(\tau).$$

   Trial equivalent effective stress:

$$\bar{\sigma}(\tau) = J(t)^{-1}\sqrt{\frac{3}{2}\bar{\boldsymbol{s}}(\tau)\cdot\bar{\boldsymbol{s}}(\tau)}.$$

2. Check of the trial stress state
   If $\bar{\sigma}(\tau) < \sigma_y(t_0)$, the trial stress is elastic.
   It results:

$$\bar{\sigma}(t) = \bar{\sigma}(\tau), \quad \sigma_y(t) = \sigma_y(t_0), \quad \boldsymbol{\epsilon}^e(t) = \boldsymbol{\epsilon}^e(\tau), \quad \bar{\sigma}(t) = \bar{\sigma}(\tau).$$

   Cauchy stresses:

$$\boldsymbol{\sigma}(t) = J(t)^{-1}\, \boldsymbol{R}^e(\tau)\, \bar{\boldsymbol{\sigma}}(\tau)\, \boldsymbol{R}^e(\tau)^T.$$

   Go back to point 1.
3. Plastic step
   The effective stress function (4.52) is solved numerically obtaining the effective stress in the intermediate configuration and the plastic strains:

$$f[\bar{\sigma}(\tau)] = a^2[\bar{\sigma}(\tau)] - d^2 = 0 \Rightarrow \bar{\sigma}(t),\ \bar{e}^p(t).$$

   Thus, the following variables are computed in sequence.
   Plastic multiplier from $(4.49)_1$:

$$\lambda(t) = \frac{3}{2}\frac{\bar{e}^p(t) - \bar{e}^p(t_0)}{J(t)\,\bar{\sigma}(t)}.$$

   Deviatoric stresses in the intermediate configuration:

$$\bar{\boldsymbol{s}}(t) = \frac{\bar{\boldsymbol{s}}(\tau)}{1 + 2\mu\lambda(t)}.$$

   Total stresses in the intermediate configuration:

$$\bar{\boldsymbol{\sigma}}(t) = \bar{\boldsymbol{s}}(t) + \frac{1}{3}\mathrm{tr}\left[\boldsymbol{\sigma}(\tau)\right]\boldsymbol{I}.$$

   Cauchy stresses:

$$\boldsymbol{\sigma}(t) = J(t)^{-1}\, \boldsymbol{R}^e(\tau)\, \bar{\boldsymbol{\sigma}}(t)\, \boldsymbol{R}^e(\tau)^T.$$

   Plastic deformation gradient, by integration of 4.64 and by using 4.65:

$$\dot{\boldsymbol{F}}^p(\boldsymbol{F}^p)^{-1} = \lambda\,\bar{\boldsymbol{s}} \Rightarrow \boldsymbol{F}^p(t) = \exp\left[\lambda(t)\bar{\boldsymbol{s}}(t)\right]\boldsymbol{F}^p(t_0).$$

The description of the solution strategy is closed by a few final remarks:

1. The previous equations are also used in bidimensional analyses (plane stress or plane strain), provided that the correct reduced constitutive relationships are used.
2. It is possible to extend the procedure to structural elements, such as beams, plates, and shells, taking care of the effects related to the change in the transversal dimensions (thickness).
3. It is possible to extend the procedure to materials showing viscous and temperature-dependent behavior, by following the scheme described for the MN formulation.
4. In the case of incompressible materials, it is always preferable to use mixed formulations (i.e., also to discretize the pressure field) both in two and three dimensions, to rule out spurious locking effects.

4.7 FINITE ELEMENT SOLUTION

The equilibrium equation in weak form, written at time t, is valid for a continuum displacement field. Let us consider a body discretized into finite elements, where, besides the displacement components, the rotation are also assumed to be independent variables.

The continuum problem is approximated by linearizing the virtual work equation with respect to all the independent variables. Because of the approximation, in both TL and UL formulations, the internal work computed at the first iteration does not coincide with the external work. The difference defines the errors:

$$\mathrm{Err}_{TL}^{(1)} = W^0(t) - \int_{V^0} S_{hk}^{(1)}\, \delta E_{hk}^{(1)}\, dV^0, \tag{4.65}$$

$$\mathrm{Err}_{UL}^{(0)} = W^t(t) - \int_{V^{t(0)}} \sigma_{hk}^{(1)}\, \delta e_{hk}^{(1)}\, dV^t. \tag{4.66}$$

The right-hand sides of 4.65 and 4.66 correspond to the right-hand sides of the relations 4.31 and 4.34, except that here they are evaluated in the current configuration, by using suitable stress and strain measures. The left-hand sides of 4.65 and 4.66 represent the out-of-balance work resulting from the linearization, at the current solution.

Obviously, a good solution has a small error. To reduce the magnitude of the error it is necessary to adopt an iterative procedure, where the equations are solved several times, by using the displacements computed at the previous iteration.

In TL formulation, the iterative expression of the displacement equation becomes

$$\int_{V^0} C_{hkij}^{t(k-1)} \Delta e_{ij}^{(k)} \delta \Delta e_{hk}\, dV^0 + \int_{V^0} S_{hk}^{(k-1)}(t) \delta \Delta \eta_{hk}^{(k)}\, dV^0 = W^0(t) - \int_{V^0} S_{hk}^{(k-1)}(t) \delta \Delta e_{hk}^{(k-1)}\, dV^0, \tag{4.67}$$

where the material tangent stiffness C_{hkij}^{t} at time t is referred to the undeformed configuration at time t_0.

In UL formulations, the iterative expression becomes

$$\int_{V^{t(k-1)}} C_{hkij}^{t(k-1)} \Delta e_{ij}^{(k)} \delta \Delta e_{hk}\, dV^t + \int_{V^{t(k-1)}} \sigma_{hk}^{(k-1)}(t) \delta \Delta \eta_{hk}^{(k)}\, dV^t = W^{t(k-1)}(t) - \int_{V^{t(k-1)}} \sigma_{hk}^{(k-1)}(t) \delta \Delta e_{hk}^{(k-1)}\, dV^t, \tag{4.68}$$

where the material tangent stiffness C_{hkij}^{t} at time t is referred to the current configuration at time t.

Between k and $(k + 1)$ iteration, the displacements are updated as

$$u_h^{(k)}(t) = u_h^{(k-1)}(t) + \Delta u_h^{(k)}(t), \quad u_h^{(0)}(t) = u_h(t_0). \tag{4.69}$$

Equations 4.67 or 4.68 and 4.69 define the Newton–Raphson procedure. All the variables are updated at each iteration, and only at the first iteration the variables evaluated at the end of the previous step are accounted for.

For loads that do not change direction with deformations, the expression of the external work (4.10) can be computed simply by evaluating the value of loads at time t:

$$W^0(t) = \int_{V^0} \rho b_i(t) \delta u_i dV^0 + \int_{S_f^0} \rho^0 t_i(t) \delta u_i dS^0. \tag{4.70}$$

If isoparametric finite elements are used, the inertia can be included in the external work. Because of the identity

$$\int_{V^0} \rho^0 \ddot{u}_i(t) \delta u_i dV^0 = \int_{V^t} \rho^t \ddot{u}_i(t) \delta u_i dV^t,$$

the mass matrix can be computed only once, at the beginning, for the initial configuration of the body.

When the external work is a function of the deformations, 4.70 cannot be used. Thus, the external work can be approximated with good accuracy by using the load intensity at time t, and considering the last calculated volumes and areas.

It is important to observe that

1. For an efficient integration scheme, the effect of the unknown incremental displacements must be included into the stiffness matrix. According to the applied load, the stiffness matrix may result nonsymmetric, causing an increase of the computational cost.
2. The virtual work equations are discussed here with reference to static or dynamic calculations performed with an implicit integration scheme. If a dynamic analysis is performed with an explicit integration scheme, the variables necessary in the calculation (velocities, accelerations) are computed at the beginning of the step. The explicit method is reduced to the evaluation of the internal work, and the continuum mechanics equations become
   - Total Lagrangian:

$$\int_{V^0} S_{hk}(t_0) \delta E_{hk} dV^0 = W^0(t).$$

   - Updated Lagrangian:

$$\int_{V^t} \sigma_{hk}(t) \delta e_{hk} dV^t = W^t(t).$$

- Materially nonlinear:

$$\int_V \sigma_{hk}(t_0)\delta e_{hk} dV = W(t).$$

The inertia is included in the external loads.

4.7.1 Finite Element Linearization of the Equilibrium Equations

The derivation of the linearized virtual work equation is obtained here in detail only for the TL formulation (4.27). For the sake of simplicity, the external work W^0 is assumed to be independent of the deformations:

$$\int_{V^0} S_{ij}(t)\delta E_{ij}(t)\, dV^0 = W^0(t).$$

Denoting with a_k the generic nodal degree of freedom (displacement or rotation) of the chosen finite element discretization, and recalling that the current time step is here defined as $\Delta t = t - t_0$, the internal work is expressed through the Taylor expansion:

$$S_{ij}(t)\delta E_{ij}(t) \approx S_{ij}(t_0)\delta E_{ij}(t_0) + \left.\frac{\partial(S_{ij}\delta E_{ij})}{\partial a_k}\right|_{t_0} da_k,$$

where da_k denotes the variation of a_k. Since the deformations change with the variation a_l, it results

$$\delta E_{ij}(t_0) = \left.\frac{\partial E_{ij}}{\partial a_l}\right|_{t_0} \delta a_l.$$

The variation is taken about the configuration at time t_0 with respect to a_l. By developing the right-hand term in 4.71, one obtains

$$\left.\frac{\partial(S_{ij}\delta E_{ij})}{\partial a_k}\right|_{t_0} da_k = \left.\frac{\partial S_{ij}}{\partial a_k}\right|_{t_0} \delta E_{ij}(t_0)\, da_k + S_{ij}(t_0)\left.\frac{\partial \delta E_{ij}}{\partial a_k}\right|_{t_0} da_k = \tag{4.71}$$

$$\left.\frac{\partial S_{ij}}{\partial E_{rs}}\right|_{t_0} \left.\frac{\partial E_{rs}}{\partial a_k}\right|_{t_0} \left.\frac{\partial E_{ij}}{\partial a_l}\right|_{t_0} \delta a_l\, da_k + S_{ij}(t_0)\frac{\partial}{\partial a_k}\left(\left.\frac{\partial E_{ij}}{\partial a_l}\right|_{t_0}\right)\delta a_l da_k$$

$$= \left(C_{ijrs}\left.\frac{\partial E_{rs}}{\partial a_k}\right|_{t_0}\left.\frac{\partial E_{ij}}{\partial a_l}\right|_{t_0} + S_{ij}(t_0)\left.\frac{\partial^2 E_{ij}}{\partial a_k\, \partial a_l}\right|_{t_0}\right)\delta a_l\, da_k. \tag{4.72}$$

C_{ijrs} is the tangent stiffness matrix of the material for the configuration at time t_0. Finally, the first and second derivatives of the Green–Lagrange tensors are written as

$$\begin{aligned}\frac{\partial E_{ij}}{\partial a_k} &= \frac{1}{2}\left(\frac{\partial u_{i,j}}{\partial a_k}+\frac{\partial u_{j,i}}{\partial a_k}+\frac{\partial u_{n,i}}{\partial a_k}u_{n,j}+u_{n,i}\frac{\partial u_{n,j}}{\partial a_k}\right)\\ \frac{\partial^2 E_{ij}}{\partial a_k\,\partial a_l} &= \frac{1}{2}\left(u_{n,i}\frac{\partial^2 u_{n,j}}{\partial a_k\,\partial a_l}+u_{n,j}\frac{\partial^2 u_{n,i}}{\partial a_k\,\partial a_l}+\frac{\partial u_{n,i}}{\partial a_k}\frac{\partial u_{n,j}}{\partial a_l}+\frac{\partial u_{n,i}}{\partial a_l}\frac{\partial u_{n,j}}{\partial a_k}\right).\end{aligned} \tag{4.73}$$

If the displacement interpolation is linear in the nodal degrees of freedom, as usually happens in solid elements, the second derivatives become

$$\frac{\partial^2 E_{ij}}{\partial a_k\,\partial a_l}=\frac{\partial u_{n,i}}{\partial a_k}\frac{\partial u_{n,j}}{\partial a_l}.$$

By replacing 4.71 and 4.72 in 4.74, the TL finite element virtual work equation is obtained:

$$\left(\int_{V^0} C_{ijrs}\frac{\partial E_{rs}}{\partial a_k}\frac{\partial E_{ij}}{\partial a_l}dV^0+\int_{V^0} S_{ij}\frac{\partial^2 E_{ij}}{\partial a_k\,\partial a_l}dV^0\right)da_k\,\delta a_l=W^0(t)-\left(\int_{V^0} S_{ij}\frac{\partial E_{ij}}{\partial a_l}dV^0\right)\delta a_l. \tag{4.74}$$

When the discretization involves isoparametric solid elements, where the degrees of freedom are only the nodal displacements, Equation 4.74 can be obtained in an alternative way, starting from the linearized expression of the internal work (4.31). But when structural finite elements are used (such as beams, plates, and shells), and rotational degrees of freedom are involved, it is always better to use Equation 4.74. In fact, 4.74 includes directly the second derivatives of the displacement gradient with respect to all the degrees of freedom. In TL-linearized formulation, Equation 4.31, the second derivatives of the displacement gradient will not be appeared explicitly, but will be included in the right-hand side terms of the equations. Their effect, though, has to be considered, since they contribute to the stiffness matrix when the displacement is not linear function of the nodal variables. Finally, relation 4.74 is useful especially for the formulation of mixed problems, where static variables (e.g., the pressure) appear in the unknowns.

A similar relation is obtained for the UL approach.

4.7.2 Matrix Equation for Solid Elements

The assembling of the matrices that govern static or dynamical problems in nonlinear formulations follows closely, in the general case, the assembling of the matrices for linear finite element analysis. Once the interpolation functions of coordinates and displacements have been chosen, the virtual work theorem is invoked for each degree of freedom, and the finite element equations are obtained.

Unlike the linear case, it is mandatory to use isoparametric elements, where the interpolation functions of the displacements are the same interpolation functions used for the coordinates. In fact, the coordinates in the deformed configuration are the sum of the coordinates in the undeformed configuration and of the nodal displacements. Therefore, the use of the same interpolation functions guarantees a consistent solution procedure. The most relevant consequence is that remarks on the convergence rate, valid for the linear finite element method, can also be extended to the incremental analysis. In particular, the compatibility of the displacements on

the element boundaries, in general imposed on the initial configuration, is also guaranteed in the deformed configurations.

By restricting the focus on the linearized equations of the virtual work theorem, the interpolation of coordinates and displacements originates the matrix equations reported in the following sections. The extension of the expressions to iterative procedures is straightforward.

4.7.2.1 Materially Nonlinear

There is no difference between the deformed and the undeformed configuration. The force array $\boldsymbol{F}^{\text{int}}(t_0)$ collects the integral of the Cauchy stress $\boldsymbol{\sigma}$ at time t_0:

$$\boldsymbol{F}^{\text{int}}(t_0) = \int_V \boldsymbol{B}_L^T \sigma dV$$

and $\boldsymbol{B}_L$ is the matrix that connects the linear part of the strain array to the displacements. $\boldsymbol{K}(t_0)$ is the small strain tangent stiffness matrix t_0, which does not account for geometrical effects:

$$\boldsymbol{K}(t_0) = \int_V \boldsymbol{B}_L^T \boldsymbol{C} \boldsymbol{B}_L dV$$

and $\boldsymbol{C}$ is the constitutive tangent stiffness.

- Static analysis:

$$\boldsymbol{K}(t_0)\Delta\boldsymbol{U} = \boldsymbol{R}(t) - \boldsymbol{F}^{\text{int}}(t_0)$$

- Implicit dynamic analysis:

$$\boldsymbol{M}\ddot{\boldsymbol{U}}(t) + \boldsymbol{K}(t_0)\Delta\boldsymbol{U} = \boldsymbol{R}(t) - \boldsymbol{F}^{\text{int}}(t_0)$$

- Explicit dynamic analysis:

$$\boldsymbol{M}\ddot{\boldsymbol{U}}(t_0) = \boldsymbol{R}(t_0) - \boldsymbol{F}^{\text{int}}(t_0)$$

4.7.2.2 TL Formulation

The array $\boldsymbol{F}^{\text{int}}(t_0)$ collects the forces corresponding to the second Piola–Kirchhoff stress matrix $\boldsymbol{S}$ at time t_0, computed in the undeformed configuration:

$$\boldsymbol{F}^{\text{int}}(t_0) = \int_{V^0} \boldsymbol{B}_L^T \boldsymbol{S} dV^0,$$

$\boldsymbol{B}_L$ is the matrix, referred to the initial configuration, that connects the linear part of the strains to the displacements. $\boldsymbol{K}_L(t_0)$ is the small strain tangent stiffness matrix at time t_0, referred to the undeformed configuration:

$$\boldsymbol{K}_L(t_0) = \int_{V^0} \boldsymbol{B}_L^T \boldsymbol{C} \boldsymbol{B}_L dV^0,$$

$\boldsymbol{C}$ is the constitutive tangent stiffness, referred to the initial configuration. $\boldsymbol{K}_{NL}(t_0)$ is the geometrical tangent stiffness, which accounts for the geometric nonlinearities and for the initial stresses, computed in the undeformed configuration:

$$\boldsymbol{K}_{NL}(t_0) = \int_{V^0} \boldsymbol{B}_{NL}^T \boldsymbol{S} \boldsymbol{B}_{NL} dV^0,$$

$\boldsymbol{B}_{NL}$ is the matrix linking the nonlinear part of the strains to the displacements, referred to the initial configuration.

- Static analysis:

$$[\boldsymbol{K}_L(t_0) + \boldsymbol{K}_{NL}(t_0)]\Delta \boldsymbol{U} = \boldsymbol{R}(t) - \boldsymbol{F}^{\text{int}}(t_0).$$

- Implicit dynamic analysis:

$$\boldsymbol{M}\ddot{\boldsymbol{U}}(t) + \left[\boldsymbol{K}_L(t_0) + \boldsymbol{K}_{NL}(t_0)\right]\Delta \boldsymbol{U} = \boldsymbol{R}(t) - \boldsymbol{F}^{\text{int}}(t_0).$$

- Explicit dynamic analysis:

$$\boldsymbol{M}\ddot{\boldsymbol{U}}(t_0) = \boldsymbol{R}(t_0) - \boldsymbol{F}^{\text{int}}(t_0).$$

4.7.2.3 UL Formulation

The array $\boldsymbol{F}^{\text{int}}(t_0)$ collects the contribution of the Cauchy stress $\boldsymbol{\sigma}$ at time t_0, computed with reference to the deformed configuration at time t_0:

$$\boldsymbol{F}^{\text{int}}(t_0) = \int_{V^t} \boldsymbol{B}_L^T \boldsymbol{\sigma} dV^t.$$

$\boldsymbol{B}_L$ is the matrix that relates the linear part of the strains to the displacements, referred to the time t_0. $\boldsymbol{K}_L(t_0)$ is the small strain tangent stiffness at time t_0, computed with reference to the deformed configuration:

$$\boldsymbol{K}_L(t_0) = \int_{V^t} \boldsymbol{B}_L^T \boldsymbol{C} \boldsymbol{B}_L dV.$$

$\boldsymbol{C}$ is the constitutive stiffness matrix, referred to the deformed configuration at time t_0. $\boldsymbol{K}_{NL}(t_0)$ is the tangent stiffness matrix, which accounts for the geometric nonlinearities and initial stresses, computed with reference at the deformed configuration at time t_0:

$$\boldsymbol{K}_{NL}(t_0) = \int_{V^t} \boldsymbol{B}_{NL}^T \boldsymbol{\sigma} \boldsymbol{B}_{NL} dV^t.$$

$\boldsymbol{B}_{NL}$ is the matrix, which links the nonlinear part of the strains to the displacements.

- Static analysis:

$$[\boldsymbol{K}_L(t_0)+\boldsymbol{K}_{NL}(t_0)]\,\Delta\boldsymbol{U}=\boldsymbol{R}(t)-\boldsymbol{F}^{\text{int}}(t_0).$$

- Implicit dynamic analysis:

$$\boldsymbol{M}\ddot{\boldsymbol{U}}(t)+[\boldsymbol{K}_L(t_0)+\boldsymbol{K}_{NL}(t_0)]\,\Delta\boldsymbol{U}=\boldsymbol{R}(t)-\boldsymbol{F}^{\text{int}}(t_0).$$

- Explicit dynamic analysis:

$$\boldsymbol{M}\ddot{\boldsymbol{U}}(t_0)=\boldsymbol{R}(t_0)-\boldsymbol{F}^{\text{int}}(t_0).$$

In the previous equations, $\boldsymbol{M}$ is the mass matrix, independent of the strain; $\Delta\boldsymbol{U}$ is the incremental nodal displacement array; $\ddot{\boldsymbol{U}}(t_0)$ and $\ddot{\boldsymbol{U}}(t)$ are the nodal acceleration arrays, at times t_0 and t, respectively; $\boldsymbol{R}(t_0)$ and $\boldsymbol{R}(t)$ are the external nodal load arrays, at times t_0 and t, respectively.

4.8 SPECIAL PROBLEMS

For the solution of standard statics and dynamics problems, two restrictive assumptions have been made: (1) the compatibility of the displacement field, described by regular functions and (2) the preservation of the body boundaries, with a clear distinction between the displacement boundary and the traction boundary. When one of these assumptions is missing, two new kinds of mechanical problems have to be considered. Fracture mechanics deals with problems where displacement compatibility fails, while contact mechanics deals with boundaries where both displacements and tractions are unknowns.

4.8.1 Nonlinear Fracture Mechanics

The cohesive approach to fracture mechanics [21,22] describes a crack as the progressive separation of two originally coincident surfaces S^+ and S^- (see Figure 4.18). Every point P^+ belonging to S^+ has a corresponding point P^- on S^-. It is possible to define a mean surface, equidistant from the two original surfaces, where static and kinematics quantities can be defined.

The two surfaces move away as consequence of the displacement $\boldsymbol{u}^+$ of $\boldsymbol{u}^-$ of the two points P^+ and P^-. The displacement jump is the difference:

$$[[\boldsymbol{u}]]=\boldsymbol{u}^+-\boldsymbol{u}^-.$$

The separation of the two points is contrasted by the cohesive tractions $\boldsymbol{t}^c$. The cohesive tractions are related to the displacement jump through the cohesive law, or interface law, characterized by a progressive softening of the response:

$$\boldsymbol{t}^c=f\,[[\boldsymbol{u}]]. \tag{4.75}$$

The cohesive law has to be able to describe the different types of separation, that is, the opening mode from the shear modes. Therefore, the expression of 4.75 can become quite complicated. A way to simplify the analytical treatment of the cohesive law is to define effective scalar quantities, by weighting the components of the displacement jump in the normal and tangential direction with respect to the cohesive surface [16,23]. An example of cohesive law expressed in terms of effective variables is reported in Figure 4.19a.

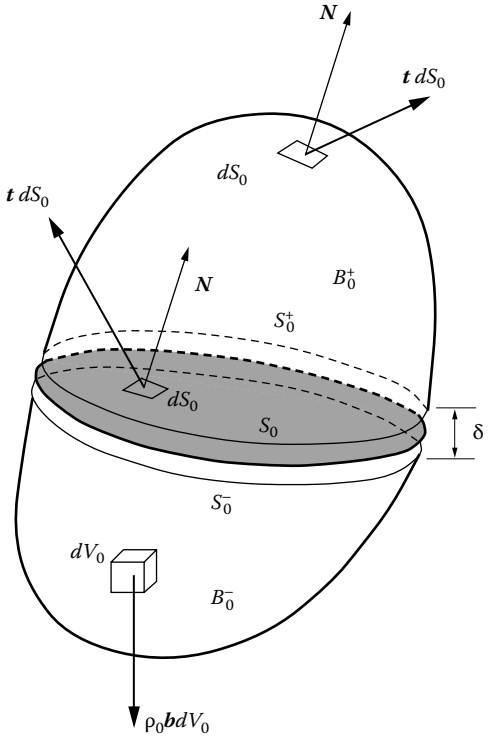

FIGURE 4.18 Cohesive surface across a continuum.

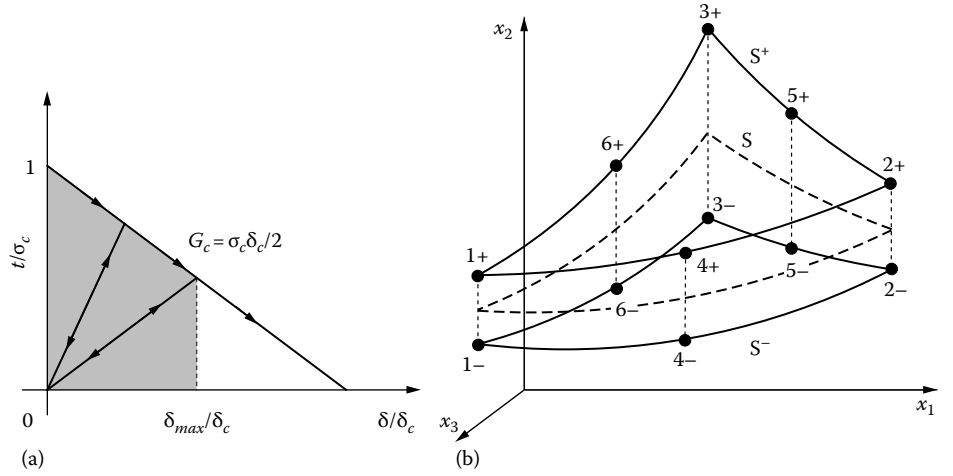

FIGURE 4.19 (a) Irreversible linear cohesive law. (b) Interface finite element, compatible with the discretization of the continuum into quadric tetrahedra.

The presence of a cohesive surface introduces a new term in the virtual work equation, that is, the work done by the cohesive tractions for the displacement jump:

$$\int_{V(t)} \sigma_{ij}(t)\,\delta e_{ij}\,dV = \int_{V(t)} \rho(t) b_i(t)\,\delta u_i\,dV + \int_{S_f(t)} t_i(t)\,\delta u_i\,dS + \int_{S_c(t)} t_i^c(t)\,\delta \llbracket u \rrbracket_i\,dS.$$

Cohesive models are especially appealing for the finite element applications. With a simple modification of a standard code, it is possible to apply the cohesive laws as mixed boundary conditions.

Alternatively, it is possible to introduce interface finite elements, made of two surfaces coinciding with the boundary surface of two adjacent solid elements (Figure 4.19).

The cohesive law governs the response of the material when fracture occurs, and defines the value of the traction $\boldsymbol{t}_c$ on the cohesive surface. The corresponding nodal forces are evaluated by integrating the cohesive tractions on the cohesive surface:

$$\boldsymbol{F}^{\text{int}}(t)^{\pm} = \mp \int_{S_0} \boldsymbol{t}_c \boldsymbol{N} dS_0, \tag{4.76}$$

where $\boldsymbol{N}$ is the shape function matrix. The tangent stiffness matrix is computed through a consistent linearization of 4.76:

$$\boldsymbol{K}(t)^{\pm\pm} = \mp \mp \frac{\partial \boldsymbol{F}^{\text{int}}(t)^{\pm}}{\partial \boldsymbol{x}^{\pm}}.$$

The tangent stiffness matrix may result nonsymmetric if geometrical nonlinearities are considered.

4.8.2 Contact Mechanics

The formulation of the contact problem, from the small strain frictionless contact to the large strain frictional contact, is always the same, although the difficulties related to the numerical solution may be very different.

Contact between two or more bodies is observed when their motion is somehow constrained. The bodies cannot assume all the possible configurations, but geometrical constraints impede their motion partially or completely. Contact involves the boundaries of the bodies (Figure 4.20), and the constraint reactions become surface normal and tangent tractions.

Figure 4.21a shows the so-called Signorini's condition that relates the normal relative displacements $u_N = [\![\boldsymbol{u}^c]\!] \cdot \boldsymbol{n}$ to the compressive tractions $T_N = \boldsymbol{t}^c \cdot \boldsymbol{n}$ when two bodies are in contact:

$$u_N \geq 0, \quad T_N \leq 0, \quad u_N T_N = 0.$$

Figure 4.21 shows the condition on the tangential velocities $\dot{u}_S$ that are observed in the direction opposite to the resisting tangential forces, only when the force reaches a limit value (Coulomb law):

$$\dot{u}_S = 0 \quad \text{if } |T_S| < \mu |T_N|, \quad \text{sign}(\dot{u}_S) = \text{sign}(T_S) \quad \text{if } |T_S| = \mu |T_N|,$$

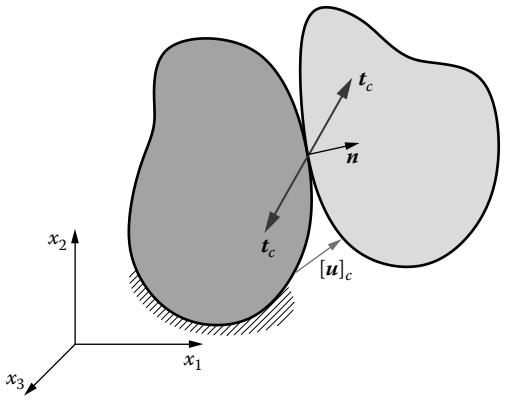

FIGURE 4.20 Smooth contact between two bodies, definition of the normal $\boldsymbol{n}$ to one of the two surfaces and of the contact tractions $\boldsymbol{t}^c$. In the contact surface, the displacement jump $[\![\boldsymbol{u}^c]\!]$ is null.

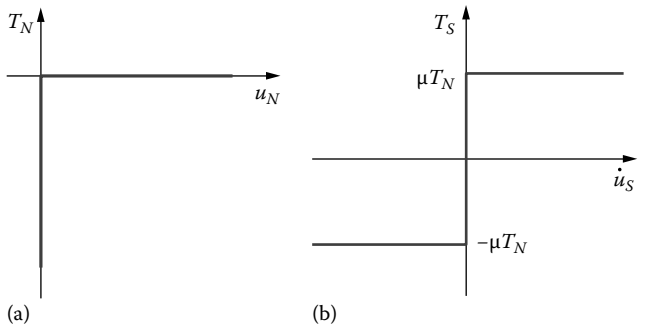

FIGURE 4.21 Frictional contact conditions: (a) Signorini's condition for the unilateral contact and (b) tangent velocity condition.

where μ is the friction coeffcient. By nature, contact is non-smooth and a rigorous treatment of the problem requires to use the non-smooth analysis [24].

A classic approach, based on the definition of a gap function between the two surfaces in potential contact, is presented here. The approach relies on the existence of a smooth contact surface [1].

For a system of N bodies in motion, the virtual work theorem is written by, accounting for the contribution of all the bodies, including the work of the contact forces. The weak form of the equilibrium equation is

$$\sum_{\text{Bodies}} \left\{ \int_{V(t)} \sigma_{ij}(t)\,\delta e_{ij}\, dV \right\} = \sum_{\text{Bodies}} \left\{ \int_{V(t)} \rho(t) b_i(t)\,\delta u_i\, dV + \int_{S_f(t)} t_i(t)\delta u_i\, dS \right\} + \sum_{\text{Contacts}} \int_{S_c(t)} t_i^c(t)\,\delta u_i^c\, dS, \tag{4.77}$$

where

S_c is the contact surface
$t_i^c(t)$ is the contact reaction
δu_i^c is the virtual displacement on the contact surfaces

For the sake of simplicity, let us consider two bodies A and B in contact (or two parts of the same body, in the case of self-contact). The contact reactions must be equal and opposite $\boldsymbol{t}^{AB} = -\boldsymbol{t}^{BA}$. Denoting with $S^{AB}(t)$ the total contact surface, the virtual contact work can be written as

$$\int_{S^A(t)} t_i^{AB}(t)\,\delta u_i^A\, dS + \int_{S^B(t)} t_i^{BA}(t)\,\delta u_i^B\, dS = \int_{S^{AB}(t)} t_i^{AB}(t)\,\delta \left[\!\left[u_i^{AB} \right]\!\right] dS.$$

The contact surface is defined always as a pair of surfaces, with possibly a different extension. One of the two surfaces (A) is called arbitrarily as contactor and the second (B) as target. Denoting the normal to the target surface with $\boldsymbol{n}$, $\boldsymbol{s}$ is a unit vector on the tangent plane that defines with $\boldsymbol{n}$ an orthonormal basis. The contact forces are split in normal and tangential components:

$$T_N = \boldsymbol{t}^{AB}(t)\cdot\boldsymbol{n}, \quad T_S = \boldsymbol{t}^{AB}(t)\cdot\boldsymbol{s}.$$

The pair $\boldsymbol{n}$, $\boldsymbol{s}$ is computed at a generic point $\boldsymbol{x}$ on the contactor surface. On the target surface, the point $\boldsymbol{y}^*(\boldsymbol{x}, t)$, closest to $\boldsymbol{x}$, is identified:

$$\|\boldsymbol{x} - \boldsymbol{y}^*(\boldsymbol{x}, t)\| = \min_{\boldsymbol{y}\in S^B}\{\|\boldsymbol{x} - \boldsymbol{y}\|\}.$$

The distance between $\boldsymbol{x}$ and $\boldsymbol{y}^*$ is given by the component of the vector $\boldsymbol{x} - \boldsymbol{y}^*$ on the normal $\boldsymbol{n}$:

$$u_N = g(\boldsymbol{x}, t) = (\boldsymbol{x} - \boldsymbol{y}^*(\boldsymbol{x}, t))\cdot \boldsymbol{n}$$

and g is usually called gap function. In presence of Coulomb friction, the tangential velocity $\dot{u}_S(\boldsymbol{x}, t)$ is introduced:

$$\dot{u}_S(\boldsymbol{x}, t) = [\dot{\boldsymbol{u}}(\boldsymbol{x}, t) - \dot{\boldsymbol{u}}(\boldsymbol{y}^*, t)]\cdot \boldsymbol{s}.$$

The solution of the frictional contact problem is obtained, therefore, from the solution of the virtual work equation written in the form (4.77), under the constraints

$$\begin{gathered} u_N \geq 0 \\ T_N \leq 0 \\ u_N T_N = 0 \\ |T_S| \leq |T_N| \\ \dot{u}_S = 0 \quad \text{if } |T_S| < \mu |T_N| \\ \operatorname{sign}(\dot{u}_S) = \operatorname{sign}(T_S) \quad \text{if } |T_S| = \mu |T_N|. \end{gathered} \tag{4.78}$$

In dynamic analyses, the inertia forces have to be included between the body forces, and additional kinematic conditions on accelerations and velocities have to be considered. In general, the typically adopted time integration schemes (trapezoidal rule) are not able to satisfy the contact conditions; therefore, they have to be enforced individually during the step-by-step solutions.

Many procedures have been proposed in the literature for the numerical solution of contact. Most of them are based on penalty approaches or on the introduction of Lagrange multipliers to account for the contact constraints (see, for example, [1,25,26]).

The formulation of frictional contact problems leads in general to nonsymmetric equation systems. This difficulty can be avoided if dissipative effects of friction are disregarded. Also, in the case of frictionless contact, though, the solution algorithms may show a considerable reduction of the convergence rate. Even with consistent approaches, the convergence ability can be spoiled by the choice of an inaccurate prediction step. A wide step, for example, may miss completely the detection of the contact.

Algorithm bases on the definition of gap functions are in general weak in the cases of corners, where the normal is not defined. In such cases, the stiffness matrix may intrinsically not consistent and introduces numerical instabilities. To avoid such issues, regularization methods for the contact surfaces have been proposed. Some of them are based on the introduction of smooth interpolation functions, definition of the distance between interior points of the bodies (pinball method), or, finally, the direct use of the non-smooth mechanics [25,26].

4.9 CONCLUSIONS

The finite element method is used to solve the mathematical problems that model physical problems in engineering analysis and design. A linear model can be adopted for many practical mechanical applications, when the only difficulty is the complex geometry of the system.

Other common problems in mechanics require to adopt nonlinear models. Nonlinearities are mainly due to the behavior of materials, the magnitude of the displacements, or the presence of unilateral constraints. The analysis of such problems can be pursued only with a nonlinear finite element approach.

Obviously, the presentation in the previous sections neglected many mechanical problems that also require to use nonlinear analysis, for example, the evaluation of the critical load, or the attainment of buckling conditions in slender structures [27]. According to the magnitude of the displacements, critical loads can be determined by computing the eigenvalues of the stiffness matrix (second-order analysis), or, in a fully nonlinear approach, through a step-by-step analysis with increasing loads. The latter approach allows for tracking the post-critical conditions.

Additionally, the presentation did not discuss the numerical difficulties in the iterative solution of the nonlinear systems. In proximity of critical conditions, the Newton–Raphson procedure may fail, and alternative solvers need to be adopted, such as the arc-length method [28], the conjugate gradient method [29], or the dynamic relaxation method [30–32].

Finally, a non-negligible consequence of finite kinematics is the geometrical distortion of finite elements. This effect may reduce dramatically the accuracy of the solution. Therefore, a continuous check on the element distortion may be necessary to obtain meaningful solutions. Adaptive remeshing techniques, able to replace distorted elements with patches of new elements, are becoming more and more popular and efficient [33].

5.1 INTRODUCTION

In general, all kinematic and constitutive relations in vehicle system dynamics are nonlinear. The modeling of such systems therefore leads to nonlinear dynamic systems, which must be investigated with respect to their properties and evolution.

It is characteristic for vehicle dynamic systems that they contain elements, which dissipate energy. Therefore, we consider only dissipative and nonconservative systems in this chapter.

In vehicle system dynamics, the dynamic problem is most often first to find the stationary state(s), second to search for other steady states, third to determine their stability, and finally to determine the behavior of the vehicle when changes between steady states, for example, by braking a car or negotiating a curve, occur. Therefore, the fundamental problem is to find the stationary and other steady states. *The analysis of a nonlinear dynamic problem must therefore always begin with a search for all the steady states depending on the parameters in the problem by solution of the full nonlinear problem.* In an appropriate frame at least one of the stationary states can often be found easily, but most often numerical methods must be used. The use of numerical methods will be discussed in Section 5.8. If multiple steady states exist, then they fortunately very often develop through so-called bifurcations or branching off from other steady states, when a control parameter in the problem is varied. This fact offers us a possibility to find multiple states by tracing already found steady-state solutions by varying the control parameter through the values where bifurcations take place and

then change to follow the new solution from the bifurcation in dependence on the control parameter. The fundamental steps in the solution of a nonlinear dynamic problem therefore consist of finding at least one stationary solution in a sufficiently large parameter interval and determine its stability in dependence on the parameter. Then find the bifurcation points where different steady solutions will be found. The new solutions and their stability must then be determined in dependence on the control parameter. The new solutions may create new bifurcation points, which must be found, and the game starts all over in these new bifurcation points. Unfortunately, there is no guarantee that *all* the steady-state solutions will be determined in this way, but experience shows that the method is very efficient. Good engineering know-how is still needed to judge whether all possible states have been found or it is necessary to use other strategies to find possible missing steady states.

Until the 1960s, the mathematics allowed us only to determine certain properties of the solutions of some nonlinear problems. In general, it was impossible to calculate the solutions of any but the simplest nonlinear problem. Various so-called asymptotic methods that expressed the solution in a series expansion that might converge were often very effective for finding approximate solutions, but the validity of the solutions was limited. Only the modern computer allows us to find solutions of complicated nonlinear problems that are valid for all values of the parameters and in the entire range of interest of the state variables.

An important property of the solution of a dynamic problem is the stability of its solutions. The stability investigation of a given solution leads to the determination of the eigenvalues with the largest real part of a *linear problem*. Early experience with nonlinear dynamic systems showed that the systems tend to a different kind of motion, when the original solution loses its stability—if it does not blow up. This new motion was therefore called an *instability* by the engineers and physicists. It is very unfortunate. The new motion is measurable and visible and it must therefore be stable. It is just another stable solution of the nonlinear problem, and its determination is a *problem of existence* of multiple solutions of nonlinear problems. The use of the term "instability" in this case is misleading—first of all because the motion called "instability" is stable—and also because the calculation of the solution is *not* a mathematical problem of stability but a problem of existence.

A nonlinear dynamic problem may have several different stable steady-state solutions—even though it is dissipative (see an example of multiple steady-state solutions in Figure 5.1). Each of them is uniquely determined by its own set of initial conditions. It means that we can relate a set of initial conditions uniquely to a stable steady-state solution of a nonlinear dynamic problem. Such a set of initial conditions is called a *basin of attraction*. In contrast, the solution of a *linear* dissipative dynamic system will always tend to a unique solution independently of the initial conditions. This fact has an important implication. If the dynamic problem has multiple stable steady states and the corresponding physical vehicle in the real world is subject to uncontrolled initial conditions, then finite probabilities exist for the vehicle to tend to anyone of the stable steady states. In other words, when several stable steady-state solutions of a dissipative problem coexist then the vehicle is *unstable to finite disturbances*.

Nonlinear mechanics deals with the formulation or modeling of processes, while nonlinear dynamics is a mathematical discipline. The topics therefore are different. We shall deal with nonlinear and *deterministic* dynamics in this chapter. Some basic information on *stochastic* dynamics is presented in Section 5.6. In nonlinear dynamics, the *existence* of solutions is the primary object of analysis in contrast to *stability*, which comes second.

In the following we shall introduce the basic notions of a *state space* and *trajectories*, because they lead to a visualization of the solutions of dynamic problems, their uniqueness (or lack of same), and stability. We shall also present the conditions under which a linearization of a nonlinear operator (problem) is permitted and indicate how the solution of the linearized problem can give valuable information about the local properties of the nonlinear problem. We shall define and examine stationary and other steady-state solutions, their stability, and bifurcations. Finally, properties of solutions that cannot exist in linear systems—such as chaos—will be described and their effects are briefly discussed.

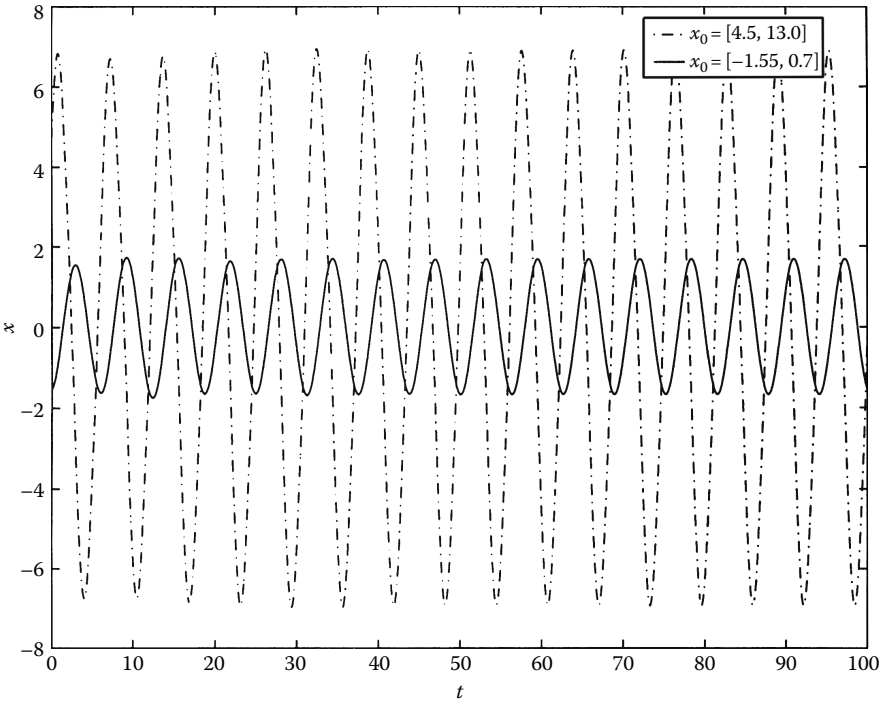

FIGURE 5.1 The two solutions of the initial value problem.

5.2 FORMULATION OF A PROBLEM IN VEHICLE DYNAMICS

The problems in theoretical vehicle dynamics are formulated as nonlinear dynamic multi-body problems. The rolling wheel–ground contact as well as the more rarely applied sliding contact are the most important features of a vehicle dynamic system, and the constitutive laws for these contacts are nonlinear. In a multi-body system the single bodies are interconnected, and several of the connections—for example, springs and dampers—obey nonlinear constitutive laws. Guides introduce constraints, which often are formulated by algebraic or transcendental equations, so the problems in vehicle dynamics must often be formulated as a system of differential-algebraic equations (DAEs). Bumper stops and dry friction contact are important nonlinearities that introduce discontinuities. The discontinuities violate the assumptions of the mathematical theorems, which form the basis of many methods that are applied for the solution of systems of DAEs.

In vehicle dynamics, the analysis of the problem is most often formulated as an initial value problem for a system of ordinary differential equations with time t as the single independent variable. The system of differential equations may be combined with algebraic or transcendental equations that express certain kinematic constraints, for example, the geometric contact between a wheelset and the rails. The constraint equations are in general nonlinear, and they must be solved together with the system of differential equations as one system of DAEs. Boundary value problems for partial differential equations or equations with time lag may, however, also enter the dynamic system, but they will not be considered in this brief survey.

The mathematical properties of nonlinear systems are fundamentally different from the mathematical properties of linear systems, and the nonlinear systems must be treated accordingly. An important difference between the properties of linear and nonlinear systems is that the principle of superposition does not apply to nonlinear systems. The principle of superposition is the basis of integral transform solution methods. Another difference is the effect of the initial conditions on the

steady-state solution of an initial value problem. A linear problem has only one steady-state solution independent of the initial conditions, but a nonlinear problem may have more steady-state solutions, where each one depends uniquely on the applied initial conditions. The existence of more steady-state solutions of a nonlinear problem is demonstrated in the following example of a nonlinear initial value problem [1].

Consider the nonlinear differential equation:

$$2.56\mathrm{d}^2x/\mathrm{d}t^2 + 0.32\mathrm{d}x/\mathrm{d}t + x + 0.05x^3 = 2.50\cos t$$

with the two initial conditions:

$$(x, \mathrm{d}x/\mathrm{d}t) = (4.5, 13.0) \quad \text{and} \quad (x, \mathrm{d}x/\mathrm{d}t) = (-1.55, 0.70) \quad \text{for } t = 0.$$

The initial value problems are easily solved with MATLAB®, and the results are shown in Figure 5.1. It is easily seen that although the excitation in both cases is a periodic function with the amplitude 2.50 and the system is damped, then there exists a steady-state large amplitude solution to the differential equation in addition to the expected steady-state solution with amplitude less than two. This is an example of *coexisting stable steady-state solutions*—called attractors, a term that will be defined later. When the corresponding linear problem is solved without the x^3 term, one and the same low amplitude steady-state periodic solution exists for both sets of initial conditions.

A dynamic system with two attractors is called *bistable*. If it has more than two attractors, it is called *multi-stable*.

Furthermore, oscillation frequencies are amplitude-dependent in nonlinear dynamics. As a consequence hereof, *the concept of resonance such as it is used in linear theory must be reconsidered and revised*.

The problems in vehicle dynamics are parameter-dependent. Examples of parameters are a wheel base, a weather-dependent friction coefficient, and the speed of the vehicle.

The state of the system is defined as the set of positions and velocities of each and every element of the vehicle in a suitable coordinate system. Both the positions and the velocities are treated as dependent variables in the dynamic system with time t as the independent variable. The dimension N of the state space equals the number of dependent variables of the dynamic system. The mathematical problem consists of finding the state of the system under external action as a function of the time and in dependence on the parameters. In Section 5.3, we shall start with the assumption that the parameters are all constant.

If time t does not enter the dynamic system explicitly, the system is called *autonomous*. If time t enters the dynamic system explicitly, or the parameters depend on time, then the dynamic system will be *nonautonomous*. An N-dimensional nonautonomous dynamic system can be converted into an $(N + 1)$-dimensional autonomous system by the introduction of time t as an additional dependent variable by the phase equation $\mathrm{d}t/\mathrm{d}\tau = 1$, and consider τ the new independent time variable. We shall therefore only consider autonomous systems in the following. If the parameters depend on the state of the dynamic system, then the parameters will give rise to additional nonlinearities.

In order to simplify the nonlinear dynamic problem, the system may be idealized within certain limits. The simplest assumption is that all the parameters are independent of the state of the system, but it is wrong for all real mechanical systems. In many cases, however, it is possible to find intervals of the action in which certain parameters in practice (i.e., within a given small tolerance) remain constant. It may for example happen that the action of a damper in the problem of interest is limited to such a small velocity interval that its nonlinear character may be neglected. Such simplifications in the theoretical model must, however, be made with great caution, because they may change the solutions of the problem *qualitatively* and/or *quantitatively* and important properties of the solution may be lost.

5.3 ON THE GEOMETRY OF NONLINEAR AUTONOMOUS DYNAMIC SYSTEMS WITH CONSTANT PARAMETERS

5.3.1 Some Definitions

The geometric theory of nonlinear dynamic systems provides the best access to an understanding of the behavior of such systems. A dynamic system is a system of first-order ordinary differential equations that often is connected with a system of algebraic or transcendental equations, which define constraints in the system. The dependent variables x_i, $i = 1, 2, \ldots, N$ are called *state variables*, and they are all real. $\boldsymbol{x}$ is the N-dimensional vector $\boldsymbol{x} = \{x_i\}$, $i = 1, 2, \ldots, N$. Time, t, is the independent variable. We denote $\mathrm{d}x_i/\mathrm{d}t$ by $\dot{x}_i$ and correspondingly $\mathrm{d}\boldsymbol{x}/\mathrm{d}t$ by $\dot{\boldsymbol{x}}$. $\boldsymbol{\lambda} = \{\lambda_j\}$, $j = 1, 2, \ldots, M$ denotes a set of M real-valued parameters. A *parameter-dependent nonlinear dynamic system* can then be written in the form

$$\dot{\boldsymbol{x}} = \boldsymbol{F}(\boldsymbol{x}; \boldsymbol{\lambda}). \tag{5.1}$$

$\boldsymbol{F}$ is an N-dimensional real-valued "sufficiently smooth" nonlinear vector function of the N-dependent variables x_i. By *function* we always mean an expression from which the value of the function is determined *uniquely* by the argument. If uniqueness is not guaranteed, we speak of a *relation*. An example of a relation is the expression $f = \pm\sqrt{x}$, since there exist two real values of f for every positive value of x. When we deal with functions, we call the set of all permissible values of the arguments x_i *the domain of the function* $\boldsymbol{F}$. The set of values that the function can assume for all permissible variations of the arguments is called *the range of the function* $\boldsymbol{F}$.

The number of degrees of freedom (DOF) K of a mechanical system equals the number of generalized coordinates of the system. The mechanical system will normally be modeled mathematically by a system of K ordinary differential equations of second order in the dependent variable q_i. The trivial substitution $q_i = x_{2i-1}$ and $\dot{q}_i = x_{2i}$, $i = 1, 2, \ldots, K$ will however transform the system of K second-order differential equations into a dynamic system of $2K$ first-order differential equations, and we then set N equal to $2K$.

We now introduce a Cartesian coordinate system with the state variables x_i as the coordinates. The system will be N-dimensional and it is denoted *the state space* or *phase space*. We can plot the values $x_i(t)$ that satisfy Equation 5.1 for fixed parameter values λ_j in the phase space. We then obtain a set of curves, depending on the initial conditions, which are called *trajectories* or *integral curves*. They are the geometric state space representations of the solutions of the initial value problems defined by Equation 5.1. t is a curve parameter and associated with each trajectory is a direction showing how the state of the system changes as time increases. The complete picture is called *the phase diagram* or *phase portrait* of the system. A point in the phase space is called an *image point* and the trajectory through an image point is often termed a *phase trajectory* in order to distinguish it from the trajectory of the motion in the physical world, which is $\boldsymbol{q}(t)$. The speed of an image point is called *the phase speed* not to be confused with the physical speed of the elements in the system. In autonomous systems $\dot{\boldsymbol{x}} = \boldsymbol{F}(\boldsymbol{x}; \boldsymbol{\lambda})$ with $\boldsymbol{F}$ sufficiently smooth, *trajectories cannot cross each other*, meaning that the motion of the system on a trajectory is determined *uniquely* by any point on that trajectory. An *equilibrium point* is an image point that does not change with time, so its phase trajectory is just a point. It corresponds to a *stationary state* in the state space and a *stationary solution* of the dynamic system. A point, in which the slope of the trajectory is not defined, is called a *singular point*; all other points are called *regular points*. An equilibrium point is a singular point.

Since a periodic solution will always return to any given state with its period T, *the trajectory of a periodic solution must be a closed curve.*

Dissipative autonomous systems are *contracting in the phase space* in the sense that a small volume bounded by a bundle of trajectories and lying between t_0 and $t_0 + \mathrm{d}t$ will decrease when it moves along its bundle of trajectories with growing t (see Figure 5.2 for two examples).

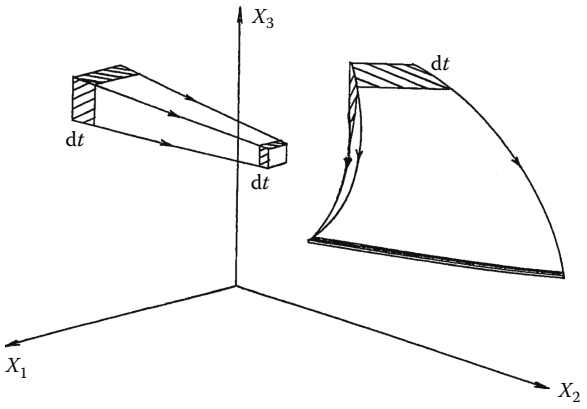

FIGURE 5.2 Examples of trajectories of a dissipative dynamic system in a state space.

5.3.2 Stability Concepts

We now introduce the four most important concepts of stability. First, we define the stability of equilibrium points or stationary solutions. Given

$$\dot{\boldsymbol{x}} = \boldsymbol{F}(\boldsymbol{x}; \lambda) \tag{5.1}$$

with the equilibrium point $\mathbf{0}$. It means that

$$\boldsymbol{F}(\mathbf{0}; \lambda) = \mathbf{0}.$$

A simple coordinate transformation will take any one point in the state space to $\mathbf{0}$.

For equilibrium points, we first define *local stability* or *Lyapunov stability.*

Definition 5.1

If there for all $\varepsilon > 0$ *exist* $\delta > 0$ *(to every* δ *there corresponds an* ε*) such that* $\|\boldsymbol{a}\| < \delta \rightarrow \|\boldsymbol{x}(t)\| < \varepsilon$ *for all t, where* $\boldsymbol{a}$ *denotes an initial condition and* $\| \ \|$ *denotes a suitable norm (or measure) then the point* $\mathbf{0}$ *is* locally stable *or* Lyapunov stable.

The definition states that a trajectory, which starts inside a ball with radius δ and center in $\mathbf{0}$ (the domain needs not be spherical), will never leave the ball with radius ε and center in $\mathbf{0}$ (the domain is not necessarily spherical) (see Figure 5.3).

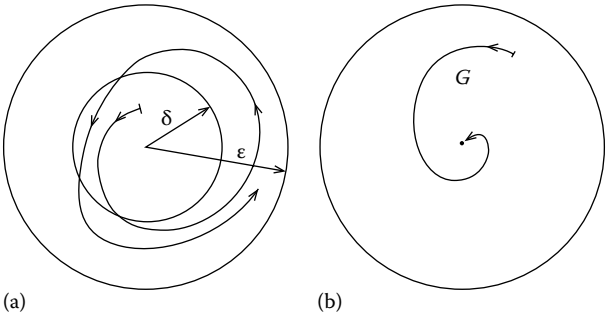

FIGURE 5.3 Trajectories near the stable point $\mathbf{0}$. (a) Locally stable and (b) asymptotically stable.

Definition 5.2

If $\boldsymbol{0}$ *is locally stable for all trajectories that start inside a domain G, which contains* $\boldsymbol{0}$*, and the following relation in addition holds*

$$\|\boldsymbol{x}(t)\| \to 0 \quad \text{for } t \to \infty$$

then $\boldsymbol{0}$ *is* asymptotically stable.

It is the second and most used concept of stability for dissipative systems. The definition states that $\mathbf{0}$ is asymptotically stable if all trajectories that start in G or enter G ultimately will come arbitrarily close to $\mathbf{0}$.

Next, we define *orbital stability*. We now consider an orbit or closed trajectory H and a tube of radius ε around H. Please remember that a closed trajectory in phase space represents a periodic solution in the physical space.

Definition 5.3

If all paths starting from initial points $\boldsymbol{a}^*$ *within a distance* δ *from any point* $\boldsymbol{a}$ *on H remain permanently within a tube of radius* ε *for* $t \to \infty$ *then the orbit H is* orbitally stable.

If all the paths come arbitrarily close to H for $t \to \infty$, then the orbit H is *asymptotically orbitally stable* (see Figure 5.4). This definition can be extended to other steady-state solutions of the dynamic system.

Points or paths that are not stable (locally or orbitally) are *unstable*. They are unstable under *infinitesimally small disturbances*.

All the stability concepts mentioned earlier refer to stability with respect to disturbances of *initial conditions*. The last concept of stability we shall use refers to disturbances of the vector function

$$\boldsymbol{F}(\boldsymbol{x}; \boldsymbol{\lambda})$$

We, therefore, finally define *structural stability*.

Definition 5.4

A dynamic system is structurally stable *if small disturbances of the vector function* $\boldsymbol{F}(\boldsymbol{x}; \boldsymbol{\lambda})$ *lead to equivalent phase diagrams*.

An observable phenomenon should always be modeled by a structurally stable system, because small errors in the modeling and fluctuations in the physical system are unavoidable. A conservative dynamic system is structurally unstable according to this definition, since the addition of an ever so small dissipation will change the phase diagram qualitatively.

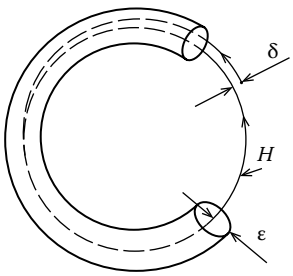

FIGURE 5.4 An asymptotically orbitally stable trajectory.

For the investigations of asymptotic stability of equilibrium points, *Lyapunov's first method* may be applied. With no loss of generality, we shall again assume that the equilibrium point is **0**. Given the autonomous system:

$$\dot{\boldsymbol{x}} = \boldsymbol{F}(\boldsymbol{x}; \boldsymbol{\lambda}) \tag{5.1}$$

with $\boldsymbol{F}(\boldsymbol{0}; \boldsymbol{\lambda}) = \boldsymbol{0}$

We assume that *the Jacobian*

$$\boldsymbol{J} = \left[\frac{\partial f_i}{\partial x_j}\right], \quad i, j = 1, 2, \ldots, N,$$

exists and provides the matrix $\boldsymbol{J_0}$ in $\boldsymbol{x} = \boldsymbol{0}$. We then write Equation 5.1 in the form:

$$\dot{\boldsymbol{x}} = \boldsymbol{F}(\boldsymbol{x}; \boldsymbol{\lambda}) = \boldsymbol{J_0 x} + \boldsymbol{G}(\boldsymbol{x}; \boldsymbol{\lambda}), \quad \boldsymbol{J_0} = \boldsymbol{J_0}(\boldsymbol{\lambda}).$$

The equation

$$\dot{\boldsymbol{x}} = \boldsymbol{J_0 x} \tag{5.2}$$

is Equation 5.1 *linearized around* **0**, and $\boldsymbol{G}(\boldsymbol{x}; \boldsymbol{\lambda})$ is a remainder, which contains all the nonlinear contributions.

Theorem 5.1

Let **0** be an equilibrium point of $\dot{\boldsymbol{x}} = \boldsymbol{F}(\boldsymbol{x}; \boldsymbol{\lambda})$.

1. *If the Jacobian* $\boldsymbol{J_0}$ *has neither zero nor purely imaginary eigenvalues*
2. $\|\boldsymbol{G}(\boldsymbol{x}; \boldsymbol{\lambda})\|/\|\boldsymbol{x}\| \to 0$ for $\|\boldsymbol{x}\| \to 0$

then it is a necessary and sufficient condition for asymptotic stability *of* **0** *that all solutions of* $\dot{\boldsymbol{x}} = \boldsymbol{J_0 x}$ *are* locally stable.

In other words, under the conditions stated, the *linearized system* determines the stability of the full nonlinear system in a certain neighborhood of **0**. Vehicle dynamic systems are dissipative systems, and local stability of $\dot{\boldsymbol{x}} = \boldsymbol{J_0 x}$ is therefore guaranteed, when all the eigenvalues of $\boldsymbol{J_0}$ have negative real parts. In Definition 5.1, δ may be very small, and in Theorem 5.1 the condition 2 may only be satisfied in a very small neighborhood of **0**. Therefore, the stability is local in the sense that the stability of the trivial solution, $\boldsymbol{x} = \boldsymbol{0}$, is only guaranteed for infinitesimally small disturbances. The same limitation holds for linear stability analyses.

In order to linearize a dynamic system, *it must be determined by a function* in order to guarantee uniqueness of the point you linearize around. When the function is expanded in a series around the point of expansion, the linear part must be the lowest order contribution when the variables approach the point of expansion; otherwise, the nonlinear terms will dominate the behavior of the function around the point of expansion.

Therefore, the coefficients of the linear terms in the expansion *must be finite and nonzero.* Therefore, $\boldsymbol{F}(\boldsymbol{x}; \boldsymbol{\lambda})$ in (5.1) cannot be linearized around **0** when for instance $\boldsymbol{F}(\boldsymbol{x}; \boldsymbol{\lambda}) = \pm\sqrt{x}$, x^2, or $\cos x$.

5.3.3 Equilibrium Solutions

We now consider equilibrium points and cycles of dissipative, autonomous problems with the parameters fixed:

$$\dot{\boldsymbol{x}} = \boldsymbol{F}(\boldsymbol{x}) \tag{5.3}$$

5.3.3.1 Equilibrium Points

We shall only consider equilibrium points for which Theorem 5.1 holds. The equilibrium points and their stability are then characterized by the sign of the eigenvalues of the Jacobian if the eigenvalues are real, and by the sign of the real part of the eigenvalues if the eigenvalues are complex. Since we have assumed that the state variables as well as the vector function $\boldsymbol{F}(\boldsymbol{x})$ are real, then the complex eigenvalues will always appear as complex conjugate pairs. If all the eigenvalues are real and of the same sign, then the equilibrium point is called a *nodal point* or a *node*. If all the eigenvalues are negative, then the nodal point is asymptotically stable; otherwise, it is unstable. If some eigenvalues are complex then the equilibrium point is called a *spiral point* or a *spiral* or a *focus*, and if the real parts of all the eigenvalues are negative then the spiral is stable. Notice that the corresponding eigenvectors span directions—in the case of nodal behavior—or planes in the case of spiral behavior (see Figure 5.5). In state spaces of dimension three or higher, an equilibrium point may have nodal properties along some directions and spiral properties in some surfaces.

If the real part of the eigenvalues has different signs, then the equilibrium point is a *saddle point* or just a *saddle*. A saddle i*s always unstable* since the eigenvectors belonging to the eigenvalues with positive real parts are directions of repulsion (see Figure 5.6). Notice that an equilibrium point is itself a trajectory, which consists of just that point. The trajectories that approach a stable equilibrium point will only get arbitrarily close to it in any finite time and never reach it. The theorem that trajectories in an autonomous system cannot cross each other thus still holds true.

The set of all the points on the trajectories that approach a stable equilibrium point is called *the basin of attraction* of that particular equilibrium point. When several stable equilibrium points coexist, it is particularly important to determine the basins of attraction for each of them, since one or more of the equilibrium points may be undesirable states (see Figure 5.7). Initial values that lead to the undesirable states should therefore be avoided.

5.3.3.2 Cycles

Cycles are state space representations of periodic motions. They are closed curves in the state space because of the periodicity. Before we consider cycles in more detail, it will be convenient to introduce the concept of a *discrete map* or just *map*. It is the discrete equivalent of our dynamic system (Equation 5.1).

An equation in the form:

$$\boldsymbol{y}_{n+1} = \boldsymbol{F}(\boldsymbol{y}_n; \boldsymbol{\lambda}), \quad n = 1, 2, \ldots$$

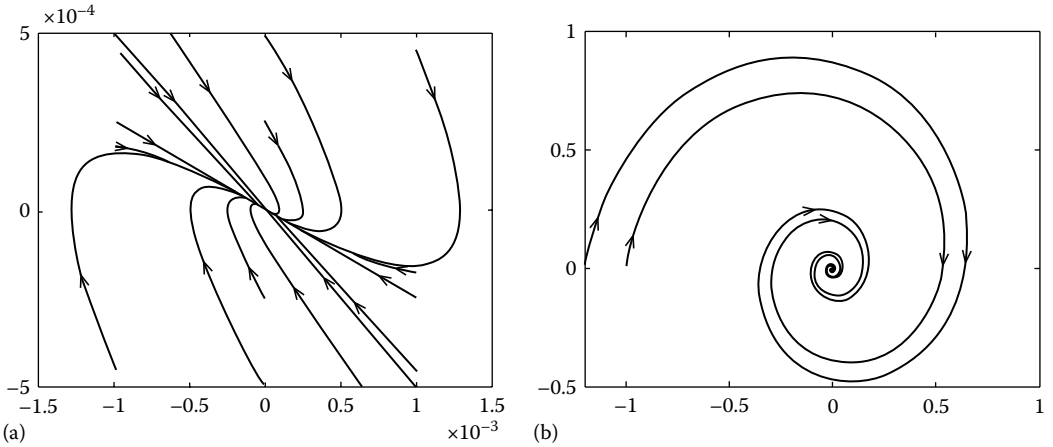

FIGURE 5.5 A stable node (a) and a stable spiral (b). If the directions of motion on the trajectories are reversed, then the equilibrium points are unstable.

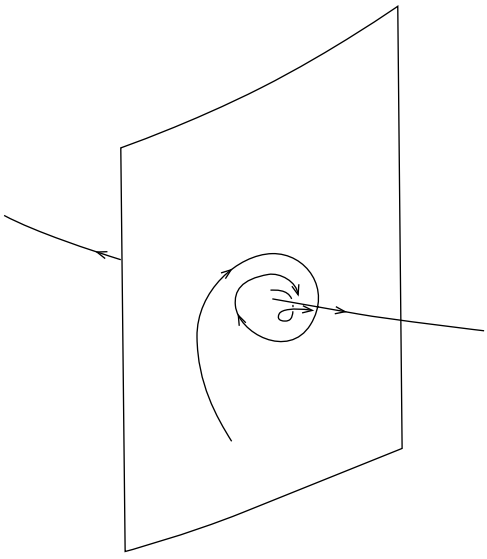

FIGURE 5.6 An example of a saddle in a 3D phase space. All saddles are always unstable. (A saddle in a phase plane is shown in Figure 5.7.)

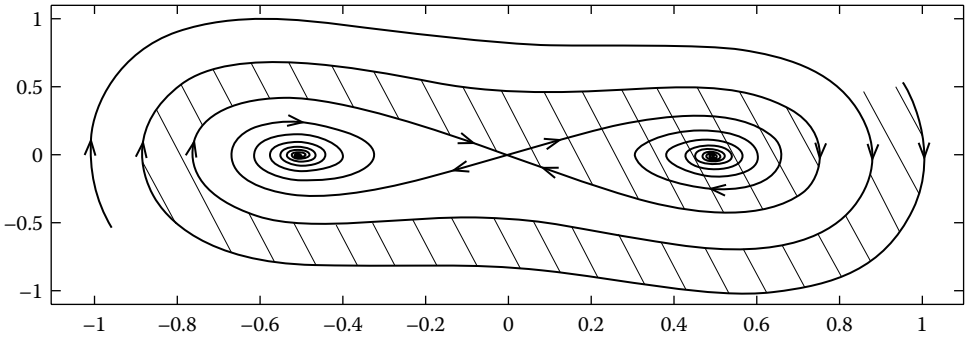

FIGURE 5.7 Two stable spirals separated by a saddle at $\boldsymbol{x} = \mathbf{0}$. The "incoming" asymptotic trajectories (insets) split the domains of attraction of the two spirals. (Notice how a saddle appears in a phase plane—compare with Figure 5.6.)

maps the nth vector $\mathbf{y}_n$ into the $(n+1)$st vector $\mathbf{y}_{n+1}$ by the *mapping function* $\boldsymbol{F}$. $\boldsymbol{F}$ is an N-dimensional real-valued "sufficiently smooth" nonlinear vector function of the N-dependent variables

$$y_n^i,\ i = 1,\ 2,\ \ldots,\ N.$$

When we investigate the dynamics of periodic or other recurrent motions, we shall use *the Poincaré map*. We introduce a plane in the state space and orient it in such a way that the trajectory intersects it transversally, that is, it is not a tangent plane to the trajectory at any point (Figure 5.8). Such a plane is called a *Poincaré section*. A cycle will intersect the Poincaré section at least twice but we now choose to consider only one of the intersection points $\boldsymbol{y}_0$. We now follow the cycle from $\boldsymbol{y}_0$ all the way around the trajectory until it intersects the Poincaré section again *in the same direction*. We call that point $\boldsymbol{y}_1$. It is the image of $\boldsymbol{y}_0$ *under the Poincaré map* $\boldsymbol{P}$. $\boldsymbol{P}$ thus takes the point $\boldsymbol{y}_0$ into $\boldsymbol{y}_1$, and in the case of a cycle $\boldsymbol{y}_1$ will in general be identical to $\boldsymbol{y}_0$ so $\boldsymbol{P}$ reduces to the identity map $\boldsymbol{I}$. The domain and range of the map $\boldsymbol{P}$ lie in the Poincaré section only. You can think of the Poincaré map as a stroboscopic image of a point moving on a recurrent trajectory.

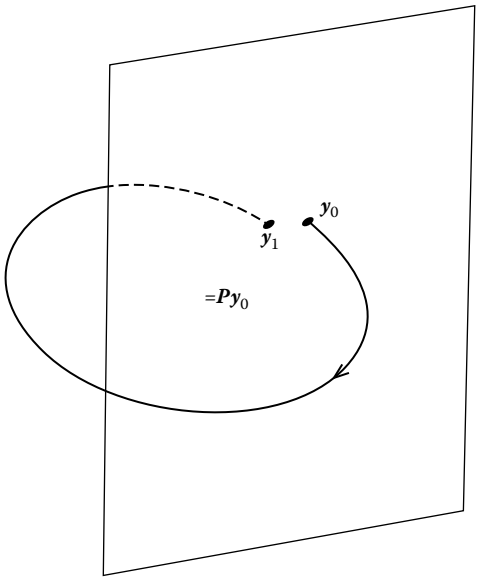

FIGURE 5.8 The Poincaré map.

The Poincaré map transforms a periodic solution of Equation 5.1 into a stationary solution in a Poincaré section of

$$\boldsymbol{y}_{n+1} = \boldsymbol{P}(\boldsymbol{y}_n; \lambda). \tag{5.4}$$

An equilibrium or fixed point $\boldsymbol{y}_0$ of the Poincaré map $\boldsymbol{P}$ has the property:

$$\boldsymbol{y}_0 = \boldsymbol{P}^m(\boldsymbol{y}_0; \lambda), \quad m = 1, 2, \ldots.$$

where $\boldsymbol{P}^m$ denotes the mth iterate of the Poincaré map $\boldsymbol{P}$. We can now apply the theory of stability of solutions of discrete maps to the equilibrium point for $\boldsymbol{P}$. In analogy with the theory for continuous systems, a linearization $\boldsymbol{P}_y$ of $\boldsymbol{P}$ is calculated and evaluated at the equilibrium point. The corresponding linear map will then be

$$\boldsymbol{y}_{n+1} = \boldsymbol{C}\boldsymbol{y}_n \tag{5.5}$$

where the elements of the matrix $\boldsymbol{C}$ are the elements of $\boldsymbol{P}_y$ evaluated at the equilibrium point. We now introduce the linear transformation

$$\boldsymbol{y} = \boldsymbol{A}\boldsymbol{z}$$

in Equation 5.5 and obtain

$$\boldsymbol{A}\boldsymbol{z}_{k+1} = \boldsymbol{C}\boldsymbol{A}\boldsymbol{z}_k$$

We assume that $\boldsymbol{A}$ is non-singular and multiply from the left with $\boldsymbol{A}^{-1}$ and obtain

$$\boldsymbol{z}_{k+1} = \boldsymbol{M}\boldsymbol{z}_k, \quad \boldsymbol{M} = \boldsymbol{A}^{-1}\boldsymbol{C}\boldsymbol{A} \tag{5.6}$$

We choose $\boldsymbol{A}$ so that $\boldsymbol{M}$ has a Jordan canonical form. If the eigenvalues ρ_m of $\boldsymbol{C}$ are distinct, $\boldsymbol{M}$ is a diagonal matrix with entries $\rho_1, \rho_2, \rho_3, \ldots, \rho_N$. Then the kth iterate of Equation 5.6 can be rewritten as

$$z_{k+1}^{(m)} = \rho_m z_k^{(m)}, \quad m = 1, 2, \ldots, N$$

where $z^{(m)}$ is the mth component of z. It follows from Equation 5.6 that for $k \to \infty$,

$$z_k^{(m)} \to 0 \quad \text{if } |\rho_m| < 1$$

$$z_k^{(m)} \to \infty \quad \text{if } |\rho_m| > 1$$

$$z_k^{(m)} = z_0^{(m)} \quad \text{if } \rho_m = 1$$

$$z_{2k+1}^{(m)} = -z_0^{(m)} \quad \text{and}$$

$$z_{2k}^{(m)} = z_0^{(m)} \quad \text{if } \rho_m = -1.$$

We see that the location of the eigenvalues ρ_m of $\boldsymbol{C}$ in the complex plane determines the stability of the equilibrium point $\boldsymbol{y}_0$. If all the eigenvalues of $\boldsymbol{C}$ lie inside the unit circle in the complex plane, the equilibrium point $\boldsymbol{y}_0$ is asymptotically stable. If at least one of the eigenvalues lies outside the unit circle, then $\boldsymbol{y}_0$ is unstable. If at least one of the eigenvalues lies on the unit circle and all the rest inside, then a linear stability analysis will be inconclusive.

If $0 < \rho_m < 1$ for all ρ_m disturbances will decay monotonously, and if for at least one eigenvalue ρ_k $-1 < \rho_k < 0$ disturbances will decay in an oscillatory fashion. We call this behavior *flipping*. If at least one eigenvalue is complex, then the disturbance will rotate around the equilibrium point while it decays or grows depending on whether all eigenvalues are inside the unit circle in the complex plane or not. A cycle is thus *orbitally asymptotically stable*, if all the eigenvalues of $\boldsymbol{C}$ lie inside the unit circle in the complex plane [4,6].

As before, the set of all the points on the trajectories in the state space that approach a stable cycle is called *the basin of attraction* of that particular cycle. A stable steady solution is called an *attractor*. It can be a point, a cycle, or a higher-dimensional or even fractal-dimensional structure. An unstable stationary periodic solution is most often a *saddle cycle*. When several attractors coexist, it is desirable to determine the basins of attraction for each of them in order to guard against unpleasant surprises caused by initial conditions that will lead to one of the undesirable attractors.

All that have been said earlier about the calculation of stability of cycles only serve to help the reader understand the concept and the relation between cycles in state space and Poincaré maps. It is not a recipe for a stability analysis of periodic solutions of nonlinear problems. The reason is that *the author has never seen any nonlinear dynamic system*

$$\dot{\boldsymbol{x}} = \boldsymbol{F}(\boldsymbol{x}; \lambda)$$

with a periodic solution, where the corresponding Poincaré map

$$\boldsymbol{y}_{n+1} = \boldsymbol{P}(\boldsymbol{y}_n; \lambda), \quad n = 1, 2, \ldots$$

could be determined explicitly. Instead *Floquet theory* (see [4,6]) is often applied directly to the continuous problem (Equation 5.1). We shall however here present an easier method that is suitable for a numerical analysis of a known periodic solution of a dynamic problem.

Given a periodic solution to Equation 5.1, $\boldsymbol{x}_0(t, T_0)$ with the known period T_0. Choose a value of t, say t_0 and calculate $\boldsymbol{x}_0(t_0, T_0)$. Put a plane S that contains $\boldsymbol{x}_0(t_0, T_0)$ in the state space transversal to the trajectory of $\boldsymbol{x}_0(t, T_0)$. Add a small disturbance $\boldsymbol{y}$ to $\boldsymbol{x}_0(t_0, T_0)$ in S, so both $\boldsymbol{x}_0(t_0, T_0)$ and $\boldsymbol{x}_0(t_0, T_0) + \boldsymbol{y}$ lie in S. Calculate the distance $d_0 = \|\boldsymbol{y}\|$ between $\boldsymbol{x}_0(t_0, T_0)$ and $\boldsymbol{x}_0(t_0, T_0) + \boldsymbol{y}$. Integrate the dynamic problem (Equation 5.1) with the initial condition $\boldsymbol{x}_0 + \boldsymbol{y}$ for one or a couple of periods T_0 and obtain another point $\boldsymbol{x}_1 = \boldsymbol{x}_0(t_0, T_0) + z$ in H. Calculate the distance $d_1 = \|z\|$ between $\boldsymbol{x}_0(t_0, T_0)$ and $\boldsymbol{x}_0(t_0, T_0) + z$. Finally, calculate the ratio $\rho = d_1/d_0$. If $\rho < 1$, then the periodic solution $\boldsymbol{x}_0(t, T_0)$ is *asymptotically orbitally stable*. Otherwise, it is unstable.

In conclusion, we shall note that recurrent solutions that are characterized by several periods are also possible in nonlinear dynamic systems. They are called *multi-periodic* solutions. In case all the periods are commensurate—that is, the ratio between each pair of periods is a rational number—then the resulting motion is periodic. If that is not the case, then the resulting motion is *quasi-periodic*.

5.3.3.3 Chaos

It is a well-known fact that deterministic nonlinear dynamic systems can behave erratically. We want here to make a clear distinction from random motion. We shall call a process *random*, when uncertainties in the dynamic system appear as probabilistic relations or state variables. Such systems are not considered here.

The kind of erratic behavior in deterministic systems is therefore of another character, and it is often called *chaos*. There exist both *chaotic attractors* also called *strange attractors* and *chaotic repellers*. Since only the attractors can be observed in real-life situations, we shall only describe those. There is a third important form of chaotic motion—*chaotic transients*—which will be discussed briefly later.

Chaotic motion is *recurrent* but it is neither periodic nor quasi-periodic. Since it is recurrent but nonperiodic, the trajectories of a chaotic motion will "return" to the neighborhood of points they passed earlier without ever closing up at any point. Furthermore, all trajectories on a chaotic attractor are orbitally unstable. They reject each other like saddle cycles, so in order to hold the bundle of all trajectories inside a bounded domain a *reinjection mechanism* must be at work in the dynamic process. That reinjection mechanism takes a bundle of trajectories and folds them back onto the other trajectories without touching any of them. This action is the cause of *mixing* in chaotic dynamics. In a 3D phase space, the attractor therefore consists of many infinitely thin "layers" in which the trajectories are imbedded—a structure that can be described by the mathematical concept of a *fractal dimension*. The layers are separated and so close to each other that the attractor seems 2D in the 3D phase space.

In Figure 5.2 (right-hand side), an example of a set of trajectories that repel each other in a surface and contract in the direction normal to the surface is shown. This action is typical for chaos. Due to the dissipation, the volume elements in phase space must decrease with time—as earlier mentioned—but that property does not prohibit a development as shown in Figure 5.2. We only need still to fold the two diverging "wings" back on top of each other and bend the whole structure around a cylinder in order to obtain a picture of the structure of a simple chaotic attractor (see Figure 5.9). It shows the simplest known chaotic attractor—the so-called *Rössler attractor.* Because of the folding action, chaos in autonomous systems only exists in three- or higher-dimensional systems.

$$\dot{x} = -y - z; \quad \dot{y} = x + 0.398y; \quad \dot{z} = 2 + z(x - 4)$$

A chaotic attractor can, according to Thompson and Stewart [1], briefly be described as "a stable structure of long-term trajectories in a bounded region of phase space, which folds the bundle of trajectories back onto themselves, resulting in mixing and divergence of nearby states."

When chaos develops in a nonlinear dynamic system—in a real-life situation or a numerical simulation—the very first indication is a seemingly erratically oscillating behavior of one or more components of the system. A hallmark of chaotic motion is its *sensitivity to changes*

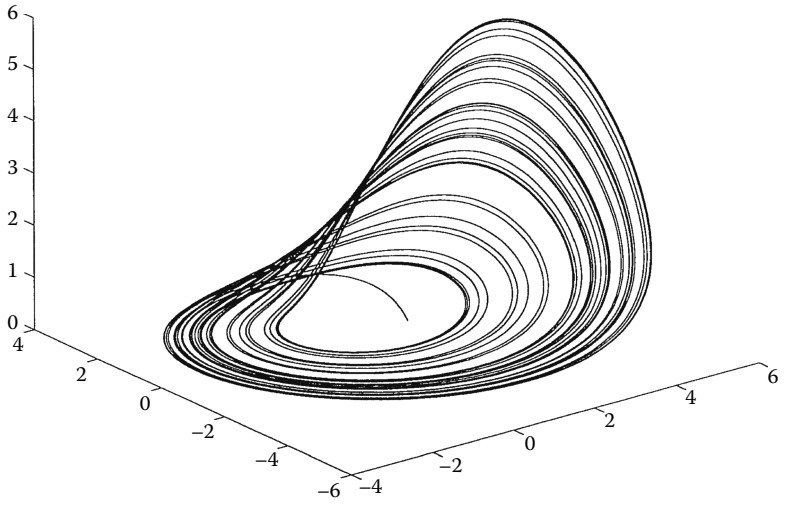

FIGURE 5.9 Rössler's chaotic attractor. It is a steady solution of the dynamic system.

in the initial conditions, but there exist other indicators. According to Moon [2], the following features characterize chaos:

1. Broad spectrum of Fourier transform when the motion is generated by a single frequency (measured by fast Fourier transform [FFT]).
2. Fractal properties of the motion in phase space, which denote a chaotic attractor (measured by Poincaré maps or fractal dimensions).
3. The complexity of the motion (measured by Lyapunov exponents). See a book on nonlinear dynamics [1–9].

When one suspects a motion to be chaotic, the first test is to watch a time series of a component of the motion. Then look at a phase diagram and at least one Poincaré section (see Figure 5.10). Next—if possible—repeat the process with slightly changed initial conditions. If the values of the state variables are changed in regions of the long-time evolution when the initial conditions are changed, then the process is chaotic. You can also quantify the degree of disorder by computations of measures of the fractal dimension of the attractor or—the author's own favorite—a calculation of the largest Lyapunov exponent(s). If a series of calculations of the largest Lyapunov exponent converges to a positive value, then the motion is chaotic.

When the dynamics is chaotic and multiple attractors exist, then the boundaries of the basins of attraction or the basins themselves may be *fractal dimensional*. As a consequence thereof, there exist points $\boldsymbol{X}_n$ in one of the basins of attraction with the property that there exists at least one point in the other basin of attraction in any neighborhood of $\boldsymbol{X}_n$. In other words, when the boundary of a domain of attraction or the domain itself is fractal dimensional then the result of an experimental investigation of the dynamic problem is in general unpredictable.

We shall conclude this brief introduction to chaos by defining *transient chaos*. It is a motion that looks chaotic and appears to show the characteristic features of a chaotic attractor, but it eventually settles into a regular motion or a chaotic attractor. It often appears when multiple attractors exist in phase space. Dynamic systems with chaotic transients must be treated with caution. The transients often decay with ever-decreasing oscillations into a regular motion, but cases have been found where chaotic transients have amplitudes, which are larger than the amplitudes of the attractor, which the transient approaches. Such chaotic transients can be the cause of catastrophic developments in a dynamic system. Pascal [10] has investigated the derailment of a two-axle freight wagon, which moved chaotically.

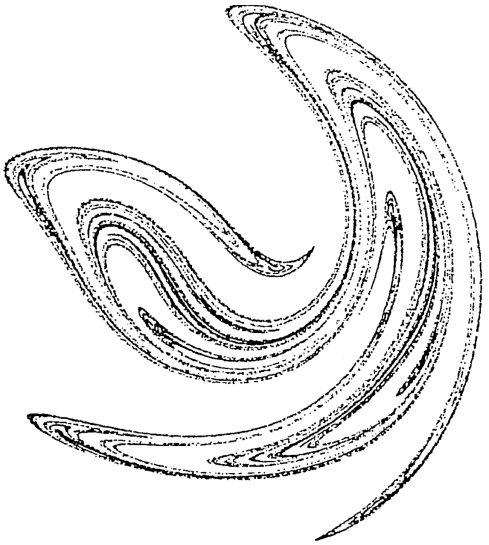

FIGURE 5.10 A Poincaré section plot of one of Ueda's chaotic attractors. The banded structure is typical of chaos. (Thompson, J.M.T. and Stewart, H.B., *Nonlinear Dynamics and Chaos*. 1986. Copyright Wiley-VCH Verlag GmbH & Co. KGaA. With permission.)

In general, chaos is considered the ultimate development of the dynamics of a parameter-dependent system when one or several parameters grow. However, in chaotic systems patterns may develop whereby a reorganization of the dynamic system in clear structures occurs. Maicz et al. [11] treat an example from railway vehicle dynamics.

5.4 PARAMETER-DEPENDENT SYSTEMS AND BIFURCATIONS

We shall concentrate the survey on systems with only one varying parameter λ. It is called a *controlled* parameter. In vehicle dynamic problems the speed of the vehicle, V, is such a parameter. The solutions $\boldsymbol{x}(t; \lambda)$ of the nonlinear dynamic problem

$$\dot{\boldsymbol{x}} = \boldsymbol{F}(\boldsymbol{x}; \lambda) \tag{5.1}$$

will then depend on the parameter λ as well as on time. When we vary λ in a continuous fashion, the solution will change continuously (according to our assumptions) but what is more important, *the number of solutions may change*, that is, in addition to the already known solution other solutions may appear or disappear at certain parameter values. Obviously our dynamic system is not structurally stable at such parameter values, since an infinitesimal change in the parameter value will change the phase diagram. These features will be depicted in a *parameter-state space diagram*, where the parameter λ is the independent variable. In order to be able to present the diagram in a plane, the states in the phase space are represented by a norm for instance the maximum amplitude or a Euclidean norm.

Very often in nonlinear dynamics, a change in the number of solutions happens through a *branching* or *bifurcation* from an existing solution under a continuous change of the parameter. Another common form of bifurcation is a solution that "turns around" in the sense that the sign of the parameter increments changes in order to follow the solution in the parameter-phase space diagram. Such a bifurcation is called a *fold* or *saddle-node bifurcation*, because the solution changes stability when "it moves around the fold" (see Figure 5.11). We call all these changes *local bifurcations*. They are very important for the analysis of the dynamics of the system, and they occur only in nonlinear systems.

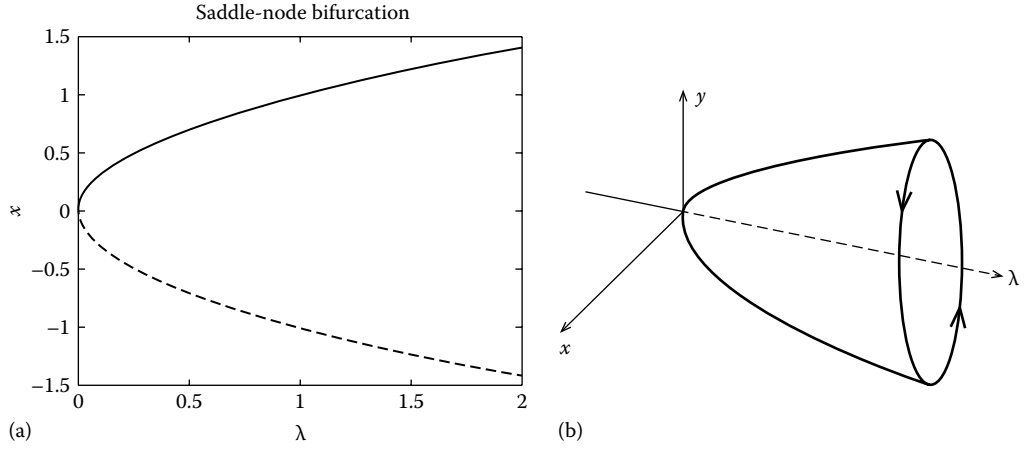

FIGURE 5.11 A saddle-node bifurcation (a) and a Hopf bifurcation (b). A full line denotes a stable and a broken line an unstable solution.

They have in common that the parameter values where bifurcation occurs—*the bifurcation points*—can be found by an analysis of the parameter-dependent eigenvalues of the associated Jacobian. We shall assume in the following that the solution we want to investigate—the original solution—is *asymptotically stable* to start with. In all the cases, the original solution will *lose stability* in the bifurcation point. This is the connection to the well-known linear stability theory.

We can also introduce structural stability of bifurcations. The phrase, however, is hardly ever used in that context. Instead, we denote a bifurcation *generic*, that is, "commonly occurring" when a small change of the dynamic system does not change the properties of the bifurcation.

There are only two generic bifurcations from an equilibrium point under one control parameter. They are the earlier mentioned *saddle-node*, when the largest eigenvalue of the Jacobian becomes positive, and the *Hopf bifurcation* (named after the mathematician, who first described it), which is a bifurcation of a *periodic solution* (see Figure 5.11). In that case, a complex conjugate pair of eigenvalues of the Jacobian crosses the imaginary axis in the complex plane into the positive real half plane. These two kinds of bifurcations are very common in vehicle dynamics.

If we allow more simultaneously acting control parameters, then two additional generic bifurcations are possible. They are the *transcritical bifurcation* and the *pitchfork bifurcation* or *symmetry breaking bifurcation*, when it occurs in systems that are symmetric in some way (see Figure 5.12).

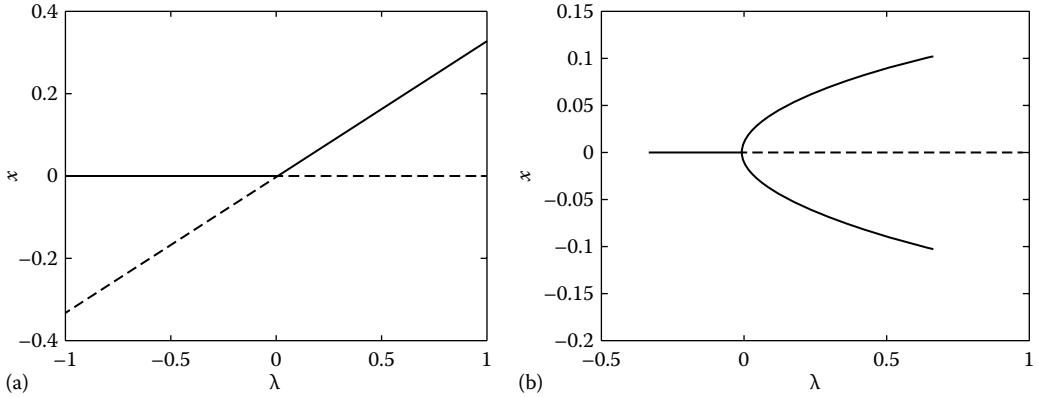

FIGURE 5.12 A transcritical bifurcation (a) and a pitchfork bifurcation (b). A full line denotes a stable and a broken line an unstable solution.

In both cases the largest eigenvalue of the Jacobian becomes positive when λ grows through the bifurcation point, and a computation of the *normal form* (see [6]) is necessary to distinguish them from the saddle-node bifurcation. Today, *center manifold reduction* and *normal forms* are commonly used for local bifurcation analyses. The center manifold reduction theorem states that the change of dynamic behavior of an *N*-dimensional dynamic system around the generic bifurcations can be described by the change of dynamic behavior on a curve or 2D surface in the parameter-phase space. The curve or surface is called a *center manifold* (see Section 5.5). This important theorem guarantees that the bifurcations characterized by one or two eigenvalues of the Jacobian crossing the imaginary axis in the complex plane are the only generic ones that will be found in any *N*-dimensional dissipative dynamic system. The normal form is the simplest possible expression that is necessary to characterize the nonlinear dependence of the amplitudes of the solutions on the parameter near the bifurcation point.

All these bifurcations are also generic for cycles. Only instead of an eigenvalue crossing the imaginary axis, an eigenvalue must escape from the unit disk. A Hopf bifurcation from a cycle creates generically a quasi-periodic motion. Its trajectory lies on a torus in state space and the bifurcation is often called a *Naimark bifurcation*. For cycles there exists an additional bifurcation, the *flip bifurcation* or *period-doubling bifurcation*. In a flip bifurcation, a new periodic motion develops with twice the period of the original motion. A plot of the trajectory of a period-two solution could be the edge of a Möbius strip. The best-known transition to chaos is an infinite sequence of period-doubling bifurcations.

For cycles the analog of "the eigenvalue of the Jacobian crossing into the positive real half plane" is "the Floquet multiplier crossing the unit circle in the complex plane." The Floquet multiplier in dynamic systems is the analog of ρ_m introduced in Section 5.3.3.2. If the Floquet multiplier crosses "1," then we have a fold, or a transcritical, or a pitchfork bifurcation, where again additional calculations are necessary to determine the type. If the Floquet multiplier crosses "–1" we have a period-doubling bifurcation, and if it crosses almost anywhere else (a few special points are excluded) it is a Naimark bifurcation.

There exist conditions for the stability of the bifurcating solution—or new branch—from equilibrium points. For the case of a Hopf bifurcation, see Figure 5.13.

As a main rule, an analysis of a bifurcation consists of three parts:

1. Determination of all the branches
2. Determination of the stability of the original solution on the other side of the bifurcation point
3. Determination of the stability of the new solution(s)

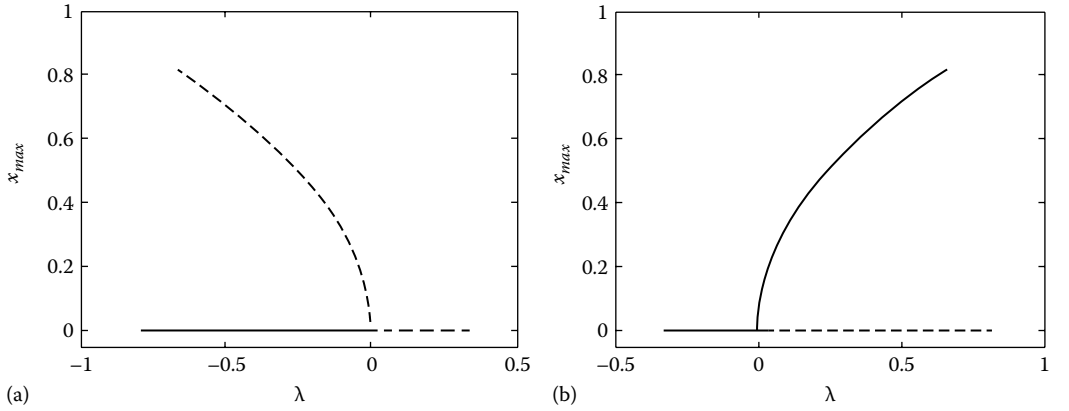

FIGURE 5.13 A subcritical Hopf bifurcation, the periodic solution is unstable (a) and a supercritical Hopf bifurcation, the periodic solution is stable (b). A full line denotes a stable and a broken line an unstable solution.

However, there are other situations in which solutions can appear or disappear. Consider a case where we follow a certain solution in parameter-state space and a parameter value is reached at which a saddle-node appears somewhere in the parameter-phase space away from the solution we follow. Relative to our "certain solution," the saddle-node bifurcation is a *global bifurcation*. There exist many other kinds of global bifurcations, which due to their nature cannot be investigated by "local methods" such as a linearization around a known point in parameter-phase space. For further information, the reader is referred to one of the several books on nonlinear dynamics [1–9].

For the sake of completeness, we just mention *tori* as examples of other equilibrium sets in the phase space. Quasi-periodic functions and multi-periodic functions all lie on tori in appropriate phase spaces. We refer to the literature on nonlinear dynamics for information on their properties and the bifurcations that are connected with them.

5.5 CENTER MANIFOLD REDUCTION THEOREM

The center manifold reduction theorem is the mathematical basis for linking the results we presented in the preceding section to vehicle dynamic systems with their in general high number of DOF. The theorem basically states that all the bifurcations that may be found in high-dimensional parameter-state spaces in general are those described in Section 5.4. The theorem is, however, proven only for systems of differential equations and is valid only for bifurcations from equilibrium points and limit cycles. Furthermore, the dynamic systems must also satisfy certain conditions of smoothness, and *vehicle dynamic systems will rarely satisfy either one of these conditions*. Vehicle dynamic systems are often formulated as differential-algebraic systems, and *the systems are rarely smooth*. In Section 5.7, we shall therefore briefly describe some of the effects discontinuities like impacts and dry friction with stick-slip may have on the bifurcations.

5.6 ON STOCHASTIC DYNAMICS AND THE INFLUENCE OF NOISE

Stochastic elements in the vehicle dynamic models and data represent uncontrolled environmental impacts, thermal fluctuations, or hidden internal dynamics. In sharp contrast to linear systems or compared with systems close to equilibrium, noise and fluctuations in nonlinear dynamics may have a more crucial influence on the behavior of the systems as a result of the rare but large events leading for example to the escape from locally stable states as is found in bistable or multi-stable parameter regions in the vehicle dynamic problems. A channeling action of intrinsic nonlinearities may also influence the systems. Both effects give rise to signal and order amplification by noise or to the emergence of directed motion due to the presence of nonequilibrium fluctuations as discussed in many models and applications. It can be used constructively, in a controlled manner, to enhance nonlinear features leading to ordered behavior or to amplification of signals or deterministic responses. The traditional view on noise was guided by investigations of the linear dynamics of systems close to equilibrium. In such cases, noise introduces disorder and destroys temporal and spatial patterns such as for example symmetries in the system. In most applications, therefore, there have been attempts to minimize the effects of noise.

In a mathematical model of a vehicle dynamic system, noise can be modeled by added perturbations with certain spectral properties or by a representation of driving forces and/or parameters by probability distributions. The parameter dependence of the solutions will be then be expressed by probability distributions. It happens that unknown parameters are a part of the dynamic problem. In order to estimate them in the state space problem, the unknown parameters are often included in the state variables and special methods must be applied for the state estimation. The resulting state space model is in general a nonlinear one, and the extended Kalman filter is then most often used for the state estimation. These cases all lead to a system of *stochastic*

differential equations. For the solution of stochastic differential equations, the reader is referred to the literature (see Øksendal [12]).

For general information on the topic, the following references may prove valuable: The European Science Foundation (ESF) has funded a program on "Stochastic Dynamics: Fundamentals and Applications" (STOCHDYN). It ended in May 2008. Information may be found on the web address: www.esf.org/index.php?id=2266.

When the dynamic systems that we considered in the preceding sections are subjected to noise, some bifurcations may change character. The two generic bifurcations, saddle-node and Hopf, are preserved but the curves that characterize the Hopf bifurcation are smeared out in such a way that the transition to the periodic state takes place in a neighborhood of the bifurcation point of the corresponding deterministic system. An example is shown in Figure 5.14. The bifurcation diagram in Figure 5.14 actually demonstrates the influence of dry friction lateral damping on the dynamics of a railway wheelset (see [13]). Figure 5.14 compares the bifurcation diagram of a wheelset with friction damping with the bifurcation diagram of the same model but with no friction damping. In general, noise will smear out and eliminate a supercritical Hopf bifurcation in the same way as that shown in Figure 5.14.

Under added noise a supercritical pitchfork bifurcation breaks up into a branch with no bifurcation point together with a saddle-node bifurcation in the neighborhood of the bifurcation point of the corresponding system without noise. Near that neighborhood, the system may flip between the resulting two stable branches depending on the noise level (see Figure 5.15). A transcritical bifurcation breaks up under added noise in two different ways. One is into a stable branch and an unstable branch, both without bifurcation points. It means that the bifurcation disappears (see Figure 5.16). Near the bifurcation point of the corresponding noise-free system, the stable system may drift away from the branch if the noise level is sufficiently high. The second possibility is a breakup into two saddle-node bifurcations in the neighborhood of the bifurcation point of the corresponding

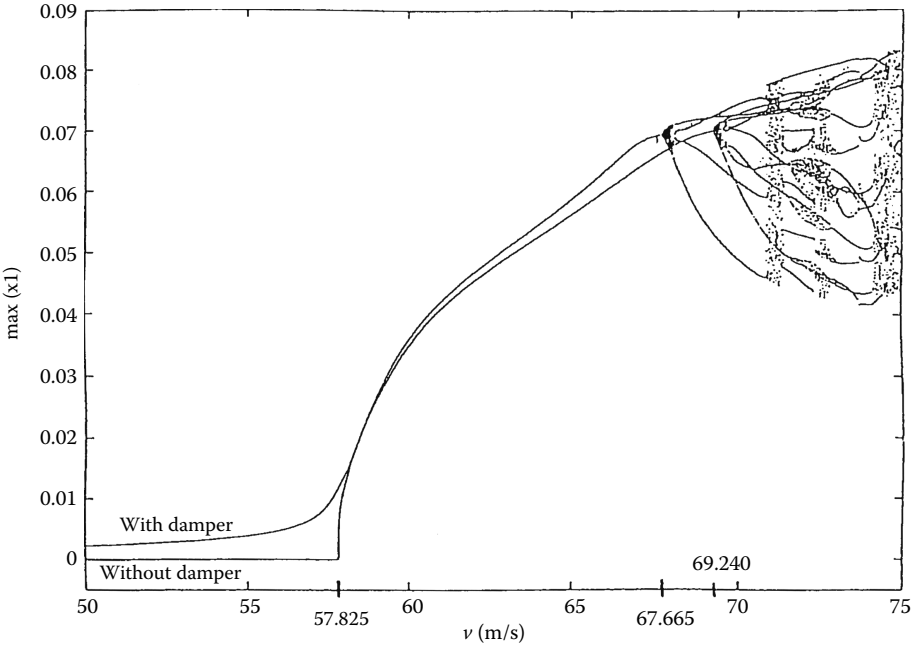

FIGURE 5.14 Two diagrams of the bifurcation in a wheelset model without damper and one with non-smooth dry friction damping.

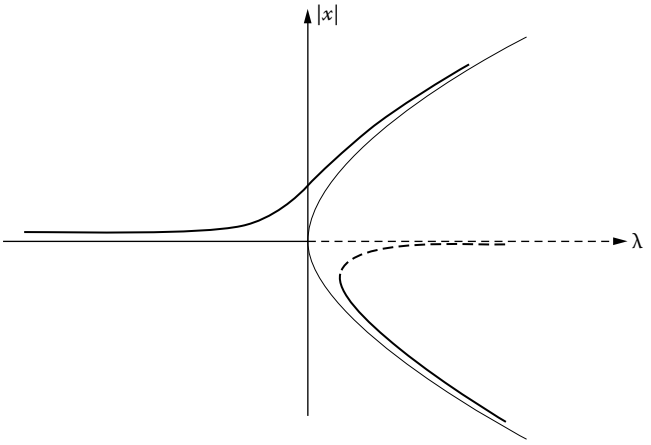

FIGURE 5.15 An example of the breakup of a pitchfork bifurcation under the influence of noise. A full line indicates a stable and a broken line an unstable solution. The thin lines and curves indicate the original pitchfork bifurcation, located in the origin of the parameter-phase diagram.

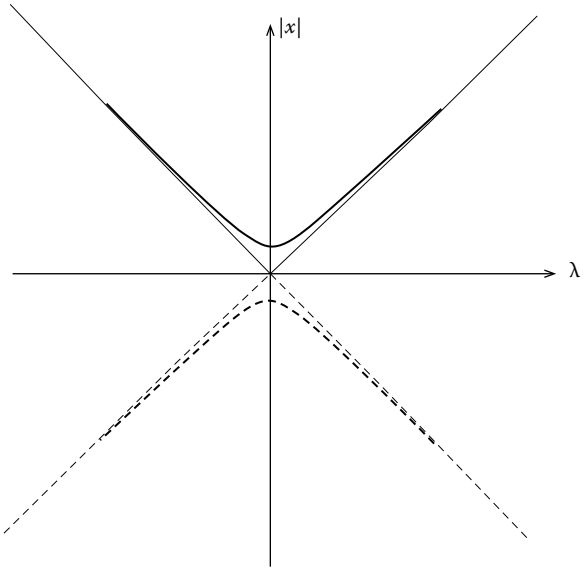

FIGURE 5.16 A first example of the breakup of a transcritical bifurcation under the influence of noise. A full line indicates a stable and a broken line an unstable solution. The thin lines indicate the original transcritical bifurcation, located in the origin of the parameter-phase diagram.

noise-free system (see Figure 5.17). Note that in this case the noise has changed the original transcritical bifurcation from a *continuous* bifurcation to a *dangerous* bifurcation. In the neighborhood of the bifurcation point of the corresponding noise-free system, the post-bifurcation response jumps to a remote attractor, which may be bounded or unbounded. Unbounded responses have disastrous consequences. Typically a bounded response will remain on the path of the new attractor, when the direction of change of the control parameter is reversed resulting in hysteresis.

In stochastic dynamic systems, an additional kind of bifurcation may occur. It is called *stochastic resonance*. It often occurs in bistable systems with noise. When the noise level is low,

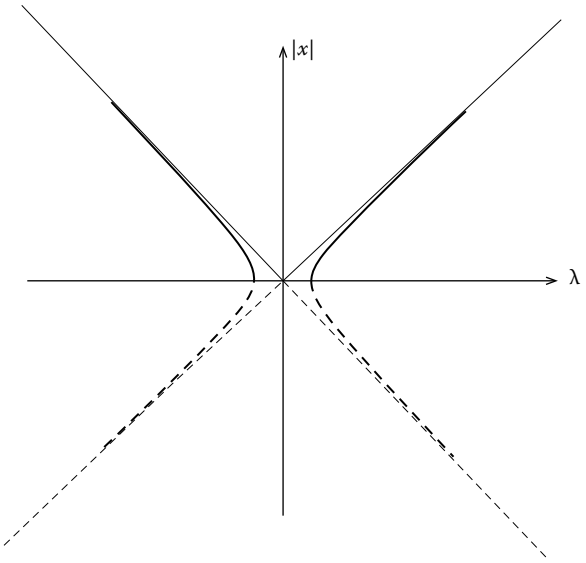

FIGURE 5.17 A second example of the breakup of a transcritical bifurcation under the influence of noise. A full line indicates a stable and a broken line an unstable solution. The thin lines indicate the original transcritical bifurcation, located in the origin of the parameter-phase diagram.

the trajectories of the motion remain within one of the basins of attraction. If a sufficiently large instantaneous singular excitation occurs, then the trajectory will jump from one basin of attraction to another, and then remain there. For large noise intensities, the dynamics is dominated by the noise—an undesirable situation in vehicle dynamic applications. There may, however, exist moderate noise intensities that force the dynamic system to flip between the basins of attraction without dominating the dynamics of the system. Stochastic resonance thus occurs in bistable dynamic systems, when the system response is driven by a combination of a periodic and a wide band stochastic force (noise). The combination of the two forces may then cooperate/compete to make the system switch between the basins of attraction. See an example from Gammaitoni et al. [14] in Figure 5.18.

When the noise is small very few switches occur, mainly at random with no significant periodicity in the system response. When the noise is very strong, a large number of switches occur for each period of the periodic motion and the system response does not show a characteristic periodicity. There exists, however, an optimal value of the noise that corresponds with the periodic motion in such a way that the dynamic system makes almost one switch per period. Such a favorable condition is determined by the matching of two time scales: the period of the periodic motion (the deterministic time scale) and the Kramers rate (i.e., the inverse of the average switch rate induced by the noise alone: the stochastic time scale); thus the term *stochastic resonance*. A comprehensive overview of stochastic resonance has been written by Gammaitoni et al. [14].

5.7 ON NON-SMOOTH SYSTEMS

New concepts that are important for the analysis of non-smooth systems in the state space will be introduced, and some of the possible bifurcations in non-smooth systems will be briefly surveyed in this section.

In non-smooth dynamic systems, the location of the discontinuities in the state space must be defined by additional functions $h_i(x_j) = 0$, $i = 1, 2, \ldots, M$; $j = 1, 2, \ldots, N - 1$, where M is the number of discontinuities and N is the dimension of the state space. In the N-dimensional vehicle dynamic

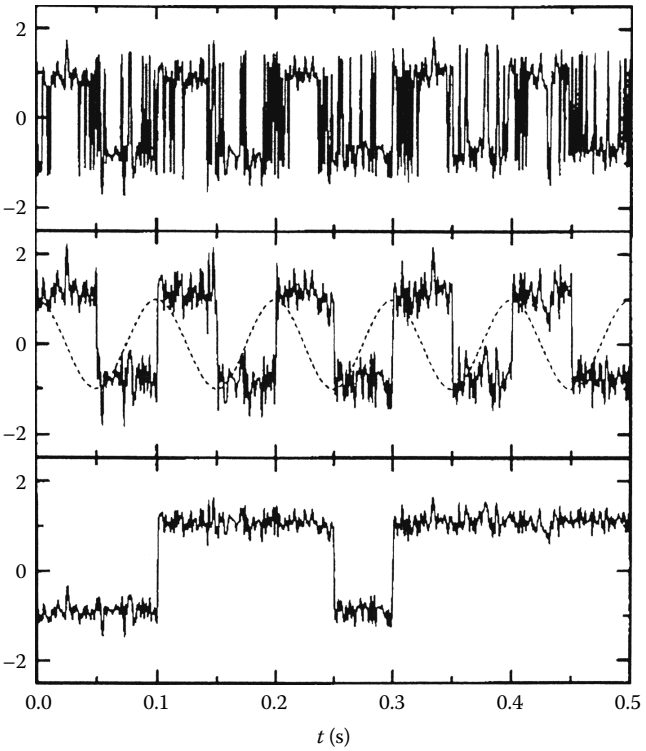

FIGURE 5.18 An example of input/output synchronization in a bistable system. The noise intensity is increasing from the bottom to the top with constant frequency. The dashed curve shows the input signal. (With permission from Gammaitoni, L., Hänggi, P., Jung, P., and Marchesoni, F., *Reviews of Modern Physics*, 70, 1, 223–287, 1998. Copyright 1998, by the American Physical Society.)

problems, the functions $h_i(x_j) = 0$ define *hypersurfaces*, each of which splits the state space into two subspaces. The hypersurfaces are the so-called *switching boundaries* and they will in general intersect each other. A simple example in the phase plane (x_1, x_2) is an elastic impact at $x_1 = 0$. When a trajectory in that phase plane hits the line $x_1 = 0$ in the point $(0, x_2)$, the velocity x_2 changes sign and the trajectory will continue from the point $(0, -x_2)$. The outgoing trajectory will return into the half plane it came from with a slope, which has the opposite sign of that of the incoming trajectory. Whenever a trajectory in the state space touches a switching boundary, an *event* occurs. A switching boundary may divide two domains in the state space with different DOF of the dynamic system. Systems with such a switching boundary are called *structure varying* systems. In Section 5.8, we shall outline a numerical procedure for the handling of the events. Further material is found in Leine and Nijmeijer [15] where numerical integration methods for the solution of non-smooth dynamic systems are presented.

Systems that have a continuous as well as a discrete nature are also called *hybrid systems*.

In nonlinear, non-smooth dynamic systems, the eigenvalues of the linearized systems may cross the imaginary axis in continuous dependence on the control parameter, but they may also jump across the imaginary axis from the negative to the positive real half plane, when an event occurs. In case the eigenvalues depend continuously on the control parameter, the bifurcations are created in the way we already described in Section 5.4, but the bifurcating solutions may depend differently on the control parameter in a neighborhood of the bifurcation point. Slivsgaard [16] found in her analysis of the dynamics of the prototype single-axle bogie for the Copenhagen S-train that the bifurcating stable, periodic solution will initially grow linearly with a finite slope from the bifurcation point. True [17] demonstrated in a simple example, that will be presented later, that the new behavior is generic for a group of non-smooth dynamic systems.

In their book, Leine and Nijmeijer [15] discuss bifurcations of nonlinear, dynamic systems, where the eigenvalues jump across the imaginary axis. They call the phenomenon a *discontinuous bifurcation*. When the eigenvalues of the linearized system depend continuously on a single control parameter in the neighborhood of the bifurcation point, then in the generic case only one real-valued or one pair of complex conjugate eigenvalues will cross the imaginary axis at a time. If however the eigenvalues jump in a discontinuous bifurcation, then more eigenvalues may jump at the same time, which may lead to different kinds of bifurcations. Some of the eigenvalues may even jump back again, so it is not at all easily recognized that they have jumped back and forth across the imaginary axis. Such cases may lead to new kinds of bifurcations. A similar situation occurs in maps. The analog here is a jump of the Floquet multiplier(s) across the unit circle. We refer to Leine and Nijmeijer [15] for more information.

Leine and Nijmeijer [15] also discuss the bifurcations that result from smooth approximations of the non-smooth systems. They demonstrate in simple analytic examples that *smoothing may change the character of the bifurcations*. This feature revives the discussion of "to which degree vehicle dynamics can be non-smooth." In an impact contact forces are produced, but should the impact be modeled as an ideally elastic one with an instantaneous infinitely large contact force—possibly with a coefficient of restitution—or are the contact forces modeled better by a dynamic law extending over a finite time interval? Both cases are nonanalytic in the sense that discontinuities are introduced in the system, but the discontinuities are not equally strong. In the first case, the velocity—the first derivative—has a finite jump; while in the second case, the velocity varies continuously while the acceleration—the second derivative—jumps. The second case is an example of a weaker "non-smoothness" than the first one. We shall not discuss modeling aspects here, but return to the topic in Section 5.8.

We continue this brief introduction with two simple examples of bifurcations of non-smooth systems. The first one is a non-smooth analog of the saddle-node bifurcation in Section 5.4. It is taken from the book by Leine and Nijmeijer [15]. Let us consider the non-smooth system:

$$\frac{\mathrm{d}x}{\mathrm{d}t} = \lambda - |x|$$

There exist exactly two equilibrium solutions but only for $\lambda > 0$: $x = -\lambda$ and $x = \lambda$. This yields the bifurcation diagram shown in Figure 5.19, which should be compared with Figure 5.11a.

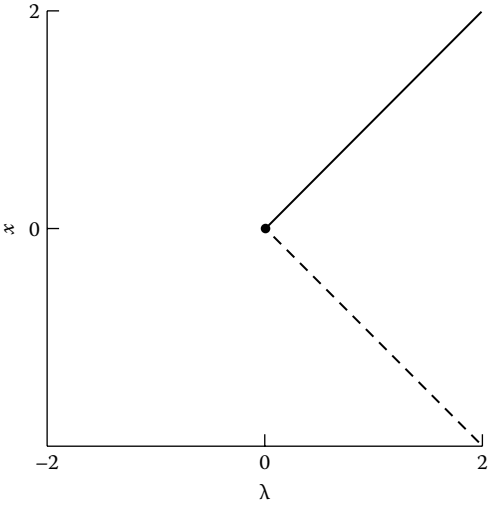

FIGURE 5.19 A discontinuous saddle-node bifurcation.

When the two figures are compared, we find that the stable and unstable solutions meet at a finite angle in the bifurcation point, when the system is non-smooth, and the solutions depend linearly on the control parameter λ. This is in contrast with the classical saddle-node bifurcation in Figure 5.11 (left). A stability analysis of the two branches shows that the stability properties are the same in the smooth and the non-smooth cases.

The other example is a non-smooth analog of the classical Hopf bifurcation shown in Figure 5.11 (right) in Section 5.4. True [17] considered the system:

$$\dot{x} = y$$

$$\dot{y} = -\left(k\sqrt{x^2 + y^2} - \lambda\right)y - x, \quad k \neq 0$$

We introduce polar coordinates by the transformation:

$$x = r\cos v, \quad y = r\sin v$$

and obtain

$$\dot{r} = (\lambda - kr)\, r\sin^2 v$$

$$\dot{v} = (\lambda - kr)\cos v \sin v - 1$$

This system has the solutions: $r = 0$ and $r = \lambda/k$.

A simple bifurcation analysis yields the bifurcation diagram in Figure 5.20. Here, we see that the bifurcating periodic solution $r = \lambda/k$ branches off linearly from the stationary solution $r = 0$, with a finite angle in contrast to the classical Hopf bifurcation. A stability analysis of the three branches shows—like in the preceding example—that the stability properties are the same in the smooth and the non-smooth cases. In both cases, the asymptotically stable stationary solution becomes unstable on the right-hand side of the bifurcation point. The periodic solution is asymptotically stable, when it exists for positive values of the parameter λ, and otherwise it is unstable.

Impacts and stick-slip caused by dry friction contact are the two sources of non-smoothness that occur most often in vehicle dynamics. In nonlinear dynamic systems, repeated impacts are considered to generate chaos in general. There is a lot of evidence hereof as well from experiments as from numerical simulations. When chaos is generated by repeated impacts, it is important to bear the nature of chaos in mind. An infinitesimal disturbance from a trajectory on a chaotic attractor will develop into a large departure from the values on the original attractor at a later point in time. This is the well-known effect of the sensitivity on initial conditions in chaos. The departed value will, however, lie on another trajectory on the same chaotic attractor. Since the uncertainties of measurements as well as the error bounds in numerical tests are finite, it means that in reality it is impossible

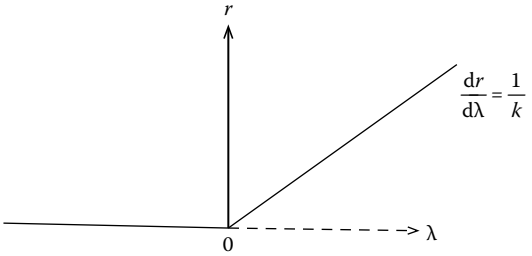

FIGURE 5.20 A discontinuous Hopf bifurcation.

to follow a trajectory on a chaotic attractor. The best we can hope for in any case is to shadow the chaotic attractor by careful measurements or suitable numerical algorithms. The modeling of the impact itself will therefore have a negligible effect on the general dynamics after the impact—as long as the dynamics stays on the same chaotic attractor. We shall return to this subject in the following section on numerics (Section 5.8).

This conclusion is also true for modeling of the stick in dry friction, but greater care must be exercised in that case. The stick has other important consequences for the dynamics. Stick will break some symmetries in the system. There is no proof of this, but the author has found this to be the case in all the vehicle dynamic systems his coworkers and he have analyzed. Thereby chaos is more likely to develop. Stick may also change stationary points in the state space into *set-valued stationary domains* and more generally equilibrium points into *set-valued equilibrium domains*. As an example of a stationary domain, let us consider a rolling railway wheelset that carries a car body in a suspension with dry friction damping. On straight track, the damper(s) may stick in positions that hold the wheelset fixed in a nonzero lateral displacement. The state is stable. The entire set of stable stationary lateral displacements and stationary yaw angels depends in general on the speed of the vehicle. In the case of the single rolling wheelset, the stable stationary domains will constitute a 3D hypersurface in the parameter-state space. The theory of bifurcations for smooth systems must be modified for dynamic systems with these properties. Such a wheelset may however, under different conditions, oscillate and reach equilibrium on one of several different cycles in the state space, each of which depends on the initial condition. These cycles in the parameter-state space constitute an equilibrium domain.

Leine and Nijmeijer [15] also discuss dry friction problems. Other examples of the special effects of dry friction damping on the dynamics of vehicles may be found in the following chapters.

Hoffmann et al. [18] investigated numerically the dynamics of a two-axle freight wagon with UIC standard suspension. The UIC suspension carries the car body in links with rolling dry friction in the contact surfaces between the elements of the links. Hoffmann et al. have calculated a bifurcation diagram, which has a hysteresis loop. The calculation was started with symmetric initial conditions, for example, the lateral displacement and the yaw angle of the wheelsets were zero. It is a stable stationary solution of the dynamic problem. After going around in the hysteresis loop, the stable stationary solution did not return to zero, but ended on a stable stationary nonzero solution. Their result is shown in Figure 5.21.

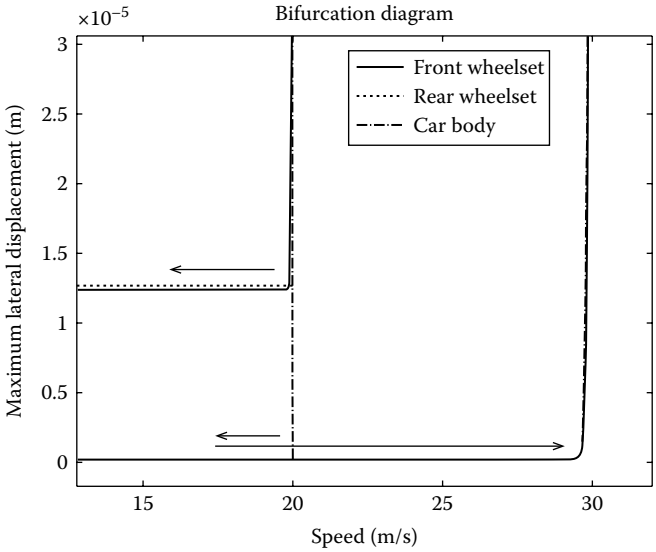

FIGURE 5.21 The "open hysteresis loop" in a model of a freight wagon with dry friction in the suspension verifying the existence of a stable stationary domain.

True and Asmund [13] investigated a numerical model of a single wheelset under a railway freight wagon. The model was simplified to illustrate only the effect of the coupling between lateral dry friction dampers with stick-slip and the creep forces. Therefore the kinematics of the wheel-rail geometry was linearized, and the wheels had no flanges. Figure 5.14 taken from [13] shows an interesting comparison between the bifurcation diagrams for the wheelset with no dampers and one with dry friction dampers. With no dampers the dynamic system can be reduced to a set of differential equations, and the mathematical theory in Section 5.4 applies. The bifurcation diagram is a classical one, with a trivial solution, which is asymptotically stable up to the Hopf bifurcation point, where a supercritical, asymptotically stable periodic solution branches off. The stationary trivial solution loses stability at the bifurcation point. For higher speeds, the asymptotically stable periodic solution goes through a symmetry breaking bifurcation and a series of—what looks like—period-doubling bifurcations, which lead to chaotic behavior. With the dry friction damper, the diagram is drastically changed. With the friction damper, the trivial solution is no longer asymptotically stable. We now find a set of stable symmetric periodic motions with amplitudes, which grow slowly with the speed, and which depend on the initial conditions. There exists now a whole range of stable periodic solutions with different amplitudes. Only one is shown in Figure 5.14. Its amplitude grows faster with the speed near the bifurcation point for the undamped bogie in a way that is known from nonlinear systems with noise. The Hopf bifurcation has disappeared.

Leine and Nijmeijer [15] write two chapters with "Discussion and Conclusions." We shall try to condense the conclusions relating to bifurcations that are most important for vehicle dynamics. For a deeper discussion, the reader is referred to [15] or to the review paper [19].

There exist types of bifurcations in non-smooth dynamic systems that do not have a smooth counterpart, and the mathematical theorems on bifurcations are almost all based on assumptions of some smoothness. Therefore, *conclusions about the existence of bifurcations must be taken from inspection of bifurcation diagrams.* Unfortunately, we are in general unable to find the unstable solution branches numerically; therefore, the computed bifurcation diagrams will be incomplete. Leine and Nijmeijer [15] analyze examples of bifurcations from a stationary solution in non-smooth systems. They find by analytic calculations that an eigenvalue of the Jacobian has crossed the imaginary axis. There exists, however, no mathematical proof that a crossing is a necessary condition for a bifurcation in a general non-smooth system. In our own numerical investigations of vehicle dynamic systems, we found that the crossings of eigenvalues that are known from smooth systems also take place in our non-smooth systems. We found it to be true for bifurcations from stationary solutions as well as from limit cycles. See the review paper [19] for more information.

The conclusion is that *it is necessary to calculate bifurcation diagrams in order to determine the bifurcation points in vehicle dynamic problems.* This leads to the next section in which a simple numerical method for the determination of the *stable* branches of a general nonlinear dynamic problem will be described.

5.8 ON THE NUMERICAL ANALYSIS OF VEHICLE DYNAMIC SYSTEMS

5.8.1 Numerical Solution of Smooth Problems

In this section, we shall briefly survey the numerical solution of vehicle dynamic problems. Special attention will be paid to problems with coexisting attractors and non-smooth problems. We shall demonstrate how such problems must be treated in order to obtain reliable dynamic results.

When coexisting attractors exist in a nonlinear dynamic problem, the equilibrium solutions of a specific initial value problem depend on the initial values. This is in contrast to linear dynamic problems, where coexisting attractors cannot exist. On the other hand, the solution of a given initial value problem is unique provided certain continuity conditions are satisfied. In other words, the trajectory in the state space is uniquely defined. If, however, two trajectories that converge toward two different attractors are sufficiently close in some part of the state space, then numerical time step integration

along one of the attractors may jump to and follow the other attractor. This leads to an erroneous numerical solution of the initial value problem. The jump may be the result of a bad choice of error bounds or time steps, but it may also be the result of the use of the wrong numerical routine. We shall demonstrate later the erroneous result of the application of an Euler explicit routine (which should NEVER be applied to nonlinear equations [!]) to a simple nonlinear initial value problem.

In Section 5.2, we solved

$$2.56\,\mathrm{d}^2\frac{x}{\mathrm{d}t^2}+0.32\,\frac{\mathrm{d}x}{\mathrm{d}t}+x+0.05x^3=2.5\cos t \tag{5.7}$$

numerically with two pairs of initial conditions. Two different attractors were found, and they are shown in Figure 5.1.

Let us now consider Equation 5.7 with the initial condition

$$x(0)=3.75,\quad \frac{\mathrm{d}x}{\mathrm{d}t(0)}=0.75 \tag{5.8}$$

We first solve the initial value problem (5.7 + 5.8) with a ode45 routine from MAPLE 9.5. The transient approaches the correct attractor with small amplitude that belongs to the initial conditions (5.8). The result is shown in Figure 5.22.

We next solve the same initial value problem (7 + 8) with an explicit Euler routine—also from MAPLE 9.5. The result is shown in Figure 5.23, and it is clearly seen that *the transient in this case approaches the other—and incorrect—attractor.*

The explicit Euler routine is very popular, because it works fast. As long as no other solution or measured results from a test exist for comparison, the Euler solution will be accepted. It is outright dangerous. The explicit Euler routine should never be used for the numerical solution of nonlinear dynamic problems.

This simple example demonstrates that great care must be taken, when a numerical solver is chosen for a given nonlinear dynamic problem.

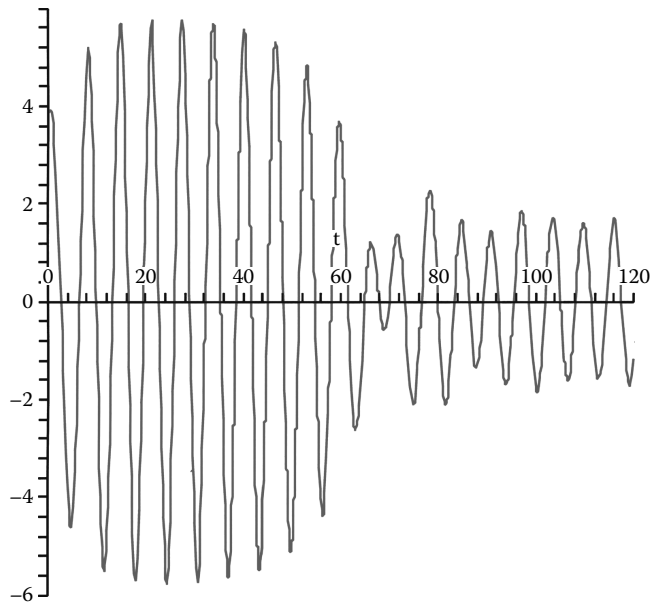

FIGURE 5.22 The numerical solution to the initial value problem (7) + (8) using a Runge–Kutta 45 routine. The transient approaches the correct attractor.

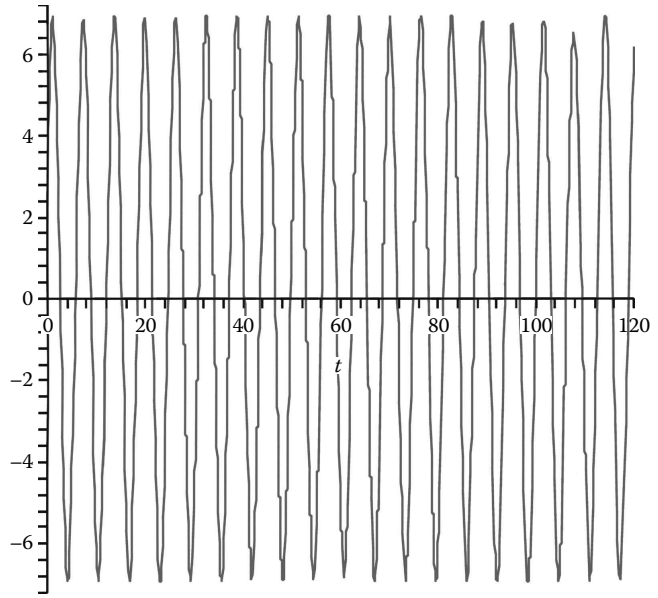

FIGURE 5.23 The numerical solution to the initial value problem (7) + (8) using an explicit Euler routine. The transient approaches *the wrong attractor.*

Garg and Dukkipati [20] discuss and demonstrate the use of explicit and implicit routines for the numerical solution of linear as well as nonlinear dynamic problems. They test a selection of routines on both linear and nonlinear dynamic problems. They compare CPU-time, stability, and artificial damping in their examples. In an *explicit* routine, the next step $\boldsymbol{x}_{n+1}$ depends explicitly on known quantities only. In Garg and Dukkipati's nonlinear example [20] with the rolling wheelset, the explicit solvers either are unstable or introduce artificial damping. The explicit solvers are inefficient for the analysis of the so-called stiff problems. Generally, a problem is said to be *stiff*, if the solution contains both slow and very fast processes. The fast processes decay very fast with time t, so a very short step length is needed to keep the explicit solvers from "blowing up" in the numerical solution. Furthermore, the explicit solvers often become unstable when they are applied to stiff problems. In order to maintain stability, the step size again needs to be very small. In *implicit* routines, the dependence is implicit, so the next step has to be calculated by the solution of an equation. Since vehicle dynamic problems are nonlinear, the said equation will also be nonlinear. It means that a nonlinear equation has to be solved numerically for each time step for example by a *predictor corrector method*. The advantages of the implicit methods in vehicle dynamics are that they can be applied safely to solve stiff problems with automatic control of the varying step lengths. Vehicle dynamic problems as well as the numerical simulations of real-world tests are usually stiff problems. Therefore, the application of implicit routines is recommended for the numerical solution of these initial value problems.

Rill [21] has applied an implicit Euler routine to vehicle dynamic problems with success. True and his coworkers have most often used the LSODA routine for the calculation of bifurcation diagrams—also successfully. LSODA changes solution strategy automatically depending on whether the problem is stiff or not. The Runge–Kutta solver ode45 has been recommended for years as the most effective routine for the purpose of shadowing chaotic attractors, but it is an explicit routine, and it therefore cannot be recommended for the numerical analysis of vehicle dynamic problems. There exist, however, also implicit Runge–Kutta solvers for stiff problems. All these Runge–Kutta solvers are a part of MATLAB. Most recently, the routine SDIRK [22], based on the theory from [23], has been applied by Hoffmann [24] to the numerical analysis

of two-axle freight wagons—a stiff problem with rolling and sliding dry friction and bumper stops. SDIRK is a recent implicit routine, which can be downloaded from the web. For a detailed description of time-stepping explicit and implicit numerical routines and recommendations for their applications, the interested reader is referred to the literature [25,26].

The time-stepping numerical methods are by far the most popular numerical methods for the solution of vehicle dynamic problems, because they lend themselves naturally to the solution of initial value problems. It should be mentioned, however, that dynamical problems can be formulated as variational problems, where a supremum of a functional is sought for example using Hamilton's principle. This formulation leads to an optimization problem in mathematics. Equilibrium solutions have been found by numerical solution of the optimization problem. It is claimed (oral information) that the stable attractors in a bifurcation diagram for a vehicle can be computed faster in that way.

The engineer without a good background in numerical analysis faces a problem when he must choose a differential equation solver (DE solver). Although a numerical solver may deliver a solution when it is applied to a given dynamic problem, it cannot be taken for granted that the solution is the correct one. It is strongly recommended that the engineer applies two different and acknowledged routines to the problem—at least initially. If the result using one of the solvers differs considerably from the results, which the other solver yields, he must conclude that at least one of the solvers is bad in his case. On the other hand, he cannot be sure that the results are correct even if the two results agree with each other.

5.8.2 Numerical Solution across a Discontinuity

When a vehicle dynamic problem is not smooth, the dynamic problem must be supplemented with functions $h_i(x_j) = 0$, which define the location of the discontinuities in the state space. The functions are *hypersurfaces* in the state space (see Section 5.7). By the word "discontinuities" is understood not only discontinuities in the functions themselves (zero-order discontinuities) but also discontinuities in the derivatives up to some order (higher-order discontinuities). The hypersurfaces are the so-called *switching boundaries*. As an example, we consider now a dynamic problem with one switching boundary $h(x_j) = 0$, $j = 1, 2, \ldots, N - 1$, where N is the dimension of the state space. The analysis is easily generalized to problems with more switching boundaries as long as we can deal with them one at a time. In the two domains, divided by the switching boundary, the problem is smooth, and thereby we solve the initial value problems in the usual manner. All we, in addition, need to consider is the region close to the point P, where the solution hits the switching boundary. The point P is called the *transition point*.

When we integrate our dynamic problem as an initial value problem in a domain where the dynamic system is smooth, we must stop the integration as soon as the trajectory crosses a switching boundary. The switching boundary is only defined in terms of the *dependent variables* $x_j(t)$. We must therefore continuously check in our solution procedure at which time t_0 the trajectory has crossed the switching boundary. It is then necessary to reformulate the solution procedure to determine time T iteratively at which the trajectory hits or touches the switching boundary. T can only be found numerically within a certain error limit, but it should be determined as accurately as possible. If an implicit solver is used, the interpolant may be used to determine T using Newton–Raphson's method. An initial guess is derived directly from the linear interpolant between the two solution points surrounding the event. We have now found the transition point P. It is defined by the values $x_j(T)$, $j = 1, 2, \ldots, N$.

In the mathematical formulation of the non-smooth dynamic problem, it must be defined what will happen at the switching boundary. The collision with the switching boundary and what happens there is called an *event*. As an example of an event, we mention a jump Δv in the first derivative of one of the state variables—say x_K—at time T.

We then formulate a new initial value problem at time T using the end-state variables found at the transition point P, adjusted by the law of the event, the new initial values for the integration. In our

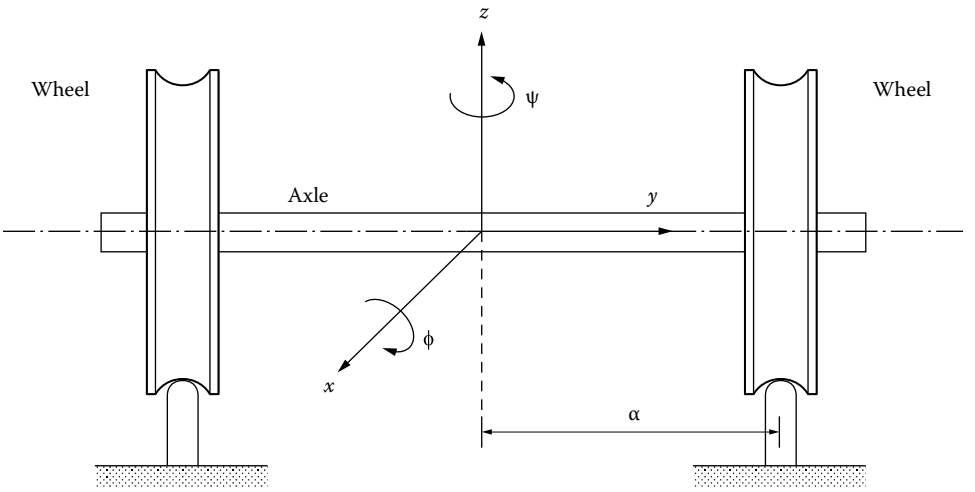

FIGURE 5.24 The wheelset model.

example, we take all our end-state variables at time T and only add the given jump Δv to the derivative of x_K at time T. The continuation of our dynamic problem is then given by the new initial values at time T combined with the smooth dynamic formulation of our problem in *the relevant domain*. In our example, the relevant domain will be *on the other side of the switching boundary*—the second domain. Then the integration continues in that domain.

As an example, we investigate the dynamics of a wheelset used on a railway wagon and presented in the book by Garg and Dukkipati [20]. The system is shown in Figure 5.24, where the wheelset is traveling along a track.

The nonlinear equations of motion for the lateral displacement and the yaw angle and the values of the different physical parameters can be found in [20].

The variation of the difference in the rolling radii of the wheelset $\frac{r_L - r_R}{2}$ with lateral displacement is shown in Figure 5.25.

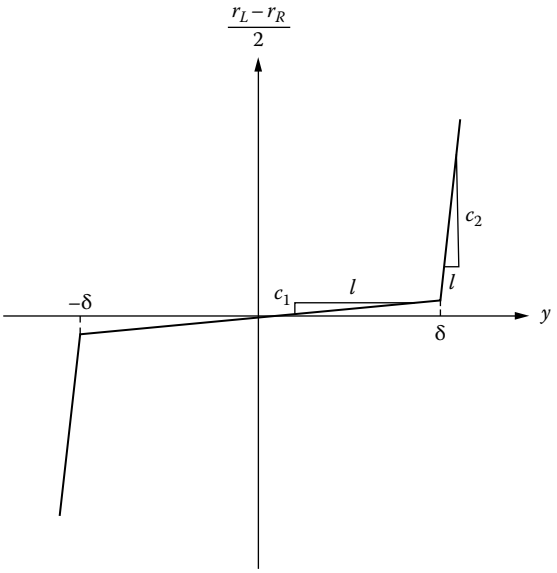

FIGURE 5.25 The variation of different variables with lateral displacements.

For different entries, we have the following values of the constants c_1 and c_2; the distance $\delta = 0.35$ in the experiments:

var	c_1	c_2
Δ_1	0	18
Δ_2	0	18
Δ_L	0.15	22
$\frac{r_L - r_R}{2}$	0.05	10

Solving the problem for an initial lateral displacement $y = 0.36$ with a velocity of 160 km/h leads to the solution In Figure 5.26, where the damping is strong and only one passage of the discontinuity occurs. Here, the solution with constant step size called ONERK4 and the solution that tracks down the discontinuity called GERK are very close.

When the velocity is increased to near the Hopf bifurcation point of this *purely theoretical problem*, where more passages of discontinuities occur, we find very different solutions. Figure 5.27 demonstrates that the constant step size solution is less accurate than the one where the discontinuities are tracked. This leads to different interpretations of the dynamic properties. This may be critical since this case is near the point where the stationary solution becomes unstable.

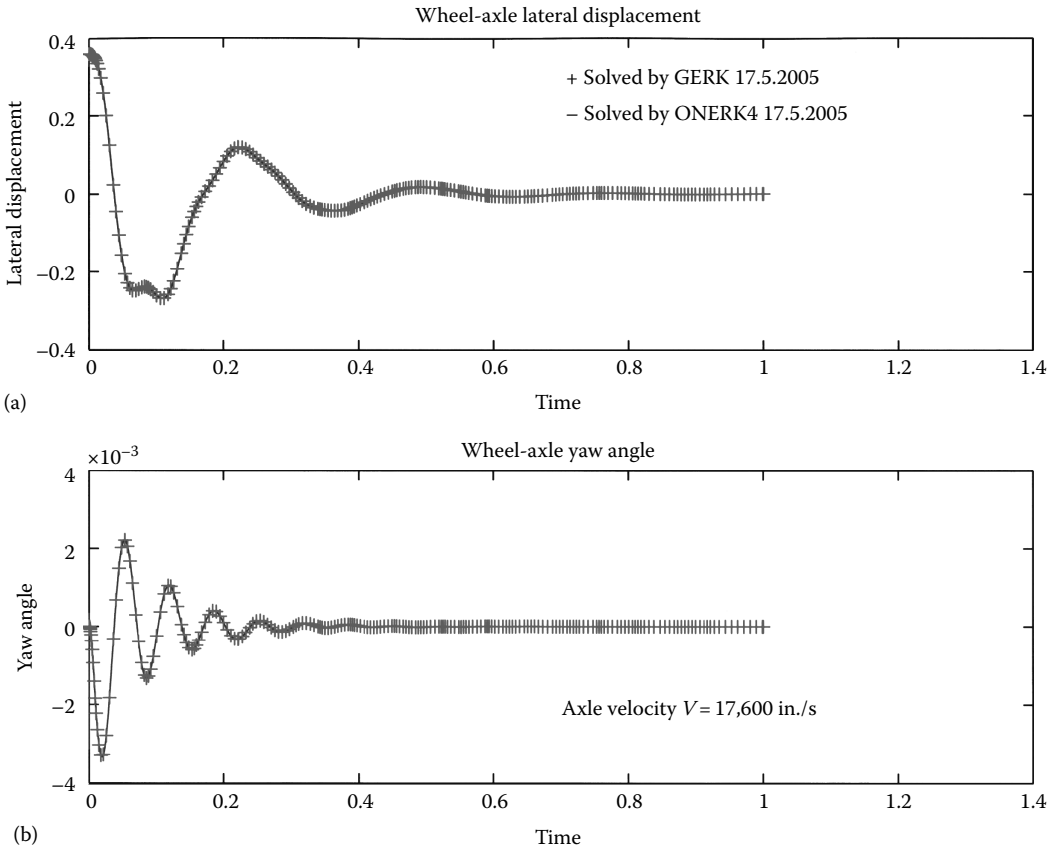

FIGURE 5.26 Wheelset dynamics solution for $V = 160$ km/h.

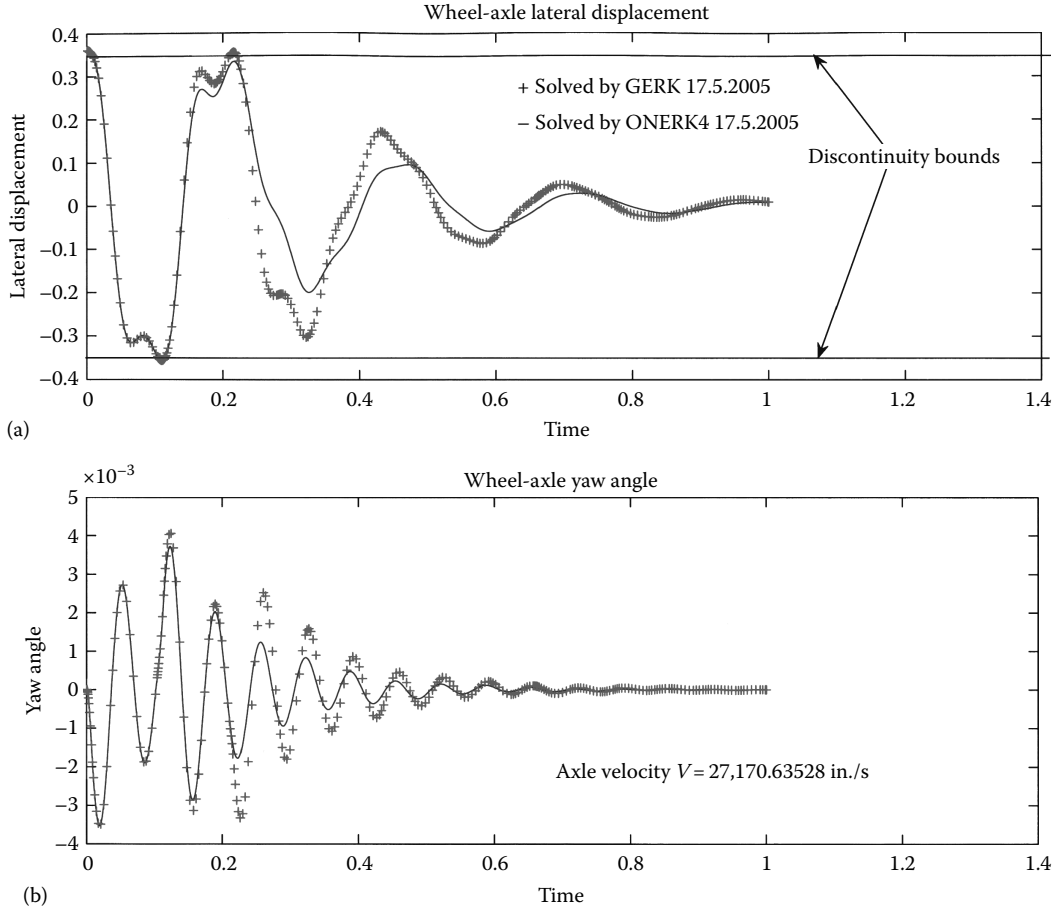

FIGURE 5.27 Wheelset dynamics solution for $V = 2484$ km/h.

Let us summarize our experience gained from different numerical treatments of discontinuities in vehicle dynamic problems. The simplest way to handle the discontinuities is to *ignore the discontinuities and integrate across them as if they do not exist*. One hopes that the "smoothing property" of the numerical routine will automatically take care of the problem with the discontinuity. If the discontinuity is in the second or higher derivatives of the functions in the dynamic problem, this strategy may work well. The strategy might work also in other cases. The general attitude is that as long as the numerical integration delivers a solution then the solution is "the correct one." This is rarely true, as we just demonstrated in the last example. A solution found in this way may even be qualitatively wrong. A chaotic dynamic behavior may be totally missed. This was illustrated by Xia and True [27]. Last but not least, the numerical solver may use a lot of CPU-time with the integration across the discontinuity, and we do not know the resulting numerical approximation of the smoothing function.

The problem with the resulting smoothing function leads to the second method of handling the discontinuities: *The smoothing functions are prescribed in each and every case*. Then—at least—we know how the numerical routine handles the discontinuity, and the CPU-time will be reduced. The smoothing function must model the physical reality in the best possible way. Many people claim that this method is the optimal one, because it models the physical reality closely. The problem with the method is, however, that "a good mathematical model" is not always known. In the work by True and Asmund [13] and True and Trzepacz [28], a smooth model of stick-slip dry friction in plane contact between steel or cast iron surfaces was applied. The results of the numerical dynamic

analysis contain a lot of chaotic dynamics as could be expected from the nature of the problem. In True and Trzepacz [28], the impacts were not modeled with smoothing functions. A comparison was, however, made between an ideally kinematic model and a dynamic model of an elastic impact. The results differed—as could be expected—but both results lay on the same chaotic attractor. Only the last model is able to yield an estimate of the contact forces. True and Trzepacz [28] used a constant step length in his integration. Only in the case of the dynamic model did he interpolate to determine the location of the impact with great accuracy. In the kinematic case, the time of reversal was simply found by a calculation of the position of the moving part. When the moving part had "entered" the part in rest, the velocity of the moving part was reversed. This approximation delivered satisfactory dynamics as long as the step length was sufficiently small. In the dynamic model, the CPU-time used for integration across the impact exploded. It is interesting to note, however, that the dynamics of the system is the same chaotic one in the two cases. The situation was discussed in Section 5.7 with relation to the modeling of the impact. The robust dynamics is closely connected with the chaotic dynamics in this case. The robustness is however not guaranteed. The dynamics of the two cases may differ.

The third—and correct—way of handling the discontinuities numerically is to *track down the transition point as accurately as possible.* The transition point is the point in the state space where the trajectory hits the switching boundary. *Then stop the time integration of the dynamic problem at that point, apply the law of transition, and continue the time integration of the dynamic problem on the relevant side of the switching boundary.* This is the safest and most accurate method to deal with nonsmooth problems. The extra CPU-time spent in the determination of the transition point is balanced by the time not spent for the integration of the dynamic problem with very small time steps along steep gradients across the discontinuity. It is the logical numerical application of the results presented in Section 5.7. The method was used with success by Hoffmann [24] to investigate the difficult problem of the dynamics of two-axle freight wagons. His models contain both rolling and sliding friction in the suspension as well as possible impacts between the axle boxes and their guidance.

The lack of proper consideration of the discontinuities in the numerical analysis leads in general to an even qualitatively erroneous result of the calculations. It is important to identify coexisting attractors in nonlinear dynamic systems. The necessity is obvious, when the attractors are characterized by different amplitudes. It may seem less obvious if the attractors have almost the same amplitudes and are only qualitatively different. If however—like in [13,27,28]—one of the attractors is a chaotic attractor, then great caution must be exercised. We refer to the discussion of chaotic transients at the end of Section 5.3. The existence of a coexisting chaotic attractor will often give rise to violently oscillating transient motions with dangerously high amplitudes. This happens for transients approaching either attractor as well the chaotic attractor as a coexisting non-chaotic attractor. It is therefore very important to identify all the chaotic attractors in a nonlinear dynamic problem. The transients may lead to accidents in the physical world.

5.8.3 A Way to Compute Stable Branches of Vehicle Dynamic Problems Numerically

In order to find the stable branches—the attractors—of a vehicle dynamic problem, use *path following in parameter-state space*. Given a stable equilibrium solution to our dynamic problem $\boldsymbol{X}(t)$ for a certain value of the control parameter, in our case this is the speed, V. We then know the solution at a time t_0 and store the state vector $\boldsymbol{X}(t_0)$. It is called the end value. The path following is performed stepwise. In each step, we increase or decrease V with a small increment and calculate the equilibrium solution of the resulting dynamic problem using the end value of the preceding step as the initial value for the new step. We take as many steps as needed. The process will end when the transient in the integration approaches another stable equilibrium solution for a certain value V_0 of the parameter V. V_0 is close to a bifurcation point that has just been passed, and which can now be determined by interpolation of the parameter V. In this way, a solution of the dynamic problem can be traced or *followed* and bifurcation points can be found in the state parameter space. At the

bifurcation points, we turn our attention to the new stable branches and follow them in dependence on V. It is highly recommendable to calculate the eigenvalues of the dynamic problem, linearized around the stable equilibrium solution and find their change with the parameter across the bifurcation point. The calculation is a valuable verification of the properties of the found bifurcation. In a bifurcation of a periodic solution from a stable stationary solution, two complex conjugate eigenvalues should cross the imaginary axis at the bifurcation point from the negative to the positive real half plane.

The success of the method is based on the assumption that the stable branches can be found as bifurcations from at least one stable solution (branch) of the problem that is known a priori. It must be emphasized that it is not guaranteed that *all* the stable branches can be found in this way in all dynamic problems. In vehicle dynamics, the aim is to design a vehicle that runs smoothly along a given track. We shall therefore make the basic assumption that the vehicle dynamic model to be investigated has a known stationary solution in a certain speed range in an appropriate moving coordinate system. In vehicle dynamics, the speed, V, is an appropriate control parameter, and in most cases "the appropriate coordinate system" is one that moves with the constant speed, $V > 0$ along the track of the vehicle. A dynamic model of a "good" vehicle will then have a trivial stable solution for sufficiently small values of the speed $V > 0$, that is, all $x_j(t) \equiv 0$. It can be used as the initial solution.

The path following procedure can be accelerated and automated by application of *the ramping method*. In the dynamic system, the control parameter V is substituted with a slowly varying monotonically growing or decaying function of time $V(t)$. In the ramping method, we start the integration of the dynamic problem as usual with the known end value and integrate up to an appropriate end time T, so that $[V(0), V(T)]$ covers the designed speed range of the vehicle. If bifurcations appear, repeat the procedure as long as necessary to determine all the attractors. The bifurcation diagram will in practice be quite well approximated by the ramping solution, but the method overshoots the bifurcation points, and one or more of closely situated bifurcation points may be missed. The bifurcation points must afterward be recalculated with greater accuracy.

The smallest parameter value V_C in a vehicle dynamic problem for which there exist more than one stable equilibrium solutions (coexisting attractors) to the dynamic problem is the *critical speed*. It is important to realize that the determination of the critical speed in general leads to a *mathematical existence problem*. In railway dynamic problems, there often exists an asymptotically stable periodic solution coexisting with the asymptotically stable stationary solution for lower speeds than the one at which the stationary solution loses stability. The periodic solution is then the result of a subcritical bifurcation of an unstable branch that gains stability in a saddle-node bifurcation. Since it is still impossible to path follow an unstable periodic solution in a differential-algebraic dynamic system, a different strategy must be used to determine the critical speed, [32,33,34].

The calculation of V_C may be performed in three steps:

1. Substitute the known steady-state solution into the vehicle dynamic problem, increase the speed V, and solve the initial value problem for a very small disturbance of the initial values, for example, for a lateral displacement of one axle of 0.1 mm and all other initial values equal to zero. Then the steady-state solution is found for a higher value of the speed. Repeat the procedure for higher and higher values of the speed until the solution of the initial value problem no longer is the known steady-state solution and stop the calculation when the transients have vanished. Store the end values of all the state variables, $\boldsymbol{X}_{e1}$. We have now followed the known steady-state solution in parameter-state space until it lost its stability. Since the known steady-state solution is now unstable, the numerical solution has converged to the nearest asymptotically stable periodic solution in state space—a new attractor.
2. We must now follow the periodic solution for decreasing speed until it ceases to exist. Reduce the speed a little and solve the vehicle dynamic problem with the end values $\boldsymbol{X}_{e1}$ as the new initial conditions. Stop the integration routine when the transients vanish and store the new end values $\boldsymbol{X}_{e2}$. We have now calculated another point on the periodic attractor.

Repeat the procedure for lower and lower values of the speed until the periodic solution ceases to exist. We have then just passed the saddle-node bifurcation point of the periodic attractor and are therefore close to the theoretical critical speed.

3. We can now determine the saddle-node bifurcation point, that is, the theoretical critical speed V_C with a desired accuracy by interpolation of the parameter V or by the Newton–Raphson's method.

Other authors have suggested other methods for the calculation of the critical speed. These other methods are discussed in an important work by True [29].

Continuation algorithms based only on Jacobians are not recommended, because we already know a solution of the full nonlinear dynamic problem. When an implicit numerical solver is applied, then the Jacobian will be calculated and updated automatically in every time step.

There exist several good commercial vehicle dynamic simulation routines. When a potential user must select a program, he must test his requirements of the program against the performance of the program and against the requirements listed in this section. The programs must contain at least two recognized implicit solvers for the solution of nonlinear dynamic problems, and the user must be able to control the numerical parameters such as step lengths—constant or varying size—and error bounds. Explicit Euler routines are of course banned from use.

If not treated properly, the interpretation of the dynamic properties from the numerical results may be very different from the properties of the real system.

We recommend when the numerical tools are selected, that a similar care is spent on the selection of the code as the care taken of the modeling. It is of the at most importance that properties that influence the dynamic behavior such as the discontinuities are properly accounted for.

5.9 A GUIDE TO VEHICLE SYSTEM DYNAMICS

Due to the nonlinear coupling with the supporting ground, it is basically impossible to split the dynamics of the total vehicle-ground system into effects caused by the properties of the vehicle and those of the support. The contact forces between the ground-rail and wheels are important unknowns in the simulations not only because they act as an input to the dynamic vehicle model but also because they are important for the design of the vehicle and the deterioration of the structure of the support. We are, however, lucky in the sense that the influence of the dynamic feedback from the vehicle on the ground is on a much larger time scale than the instantaneous action the vehicle is exposed to from the ground. The feedback can therefore be neglected in the modeling of the short-term dynamics of the vehicle.

It is, however, possible to make deductions and achieve a better understanding of the dynamics of the total system if the dynamics of some of the elements in the system is known. The dynamic features of the vehicle model should therefore be investigated first. The investigation of the full nonlinear vehicle dynamic model starts with a numerical calculation of the bifurcation diagrams for the vehicle running on an ideal support along a straight line (Section 5.8.3). The calculations must be performed for all relevant tire brands or contact geometries and for a relevant selection of adhesion coefficients. The speed is chosen as the control parameter, while all other parameters are kept constant in each run. The relevant attractors in the parameter-state space must be found and the critical speed determined. Next, the investigation continues with a set of numerical calculations of the bifurcation diagrams for quasi-stationary curving in arcs with selected radii. Again the speed is chosen as the control parameter. A lower critical speed will often be found in curves with a large radius than the one found by driving along a straight line.

When the attractors are known, we are ready to make numerical simulations of the vehicle dynamics on uneven roads, transition curves, turnouts, and in other situations where the transient response is important. These simulations also serve as a basis for comparisons with measured results from road tests and as a verification of the dynamic model. This may give rise to a great variety of nonlinear motions. In his master thesis, Christiansen [30] investigated the dynamics of the

Cooperrider [31] bogie on a sinuous track. Depending on the phase difference between the amplitude of the sinus functions of the right and left rail, Christiansen found many nonlinear phenomena known from the literature—but only when the speed was above the critical speed. The phenomena were obviously results of mode interactions with the hunting motion of the vehicle. Since most railway freight vehicles today often run at supercritical speeds, special care must be taken when their dynamics is modeled and investigated.

In every step of the investigation, it is important to pay attention to the numerics. After having spent so much effort on the construction of the theoretical model, many investigators seem to believe that the job is done. All that is needed at that point is not just any numerical solver, which can be found on the web, or which is incorporated in a commercial simulation program—often without any information about the type of solver and its parameters. We recommend, when the numerical tools are selected, that the choice is made with a care similar to the care invested in the modeling. It is of the outmost importance that properties such as the discontinuities that influence the dynamic behavior are properly accounted for (see Section 5.8.2).

It is, of course, permitted to make approximations of solutions to nonlinear systems for instance by linearization of nonlinear characteristics or terms in the dynamic system. If the total dynamic system will be linearized, it is important that the operator knows which stable solution, that is, *stable branch* he will linearize around. He must also investigate whether a linearization is permitted (see Section 5.3.3). The Jacobian $\boldsymbol{J} = [\partial f_i/\partial x_j]$, $i, j = 1, 2, \ldots, N$ must exist, and the rest term $\boldsymbol{G}(\boldsymbol{x}; \boldsymbol{\lambda})$ must satisfy $\|\boldsymbol{G}(\boldsymbol{x}; \boldsymbol{\lambda})\|/\|\boldsymbol{x}\| \to 0$ for $\|\boldsymbol{x}\| \to 0$ if the trivial solution is considered. It is therefore important to know the full nonlinear operator as well as its bifurcation diagram first. The linearized operator can yield valuable information about certain properties of the vehicle model. The eigenvalues will for instance inform about characteristic frequencies and their attenuation and potential resonances in the vehicle dynamic system.

When the analyses of the nonlinear dynamics of vehicle systems are performed with accurate theoretical multi-body system models that consist of elements with well-defined and verified dynamics, with due regard to the nonlinear nature of the systems, and the calculations are performed on modern computer systems by well-educated personnel using software that is carefully selected with regard to the nature of the specific dynamic problem, then the results will be so accurate that simulations in future can be used as a documentation for certain vehicle performance requirements and even as a part of the safety specifications. This will give the manufacturers, the national boards of safety and large user organizations—like the railway companies—a strong and reliable tool for the design and testing of vehicle systems under realistic or even unrealistic operating conditions. The models may also be valuable tools for investigations of accidents. The advantages of such theoretical analyses are lower costs compared with alternative methods, flexibility with respect to design parameters and operating conditions, and—in many cases—a faster production of results.

ACKNOWLEDGMENTS

6.1 STATE-SPACE MODELS

6.1.1 Introduction

The state-space representation of a dynamic system is given by a system of first-order differential equations. Instead of a linear or nonlinear differential equation of order n as an input/output representation, a system of n linear or nonlinear coupled differential equations of first order is obtained.

6.1.2 State-Space Representation for Linear Dynamic Systems

The state-space representation for linear dynamic systems generally consists of a state differential equation

$$\dot{\boldsymbol{x}} = \boldsymbol{A}\boldsymbol{x} + \boldsymbol{B}\boldsymbol{u} + \boldsymbol{E}\boldsymbol{z}; \quad \boldsymbol{x}(t_0) = \boldsymbol{x}_0, \tag{6.1}$$

and of the algebraic output equation

$$\boldsymbol{y} = \boldsymbol{C}\boldsymbol{x} + \boldsymbol{D}\boldsymbol{u} + \boldsymbol{F}\boldsymbol{z}. \tag{6.2}$$

The individual variables in 6.1 and 6.2 denote the following quantities:

$\boldsymbol{x}$: $(n \times 1)$—state vector
$\boldsymbol{u}$: $(r \times 1)$—vector of inputs
$\boldsymbol{y}$: $(m \times 1)$—vector of measurements
$\boldsymbol{z}$: $(q \times 1)$—disturbance vector
$\boldsymbol{A}$: $(n \times n)$—system matrix
$\boldsymbol{B}$: $(n \times r)$—input matrix
$\boldsymbol{C}$: $(m \times n)$—output matrix
$\boldsymbol{D}$: $(m \times r)$—direct feed-through matrix
$\boldsymbol{E}$: $(n \times q)$—system disturbance matrix
$\boldsymbol{F}$: $(m \times q)$—output disturbance matrix

The disturbances can be further distinguished by their nature:

- *Process faults*: They affect the state differential equation and thus have a direct influence on the state vector. They are described by the matrix $\boldsymbol{E}$. Typical examples would be unknown wind forces on a vehicle, increased bearing friction due to wear, increased drag due to low tire pressure or excitation by a road profile.
- *Measurement faults*: They only affect the output equation and are thus described by the matrix $\boldsymbol{F}$. In practice, they typically occur as sensor noise, drift, offset, or sensor breakdown.

In Figure 6.1, Equations 6.1 and 6.2 are depicted as a block diagram.

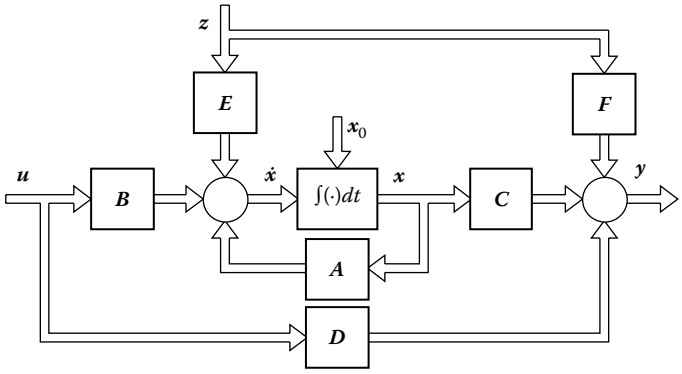

FIGURE 6.1 State-space representation of a multiple-input–multiple-output (MIMO) system.

Example 6.1

Linear single-track vehicle model for simulation and control design.

The single-track model is a simple linear vehicle model commonly used in the analysis and control design of lateral and yaw dynamics. The wheels of the each axle are considered lumped together in the center of the vehicle. The roll, pitch, and heave motions are neglected. In Figure 6.2, the single-track model is illustrated.

Its main variables and geometric parameters are

δ	Steering angle
β	Chassis sideslip angle at center of gravity (CG)
v_x, v_y	Components of velocity vector at CG in x-/y-directions
v_c	Magnitude of velocity vector at CG
a_y	Acceleration at CG in y-direction
v_V, v_H	Velocity vectors at wheel–road contact points
F_{xV}, F_{xH}	Tangential wheel forces
F_{yV}, F_{yH}	Lateral wheel forces
α_V, α_H	Sideslip angles of front and rear wheels, respectively
M	External disturbance torque or control torque
$\dot{\psi}$, $\ddot{\psi}$	Yaw angular velocity and acceleration
l_H, l_V	Distance from rear (front) axle to CG
l	Distance from rear to front axle
m, I_c	Vehicle mass and yaw moment of inertia

The linearized equations of motion are made under the following assumptions:

- Small sideslip and steering angles.
- Inertia effects due to the relative motion of wheels against chassis are neglected.

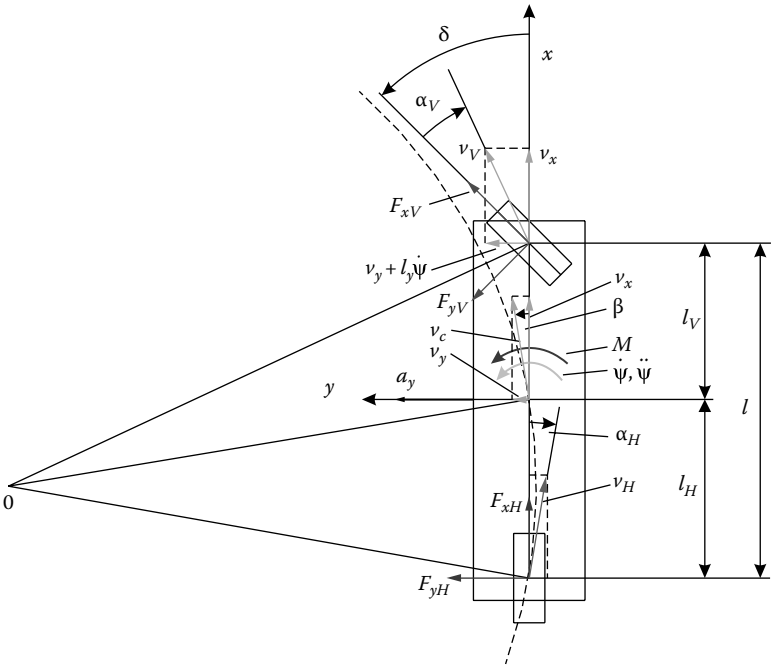

FIGURE 6.2 Single-track model: kinematics, forces, and geometry.

- The travel speed v_x is assumed to remain constant.
- The lateral tire force characteristics are given in linear form: $F_yV = k_V\alpha_V$; $F_yH = k_H\alpha_H$.
- The variability of aerodynamic forces and torques is neglected.
- The effect of different brake forces on individual wheels, for example, during interaction of ESP is modeled by the control torque M.

The equations of motion are given by Equations 6.3 through 6.5, where $l_V^* = l_V$, $l_H^* = -l_H$:

$$\text{Momentum balance in } x\text{-direction:} \quad m(-\dot{\psi}v_y) = \sum_{i=V,H} (F_{xi}\cos\delta_i - F_{yi}\sin\delta_i), \tag{6.3}$$

$$\text{Momentum balance in } y\text{-direction:} \quad m(\dot{v}_y + \dot{\psi}v_x) = \sum_{i=V,H} (F_{xi}\sin\delta_i + F_{yi}\cos\delta_i), \tag{6.4}$$

$$\text{Angular momentum balance:} \quad I_c\ddot{\psi} = \sum_{i=V,H} l_i^*(F_{xi}\sin\delta_i + F_{yi}\cos\delta_i) + M. \tag{6.5}$$

The rear steering wheel angle $\delta_H = 0$ is set to zero in this example. The sideslip angles α_i are determined by (cf. Figure 6.2)

$$\alpha_i = \delta_i - \arctan\left(\frac{v_y + l_i^*\dot{\psi}}{v_x}\right), \quad i = V, H. \tag{6.6}$$

Linearization of the equations of motion yields

$$\dot{v}_y = \dot{\psi}\frac{1}{m}\left(-v_x m - \frac{k_V l_V}{v_x} + \frac{k_H l_H}{v_x}\right) - v_y\frac{1}{m}\left(\frac{k_V}{v_x} + \frac{k_H}{v_x}\right) + \frac{k_V}{m}\delta, \tag{6.7}$$

$$\ddot{\psi} = \dot{\psi}\frac{1}{I_c v_x}(-l_V^2 k_V - l_H^2 k_H) + v_y\frac{1}{I_c v_x}(l_H k_H - l_V k_V) + M\frac{1}{I_c} + \delta\frac{l_V k_V}{I_c}. \tag{6.8}$$

The state vector is chosen as

$$\boldsymbol{x} = \begin{bmatrix} v_y \\ \dot{\psi} \end{bmatrix} \tag{6.9}$$

which results in the following state differential equation for the single-track model:

$$\begin{bmatrix} \dot{v}_y \\ \ddot{\psi} \end{bmatrix} = \begin{bmatrix} \dfrac{-(k_H + k_V)}{m v_x} & \dfrac{(-v_x^2 m - k_V l_V + k_H l_H)}{m v_x} \\ \dfrac{(l_H k_H - l_V k_V)}{I_c v_{\boldsymbol{x}}} & \dfrac{(-l_V^2 kV - l_H^2 k_H)}{I_c v_x} \end{bmatrix} \begin{bmatrix} v_y \\ \dot{\psi} \end{bmatrix} + \begin{bmatrix} \dfrac{k_V}{m} & 0 \\ \dfrac{l_V k_V}{I_c} & \dfrac{1}{I_c} \end{bmatrix} \begin{bmatrix} \delta \\ M \end{bmatrix}. \tag{6.10}$$

In contrast to the state differential equation (6.1), the output equation (6.2) rather is determined by quantities of interest by the user than by physical equations. For vehicle control concepts like ESP, the sideslip angle β at the CG is of particular interest. From Figure 6.2, it is apparent that $\beta = v_y/v_x$. This results in the following output equation:

$$y(t) = \begin{bmatrix} \dfrac{1}{v_x} & 0 \end{bmatrix} \boldsymbol{x}(t) + [\boldsymbol{0}]u(t). \tag{6.11}$$

Given the following parameters:

m	1300 [kg]	I_c	1300 [kg m^2]
l_V	1.9 [m]	l_H	0.8 [m]
v_x	19 [m/s]	k_H	1.4×10^5 [N]
k_V	5.9×10^4 [N]	g	9.81 [m/s^2]

The matrices $\boldsymbol{A}$, $\boldsymbol{B}$, and $\boldsymbol{C}$ result in

$$\boldsymbol{A} = \begin{bmatrix} -8.0713 & -19.0000 \\ 0 & -12.2683 \end{bmatrix}, \quad \boldsymbol{B} = \begin{bmatrix} 45.43 & 0 \\ 86.33 & 7.6923 \times 10^{-4} \end{bmatrix}, \quad \boldsymbol{C} = [0.0526 \quad 0]. \tag{6.12}$$

6.1.3 Transformation of State-Space Systems

For a given physical system, the choice of the state vector is not unique. Generally, there are infinitely many state representations of one and the same system. The transition from one state representation with state vector $\boldsymbol{x}$ to a different one with state vector $\hat{x}$ can be described by a non-singular $n \times n$ transformation matrix $\boldsymbol{T}$:

$$\boldsymbol{x} = \boldsymbol{T}\hat{\boldsymbol{x}} \quad \text{or} \quad \hat{\boldsymbol{x}} = \boldsymbol{T}^{-1}\boldsymbol{x}, \tag{6.13}$$

Inserting $\boldsymbol{x} = \boldsymbol{T}\hat{\boldsymbol{x}}$ into the state differential equation (6.1) and output equation (6.2), one obtains

$$\boldsymbol{T}\dot{\hat{\boldsymbol{x}}} = \boldsymbol{A}\boldsymbol{T}\hat{\boldsymbol{x}} + \boldsymbol{B}\boldsymbol{u} + \boldsymbol{E}\boldsymbol{z},$$

$$\boldsymbol{y} = \boldsymbol{C}\boldsymbol{T}\hat{\boldsymbol{x}} + \boldsymbol{D}\boldsymbol{u} + \boldsymbol{F}\boldsymbol{z},$$

where the state differential equation can be transformed to

$$\dot{\hat{\boldsymbol{x}}} = \boldsymbol{T}^{-1}\boldsymbol{A}\boldsymbol{T}\,\hat{\boldsymbol{x}} + \boldsymbol{T}^{-1}\boldsymbol{B}\boldsymbol{u} + \boldsymbol{T}^{-1}\boldsymbol{E}\boldsymbol{z}.$$

Using the relations

$$\hat{\boldsymbol{A}} = \boldsymbol{T}^{-1}\boldsymbol{A}\boldsymbol{T}, \quad \hat{\boldsymbol{B}} = \boldsymbol{T}^{-1}\boldsymbol{B}, \quad \hat{\boldsymbol{E}} = \boldsymbol{T}^{-1}\boldsymbol{E}, \quad \hat{\boldsymbol{C}} = \boldsymbol{C}\boldsymbol{T}, \quad \hat{\boldsymbol{D}} = \boldsymbol{D}, \quad \hat{\boldsymbol{F}} = \boldsymbol{F}, \tag{6.14}$$

the transformed system is obtained:

$$\dot{\hat{\boldsymbol{x}}} = \hat{\boldsymbol{A}}\hat{\boldsymbol{x}} + \hat{\boldsymbol{B}}\boldsymbol{u} + \hat{\boldsymbol{E}}\boldsymbol{z}; \hat{\boldsymbol{x}}(t_0) = \hat{\boldsymbol{x}}_0, \tag{6.15}$$

$$\boldsymbol{y} = \hat{\boldsymbol{C}}\hat{\boldsymbol{x}} + \hat{\boldsymbol{D}}\boldsymbol{u} + \hat{\boldsymbol{F}}\boldsymbol{z}. \tag{6.16}$$

Important properties of state transformations:

1. The determinant of a matrix $\boldsymbol{A}$ is invariant against the described transformation, that is, $|\boldsymbol{A}| = |\boldsymbol{T}^{-1}\boldsymbol{A}\boldsymbol{T}|$.
2. The eigenvalues of $\boldsymbol{A}$ are also invariant against the given transformation, that is, $|s\boldsymbol{I} - \boldsymbol{A}| = |s\boldsymbol{I} - \boldsymbol{T}^{-1}\boldsymbol{A}\boldsymbol{T}|$.

6.1.4 Transfer Function Matrices

State-space representations (6.1) and (6.2) can be uniquely transformed to transfer functions. The inverse transform, for example, a conversion from transfer functions to a state-space system is also possible; the result, however, is not unique (cf. 6.3). Setting $\boldsymbol{x}_0 = \boldsymbol{0}$, the Laplace transforms of the state differential equation and the output equation are

$$s\boldsymbol{X}(s) = \boldsymbol{A}\boldsymbol{X}(s) + \boldsymbol{B}\boldsymbol{U}(s) + \boldsymbol{E}\boldsymbol{Z}(s), \tag{6.17}$$

$$\boldsymbol{Y}(s) = \boldsymbol{C}\boldsymbol{X}(s) + \boldsymbol{D}\boldsymbol{U}(s) + \boldsymbol{F}\boldsymbol{Z}(s). \tag{6.18}$$

Solving (6.18) for $\boldsymbol{X}(s)$ yields $\boldsymbol{X}(s) = (s\boldsymbol{I} - \boldsymbol{A})^{-1}\boldsymbol{B}\boldsymbol{U}(s) + (s\boldsymbol{I} - \boldsymbol{A})^{-1}\boldsymbol{E}\boldsymbol{Z}(s)$. The matrix $\boldsymbol{\Phi}(s) = (s\boldsymbol{I} - \boldsymbol{A})^{-1}$ is called the transition matrix. Inserting $\boldsymbol{X}(s)$ into 6.18 leads to

$$\boldsymbol{Y}(s) = [\boldsymbol{C}(s\boldsymbol{I} - \boldsymbol{A})^{-1}\boldsymbol{B} + \boldsymbol{D}]\boldsymbol{U}(s) + [\boldsymbol{C}(s\boldsymbol{I} - \boldsymbol{A})^{-1}\boldsymbol{E} + \boldsymbol{F}]\boldsymbol{Z}(s). \tag{6.19}$$

The $(m \times r)$-transfer function matrix $\boldsymbol{G}_{SU}(s) = \boldsymbol{Y}(s)/\boldsymbol{U}(s)$ and the $(m \times q)$-transfer function matrix $\boldsymbol{G}_{SZ}(s) = \boldsymbol{Y}(s)/\boldsymbol{Z}(s)$ are therefore given by

$$\boldsymbol{G}_{SU}(s) = \boldsymbol{C}(s\boldsymbol{I} - \boldsymbol{A})^{-1}\boldsymbol{B} + \boldsymbol{D}, \tag{6.20}$$

$$\boldsymbol{G}_{SZ}(s) = \boldsymbol{C}(s\boldsymbol{I} - \boldsymbol{A})^{-1}\boldsymbol{E} + \boldsymbol{F}. \tag{6.21}$$

Example 6.2

The following state-space system is considered:

$$\boldsymbol{A} = \begin{bmatrix} -5 & 2 \\ -6 & 2 \end{bmatrix}, \quad \boldsymbol{B} = \begin{bmatrix} 2 \\ 2 \end{bmatrix}, \quad \boldsymbol{B} = [1 \quad -1], \quad \boldsymbol{D} = 0, \quad \boldsymbol{E} = \begin{bmatrix} 1 \\ 0 \end{bmatrix}, \quad \boldsymbol{F} = 0.$$

The transition matrix is

$$\boldsymbol{\Phi}(s) = (s\boldsymbol{I} - \boldsymbol{A})^{-1} = \begin{bmatrix} s+5 & -2 \\ 6 & s-2 \end{bmatrix}^{-1} = \begin{bmatrix} \dfrac{s-2}{(s+1)(s+2)} & \dfrac{2}{(s+1)(s+2)} \\ \dfrac{-6}{(s+1)(s+2)} & \dfrac{s+5}{(s+1)(s+2)} \end{bmatrix}.$$

The (scalar) transfer function $G_{SU}(s)$ is obtained from (6.20):

$$G_{SU}(s) = [1 \quad -1] \begin{bmatrix} \dfrac{s-2}{(s+1)(s+2)} & \dfrac{2}{(s+1)(s+2)} \\ \dfrac{-6}{(s+1)(s+2)} & \dfrac{s+5}{(s+1)(s+2)} \end{bmatrix} \begin{bmatrix} 2 \\ 2 \end{bmatrix} = \frac{2}{(s+1)(s+2)}.$$

The (scalar) transfer function $G_{SZ}(s)$ is obtained from (6.21)

$$G_{sz}(s) = [1 \quad -1] \begin{bmatrix} \dfrac{s-2}{(s+1)(s+2)} & \dfrac{2}{(s+1)(s+2)} \\ \dfrac{-6}{(s+1)(s+2)} & \dfrac{s+5}{(s+1)(s+2)} \end{bmatrix} \begin{bmatrix} 1 \\ 0 \end{bmatrix} = \frac{s+4}{(s+1)(s+2)}.$$

6.1.5 Stability of LTI Systems

The stability of a state-space system is determined by the homogeneous part of its state differential equation:

$$\dot{\boldsymbol{x}} = \boldsymbol{A}\boldsymbol{x}. \tag{6.22}$$

Stability is determined by means of the eigenvalues of the matrix $\boldsymbol{A}$. They are the roots of the characteristic polynomial $P(\lambda)$ given by

$$P(\lambda) = |\lambda \boldsymbol{I} - \boldsymbol{A}| = a_n\lambda^n + a_{n-1}\lambda^{n-1} + \ldots + a_2\lambda^2 + a_1\lambda + a_0 \tag{6.23}$$

Theorem 6.1

*The LTI system (6.22) is **asymptotically stable**, if the real parts of all eigenvalues of **A** are negative.*

Theorem 6.2

*The LTI system (6.22) is **marginally stable**, if the real parts of all eigenvalues of **A** are negative, except for an imaginary couple or an eigenvalue equal to zero both of which with a multiplicity of one.*

Theorem 6.3

*The LTI system (6.22) is **unstable**, if the real part of an eigenvalue of **A** is either positive or if eigenvalues of **A** with a multiplicity greater than one are located on the imaginary axis.*

6.1.6 Controllability and Observability

6.1.6.1 Controllability

Definition 6.1

The LTI system

$$\dot{\boldsymbol{x}} = \boldsymbol{A}\boldsymbol{x} + \boldsymbol{B}\boldsymbol{u}; \quad \boldsymbol{x}(t_0) = \boldsymbol{x}_0 \tag{6.24}$$

is fully state controllable, if there exists an unconstrained control input $\boldsymbol{u}(t)$ that transfers any initial state $\boldsymbol{x}(t_0)$ to any arbitrary state $\boldsymbol{x}(t_1)$ within a finite time interval $t_0 \le t \le t_1$.

Remarks:

- The earlier definition also implies that every component of the state vector $\boldsymbol{x}$ is directly or indirectly influenced by the input $\boldsymbol{u}$.
- In the earlier definition for controllability, it is not required that $\boldsymbol{x}(t) = \boldsymbol{x}(t_1)$ for $t > t_1$.

Full controllability only depends on the system matrix $\boldsymbol{A}$ and on the input matrix $\boldsymbol{B}$ and can be expressed in terms of the controllability matrix $\boldsymbol{Q}_c$.

Definition 6.2

The system (6.24) is fully state controllable if the ($n \times nr$)-controllability matrix $\boldsymbol{Q}_c$ has full rank n:

$$rank(\boldsymbol{Q}_c) = rank([\boldsymbol{B}, \boldsymbol{AB}, \boldsymbol{A}^2\boldsymbol{B}, \ldots, \boldsymbol{A}^{n-1}\boldsymbol{B}]) = n. \tag{6.25}$$

Example 6.3

The following two systems are considered:

$$\text{Case 1: } \dot{\boldsymbol{x}} = \begin{bmatrix} -5 & 2 \\ -6 & 2 \end{bmatrix}\boldsymbol{x} + \begin{bmatrix} 2 \\ 2 \end{bmatrix}u \qquad \text{Case 2: } \dot{\boldsymbol{x}} = \begin{bmatrix} -5 & 2 \\ -6 & 2 \end{bmatrix}\boldsymbol{x} + \begin{bmatrix} 2 \\ 4 \end{bmatrix}u.$$

In case 1 the controllability matrix has rank two which indicates full controllability, whereas in case 2 rank ($\boldsymbol{Q}_c$) = 1 holds. This indicates that there exists an uncontrollable subspace, that is, a domain of the state space that cannot be reached by the control input $u(T)$.

6.1.6.2 Observability

Definition 6.3

The LTI system

$$\dot{\boldsymbol{x}} = \boldsymbol{Ax} + \boldsymbol{Bu}; \quad \boldsymbol{x}(t_0) = \boldsymbol{x}_0, \tag{6.26}$$

$$\boldsymbol{y} = \boldsymbol{Cx} + \boldsymbol{Du} \tag{6.27}$$

is fully state observable if any initial state $\boldsymbol{x}_0$ can be determined from observation of the input $\boldsymbol{u}(t)$ and the output $\boldsymbol{y}(t)$ within a finite time $t_0 \leq t \leq t_1$.

Remark:
The given definition also implies that every component of the state vector $\boldsymbol{x}$ influences the outputs $\boldsymbol{y}$.

Full state observability only depends on the system matrix $\boldsymbol{A}$ and the output matrix $\boldsymbol{C}$ and can be expressed in terms of the observability matrix $\boldsymbol{Q}_0$.

Theorem 6.4

The system (6.26) and (6.27) is fully state observable if the ($mn \times n$)-observability matrix has full rank n:

$$rank(\boldsymbol{Q}_B) = rank\left(\begin{bmatrix} \boldsymbol{C} \\ \boldsymbol{CA} \\ \vdots \\ \boldsymbol{CA}^{n-1} \end{bmatrix}\right) = n. \tag{6.28}$$

6.2 STATE FEEDBACK CONTROL DESIGN

6.2.1 State Feedback Control by Pole Placement

Figure 6.3 shows a block diagram of a single-input–single-output system that is controlled by a state feedback controller. The system has the following state-space representation:

$$\dot{\boldsymbol{x}} = \boldsymbol{A}\boldsymbol{x} + \boldsymbol{b}u + \boldsymbol{E}z; \quad \boldsymbol{x}_0 = 0, \tag{6.29}$$

$$y = \boldsymbol{c}^T\boldsymbol{x} + du. \tag{6.30}$$

The control law of a state feedback controller is given as

$$u = K_w w - \boldsymbol{k}^T\boldsymbol{x}. \tag{6.31}$$

Full state feedback design commonly relies on pole-placement techniques. If the plant (6.29) is fully state controllable (cf. Section 6.1.6), then the n components of the feedback gain $\boldsymbol{k}^T = [k_1\ k_2\ \ldots\ k_n]$ can be determined uniquely by choosing n eigenvalues of the closed loop. The gain K_w is used to guarantee a closed-loop steady-state gain of one.

By inserting the control law (6.31) in (6.29) and (6.30), the state-space representation of the closed loop is obtained:

$$\dot{\boldsymbol{x}} = (\boldsymbol{A} - \boldsymbol{b}\boldsymbol{k}^T)\boldsymbol{x} + \boldsymbol{b}K_w w + \boldsymbol{E}z, \tag{6.32}$$

$$y = (c^T - d\boldsymbol{k}^T)\boldsymbol{x} + dK_w w + \boldsymbol{f}^T z. \tag{6.33}$$

6.2.1.1 Pole Placement by Comparison of Coefficients

An intuitive approach to determine the state feedback gain $\boldsymbol{k}^T$ is by comparing the coefficients of the characteristic polynomial of the closed-loop system to those of a desired polynomial. From 6.32, the characteristic polynomial of the closed loop results in

$$P_k(s, \boldsymbol{k}^T) = det[s\boldsymbol{I} - (\boldsymbol{A} - \boldsymbol{b}\boldsymbol{k}^T)]. \tag{6.34}$$

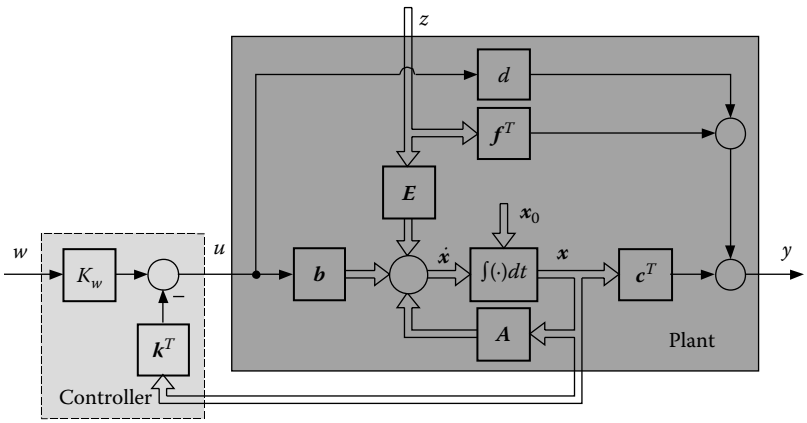

FIGURE 6.3 State feedback control.

The coefficients (6.34) are compared to a desired polynomial $P(s)$, which results in n equations for the n components of $\boldsymbol{k}^T$:

$$P(s) = (s-\lambda_1)(s-\lambda_2)\ \ldots\ (s-\lambda_n). \tag{6.35}$$

The roots λ_i of $P(s)$ are typically determined from dynamic specifications of the closed-loop step response like maximum overshoot e_m, rise time T_r, or settling time T_s.

6.2.1.1.1 Determination of the Gain K_w

The gain K_w is determined from the requirement that the steady-state gain of the closed loop is equal to one so that the output y correctly follows the reference input w.

Setting $\dot{\boldsymbol{x}} = \boldsymbol{0}$ and $\boldsymbol{z} = \boldsymbol{0}$ in 6.32 leads to

$$\boldsymbol{x}_\infty = (\boldsymbol{b}\boldsymbol{k}^T - \boldsymbol{A})^{-1}\boldsymbol{b}K_w w_\infty, \tag{6.36}$$

where ∞ indicates the steady state. Inserting 6.36 into 6.33 yields

$$y_\infty = (\boldsymbol{c}^T - d\boldsymbol{k}^T)\boldsymbol{x}_\infty + dK_w w_\infty = [(\boldsymbol{c}^T - d\boldsymbol{k}^T)(\boldsymbol{b}\boldsymbol{k}^T - \boldsymbol{A})^{-1}\boldsymbol{b} + d]\boldsymbol{K}_w w_\infty.$$

Since $y_\infty = w_\infty$ should hold, K_w must satisfy

$$K_w = [(\boldsymbol{c}^T - d\boldsymbol{k}^T)(\boldsymbol{b}\boldsymbol{k}^T - \boldsymbol{A})^{-1}\boldsymbol{b} + d]^{-1}. \tag{6.37}$$

Example 6.4

The single-track model from Example 6.1 is considered.

As a control input, the yawing torque M is chosen. In reality, M is applied by selective braking of single wheels. For the closed loop, a natural frequency of $\omega_n = 18$ and a damping constant of $\zeta = 0.8$ are chosen. This corresponds to an eigenvalue pair $p_{1,2} = -14.4 \pm 10.8i$ and a desired polynomial P_{des} of

$$P_{des} = s^2 + 28.8s + 324. \tag{6.38}$$

For the characteristic polynomial of the closed loop, one obtains

$$P(s) = s^2 + s(20.3396 + 7.692\times10^{-4}k_2) + (99.0208 + 0.0062k_2 - 0.0146k_1), \tag{6.39}$$

which yields the following comparison of coefficients:

$$\begin{aligned} s^2&: \quad 1 = 1 \\ s^1&: \quad 20.3396 + 7.692\times10^{-4}k_2 = 28.8 \\ s^0&: \quad 99.0208 + 0.0062k_2 - 0.0146k_1 = 324 \end{aligned}$$

$$\begin{bmatrix} k_1 \\ k_2 \end{bmatrix} = 10^4 \times \begin{bmatrix} -1.0721 \\ 1.0999 \end{bmatrix}. \tag{6.40}$$

The gain K_w is computed from 6.37:

$$K_w = -4.2120\times10^5. \tag{6.41}$$

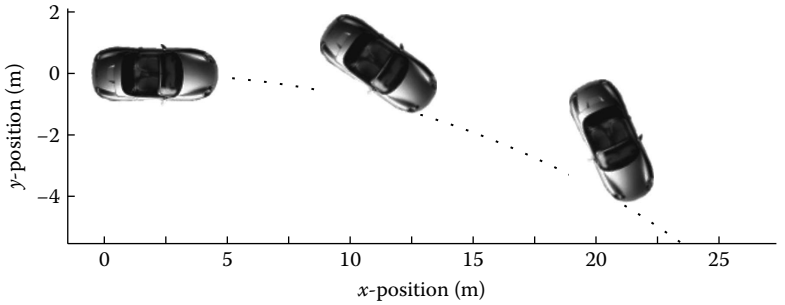

FIGURE 6.4 C/G trajectory without state feedback control.

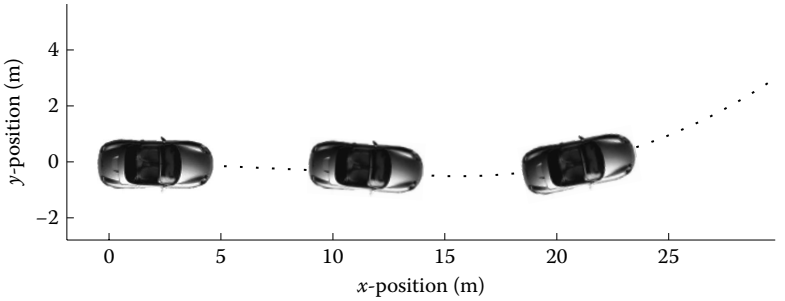

FIGURE 6.5 C/G trajectory with state feedback control.

Figures 6.4 and 6.5 show the C/G trajectories without and with the controller just designed. As initial conditions, $\upsilon_y = 0\frac{m}{s^2}$ and $\dot{\psi} = -2\frac{1}{s}$ were chosen. Additionally, after 1.5 s the driver initiates a left curve by a proper choice of δ. It is apparent that due to the high initial yaw angular velocity the car is oversteering clockwise. Figure 6.4 shows that this undesirable state is not ended without controller interaction, while in Figure 6.5 the car perfectly follows the driver's intention and swerves into a left turn.

6.2.1.2 Pole Placement by Eigenstructure Assignment

Pole placement by comparison of coefficients only delivers unique results for single-input systems. An alternative approach that can also be easily implemented in computer programs is direct eigenstructure assignment.

This approach directly looks at the eigenvalue equation of the system matrix $\boldsymbol{A} - \boldsymbol{b}\boldsymbol{k}^T$ of the closed loop (6.32):

$$(\boldsymbol{A} - \boldsymbol{b}\boldsymbol{k}^T)\boldsymbol{u}_i = \lambda_i \boldsymbol{u}_i. \tag{6.42}$$

Rearranging this equation leads to

$$(\boldsymbol{A} - \lambda_i \boldsymbol{I})\boldsymbol{u}_i = \boldsymbol{b}\boldsymbol{k}^T\boldsymbol{u}_i \Rightarrow \boldsymbol{u}_i \underbrace{(\boldsymbol{A} - \lambda_i \boldsymbol{I})^{-1}\boldsymbol{b}}_{\boldsymbol{S}(\lambda_i)} \underbrace{\boldsymbol{k}^T\boldsymbol{u}_i}_{\boldsymbol{z}_i}. \tag{6.43}$$

After choosing an eigenvalue λ_i, the associated eigenvector $\boldsymbol{u}_i$ is obtained from 6.43. For single-input systems, $\boldsymbol{z}_i$ is scalar and can be chosen $z_i = 1$ without loss of generality. This yields

$$\boldsymbol{u}_i = \boldsymbol{S}(\lambda_i). \tag{6.44}$$

With $\boldsymbol{u}_i$ from 6.44 and $z_i = 1$, one further obtains *one* equation for the determination of the feedback gain $\boldsymbol{k}^T$:

$$\boldsymbol{k}^T\boldsymbol{u}_i = 1. \tag{6.45}$$

If n eigenvalues $\lambda_1 \ldots \lambda_n$ are chosen in the manner described earlier, a complete matrix equation for the actual determination of $\boldsymbol{k}^T$ is created by collecting all equations (6.45):

$$\boldsymbol{k}^T[\boldsymbol{u}_1 \quad \ldots \quad \boldsymbol{u}_n] = [1 \quad \ldots \quad 1] \Rightarrow \boldsymbol{k}^T = [1 \quad \ldots \quad 1][\boldsymbol{u}_1 \quad \ldots \quad \boldsymbol{u}_n]^{-1}. \tag{6.46}$$

- For complex–conjugate couples, 6.43 is separated into real and imaginary parts and thus delivers *two* equations for the determination of the feedback gain.
- It is not possible to assign eigenvalues of the open-loop system to the closed loop since $\boldsymbol{S}(\lambda)$ would not exist in this case.
- The inverse in 6.46 can only be computed if the eigenvector matrix $[\boldsymbol{u}_1 \ldots \boldsymbol{u}_n]$ is non-singular. The conditioning of this matrix can be influenced implicitly by the choice of eigenvalues.
- In the multi-input case, $\boldsymbol{z}_i$ in 6.43 has as many elements as there are control inputs. This gives additional design freedom for the eigenvector $\boldsymbol{u}_i$ even after the eigenvalue λ_i has been chosen. This freedom is mostly used to ensure proper conditioning of the eigenvector matrix. An introduction to related methods is given in [12].

6.2.1.3 State Feedback with Integration of the Control Error

A common method to reject unknown disturbances is by additional integration of the control error. For a single-input system with one control variable, the control law now reads

$$u = -\boldsymbol{k}^T\boldsymbol{x} + K\int_0^t (w - y)dt \tag{6.47}$$

and the system representation is given by

$$\dot{\boldsymbol{x}} = \boldsymbol{A}\boldsymbol{x} + \boldsymbol{b}u + \boldsymbol{E}\boldsymbol{z}, \tag{6.48}$$

$$y = \boldsymbol{c}^T\boldsymbol{x} + du + \boldsymbol{f}^T\boldsymbol{z}. \tag{6.49}$$

In order to integrate 6.47 in the state feedback concept, an additional state variable $p(t)$ is defined:

$$p(t) = \int_0^t (y(\tau) - w(\tau))d\tau. \tag{6.50}$$

Differentiating $p(t)$ and inserting the output equation (6.49) yields

$$\dot{p}(t) = y(t) - w(t) = \boldsymbol{c}^T\boldsymbol{x} + du + \boldsymbol{f}^T\boldsymbol{z} - w. \tag{6.51}$$

Next, 6.48 and 6.51 are combined to one augmented state-space system:

$$\begin{bmatrix} \dot{\boldsymbol{x}} \\ \dot{p} \end{bmatrix} = \begin{bmatrix} \boldsymbol{A} & \boldsymbol{0} \\ c^T & 0 \end{bmatrix}\begin{bmatrix} \boldsymbol{x} \\ p \end{bmatrix} + \begin{bmatrix} \boldsymbol{b} \\ d \end{bmatrix}u + \begin{bmatrix} \boldsymbol{E} & \boldsymbol{0} \\ f^T & -1 \end{bmatrix}\begin{bmatrix} z \\ w \end{bmatrix}. \tag{6.52}$$

Given the augmented state vector $\hat{\boldsymbol{x}} = [x^T \quad p]^T$, the control law (6.47) now reads

$$u(t) = -\hat{\boldsymbol{k}}^T\hat{\boldsymbol{x}}(t) \quad \text{with}\, \hat{\boldsymbol{k}}^T = [\boldsymbol{k}^T \quad K]. \tag{6.53}$$

The augmented feedback gain vector $\hat{\boldsymbol{k}}^T$ can now be determined with the augmented system (6.52) using the techniques from Sections 6.2.1.1 and 6.2.1.2. Again, full state feedback requires that the system (6.53) is fully state controllable. If the original system (6.48) is fully state controllable, this can be ensured if additionally the matrix

$$\boldsymbol{G} = \begin{bmatrix} \boldsymbol{A} & \boldsymbol{b} \\ c^T & d \end{bmatrix} \tag{6.54}$$

has full rank. Inserting 6.53 in 6.52 gives the state-space representation of the closed loop:

$$\begin{bmatrix} \dot{\boldsymbol{x}} \\ \dot{p} \end{bmatrix} = \begin{bmatrix} \boldsymbol{A} & -\boldsymbol{b}\boldsymbol{k}^T & -K\boldsymbol{b} \\ \boldsymbol{c}^T & -d\boldsymbol{k}^T & -dK \end{bmatrix} \begin{bmatrix} \boldsymbol{x} \\ p \end{bmatrix} + \begin{bmatrix} \boldsymbol{E} & \boldsymbol{0} \\ \boldsymbol{f}^T & -1 \end{bmatrix} \begin{bmatrix} \boldsymbol{z} \\ w \end{bmatrix}. \tag{6.55}$$

The transfer function matrices of the closed-loop system are

$$\boldsymbol{z} = \boldsymbol{0}: \quad G_w(s) = [(c^T - d\boldsymbol{k}^T) - dK]\Phi(s) \begin{bmatrix} \boldsymbol{0} \\ -1 \end{bmatrix}, \tag{6.56}$$

$$w = 0: \quad \boldsymbol{G}_z(s) = [(\boldsymbol{c}^T - d\boldsymbol{k}^T) - dK]\Phi(s) \begin{bmatrix} \boldsymbol{E} \\ \boldsymbol{f}^T \end{bmatrix} + \boldsymbol{f}^T, \tag{6.57}$$

where

$$\Phi(s) = \begin{bmatrix} (s\boldsymbol{I} - \boldsymbol{A} + \boldsymbol{b}\boldsymbol{k}^T) & Kb \\ (d\boldsymbol{k}^T - \boldsymbol{c}^T) & s + dK \end{bmatrix}^{-1}.$$

Example 6.5

The following system is considered:

$$\dot{\boldsymbol{x}} = \begin{bmatrix} -1 & 1 \\ 2 & -2 \end{bmatrix} \boldsymbol{x} + \begin{bmatrix} 0, & 25 \\ 0 & \end{bmatrix} u + \begin{bmatrix} -1 & 0 \\ 0 & -2 \end{bmatrix} \boldsymbol{z},$$

$$y = [0 \quad 1]\boldsymbol{x}.$$

A state feedback controller with integration of the control error has to be designed such that the poles of the closed loop are located at $s_{1,2} = -2 \pm j_2$ and $s_3 = -10$.

First, the criteria for full state controllability of the augmented system (6.52) have to be checked:

$$rank([\,\boldsymbol{b} \quad \boldsymbol{A}\boldsymbol{b}\,]) = 2 \text{ and } rank\left(\begin{bmatrix} \boldsymbol{A} & \boldsymbol{b} \\ \boldsymbol{c}^T & 0 \end{bmatrix}\right) = 3$$

The characteristic polynomial of the closed-loop system is

$$P_k(s, \boldsymbol{k}^T, K) = det[s\boldsymbol{I} - \hat{\boldsymbol{A}} + \hat{\boldsymbol{b}}\,[\boldsymbol{k}^T \quad K]] = \begin{vmatrix} s+1+0.25k_1 & -1+0.25k_2 & 0.25K \\ -2 & s+2 & 0 \\ 0 & -1 & s \end{vmatrix} =$$

$$= s^3 + (3+0.25k_1)s^2 + (0.5k_1 + 0.5k_2)s + 0.5K$$

and the desired polynomial $P(s)$ is

$$P(s) = (s^2 + 4s + 8)(s + 10) = s^3 + 14s^2 + 48s + 80.$$

A comparison of coefficients yields

$$3 + 0.25k_1 = 14 \quad k_1 = 44$$

$$0.5k_1 + 0.5k_2 = 48 \Rightarrow k_2 = 52 \Rightarrow u = -[44 \quad 52]\boldsymbol{x} + 160\int(w - y)dt$$

$$0.5K = 80 \quad K = 160.$$

Equations 6.55 through 6.57 deliver the transfer function matrices:

$$G_w(s) = [(\boldsymbol{c}^T - d\boldsymbol{k}^T) - dK]\Phi(s)\begin{bmatrix} 0 \\ 0 \\ -1 \end{bmatrix} = \frac{80}{s^3 + 14s^2 + 48s + 80},$$

$$\boldsymbol{G}_z(s) = [(\boldsymbol{c}^T - d\boldsymbol{k}^T) - dK]\Phi(s)\begin{bmatrix} \boldsymbol{E} \\ \boldsymbol{f}^T \end{bmatrix} = \boldsymbol{f}^T = \begin{bmatrix} \dfrac{-2s}{s^3 + 14s^2 + 48s + 80} & \dfrac{-2s(s+12)}{s^3 + 14s^2 + 48s + 80} \end{bmatrix}.$$

It is apparent that $G_w(s)$ has a steady-state gain of one whereas both elements of $G_Z(s)$ have globally differentiating behavior.

6.2.2 State Estimation by Observers

In the previous sections, it was assumed that all elements of the state vector $\boldsymbol{x}(t)$ are available. In most applications, however, this is not the case. Often, some elements of the state vector are not measurable at all. In these situations, an estimate $\hat{\boldsymbol{x}}$ of the state vector $\boldsymbol{x}$ is computed by the so-called Luenberger state observer. It is assumed that a number of measurements from the system is available that are combined in a measurement vector $m(t)$. The dynamic system is thus described by

$$\dot{\boldsymbol{x}} = \boldsymbol{A}\boldsymbol{x} + \boldsymbol{B}\boldsymbol{u}, \tag{6.58}$$

$$\boldsymbol{m} = \boldsymbol{C}^*\boldsymbol{x} + \boldsymbol{D}^*\boldsymbol{u}. \tag{6.59}$$

A full Luenberger observer is given by

$$\dot{\hat{\boldsymbol{x}}} = \boldsymbol{A}\hat{\boldsymbol{x}} + \boldsymbol{B}\boldsymbol{u} + \boldsymbol{H}(m - \boldsymbol{C}^*\hat{\boldsymbol{x}} - \boldsymbol{D}^*\boldsymbol{u}), \tag{6.60}$$

where

$\hat{\boldsymbol{x}}$ is the estimate of the state vector
$\boldsymbol{H}$ is the observer gain matrix

It is apparent that the Luenberger observer is by itself a state-space system with $\hat{\boldsymbol{x}}$ as the state variable and $u(t)$ and $\boldsymbol{m}(t)$ as inputs. The reconstruction error is given as $\tilde{\boldsymbol{x}} = \boldsymbol{x} - \hat{\boldsymbol{x}}$. The dynamic behavior of $\tilde{\boldsymbol{x}}(t)$ is obtained by subtraction of 6.60 from 6.58:

$$\dot{\tilde{\boldsymbol{x}}} = (\boldsymbol{A} - \boldsymbol{H}\boldsymbol{C}^*)\tilde{\boldsymbol{x}}. \tag{6.61}$$

If the system (6.58) and (6.59) is fully state observable, the poles of the observer system matrix $\boldsymbol{A} - \boldsymbol{H}\boldsymbol{C}^*$ can be assigned arbitrarily by proper choice of the observer gain matrix $\boldsymbol{H}$ (with exception of the poles of $\boldsymbol{A}$).

6.2.2.1 Observer Design by Pole Assignment

6.2.2.1.1 Observer Design by Comparison of Coefficients

If the measurement vector $\boldsymbol{m}$ contains only one element, the observer gain matrix can be determined by comparison of coefficients. The characteristic polynomial of the system (6.61) is

$$P_B(s, \boldsymbol{H}) = det(s\boldsymbol{I} - \boldsymbol{A} + \boldsymbol{H}\boldsymbol{C}^*). \tag{6.62}$$

The n eigenvalues of $\boldsymbol{A} - \boldsymbol{H}\boldsymbol{C}^*$ are determined by the elements of the $(1 \times n)$ observer gain $\boldsymbol{H}$ by comparison to a desired polynomial:

$$P_B(s) = (s - \lambda_{B1})(s - \lambda_{B2}) \ldots (s - \lambda_{Bn}). \tag{6.63}$$

Observer poles should generally be significantly faster than the poles of the closed loop (see Example 6.6).

6.2.2.1.2 Observer Design by Eigenstructure Assignment

Eigenstructure assignment aims at assigning eigenvalues and eigenvectors to the observer system matrix $\boldsymbol{F} = \boldsymbol{A} - \boldsymbol{H}\boldsymbol{C}^*$. Here, the following approach is chosen:

$$\boldsymbol{u}_i^T(\boldsymbol{A} - \boldsymbol{H}\boldsymbol{C}^*) = \boldsymbol{u}_i^T\lambda_i. \tag{6.64}$$

In 6.64, $\boldsymbol{u}_i^T$ is a *left eigenvector* of $\boldsymbol{A} - \boldsymbol{H}\boldsymbol{C}^*$. Taking the transpose of 6.64 yields

$$(\boldsymbol{A}^T - \boldsymbol{C}^{*T}\boldsymbol{H}^T)\boldsymbol{u}_i = \boldsymbol{u}_i\lambda_i. \tag{6.65}$$

Formally, 6.65 resembles an eigenvalue equation of the form 6.42. Comparing the associated terms in 6.42 and 6.65 shows that there is a duality between state feedback control and observation. This duality is highlighted in the following table:

Controller	Observer
$\boldsymbol{A}$	$\boldsymbol{A}^T$
$\boldsymbol{B}$	$\boldsymbol{C}^{*T}$
$\boldsymbol{K}$	$\boldsymbol{H}^T$

Using this information, the results from Section 6.2.1.2 can be applied almost directly for observer design.

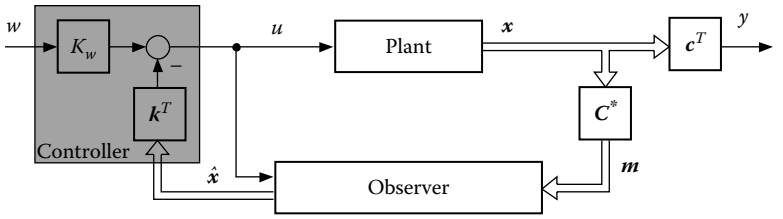

FIGURE 6.6 Luenberger observer in the control loop.

6.2.2.1.3 *Separation Principle*

Figure 6.6 shows the block diagram of a state feedback control loop where instead of the actual state vector $\boldsymbol{x}$ its estimate $\hat{\boldsymbol{x}}$ is used in the control law:

$$u = K_w w - \boldsymbol{k}^T \hat{\boldsymbol{x}}. \tag{6.66}$$

An observer in series with the control law (6.66) is commonly called *compensator.*

One important question to be answered is how the closed-loop system behaves if the control law (6.66) is applied. Since $\hat{\boldsymbol{x}}$ is only an estimate of $\boldsymbol{x}$, it would be justified to cast doubts on the stability of the resulting closed loop.

The answer to this question is given by the separation principle.

Theorem 6.5

Separation principle

If the system under consideration is fully state controllable and fully state observable, the poles of the closed loop (6.32) and the poles of the observer (6.61) can be assigned independently. The poles of the closed loop with control law (6.66) are then the combination of the controller poles and observer poles. The characteristic equation of the system then is

$$det[s\boldsymbol{I} - (\boldsymbol{A} - \boldsymbol{b}\boldsymbol{k}^T)] \cdot det[s\boldsymbol{I} - (\boldsymbol{A} - \boldsymbol{H}\boldsymbol{C}^*)] = 0. \tag{6.67}$$

Example 6.6

The following system is considered:

$$\dot{\boldsymbol{x}} = \begin{bmatrix} -1 & 1 \\ 2 & -2 \end{bmatrix} \boldsymbol{x} + \begin{bmatrix} 0.25 \\ 0 \end{bmatrix} u + \begin{bmatrix} -1 & 0 \\ 0 & -2 \end{bmatrix} \boldsymbol{z} \quad \text{and} \quad y = \begin{bmatrix} 0 & 1 \end{bmatrix} \boldsymbol{x}.$$

Based on the output $y(t)$, an observer has to be designed with two real poles at –20 ($\lambda_{B1} = \lambda_{B2} = -20$.)

The rank of the observability matrix is two so that full state observability can be achieved with $y(t)$. The observer system matrix is given by

$$\boldsymbol{A} - \boldsymbol{h}\boldsymbol{c}^T = \begin{bmatrix} -1 & 1 \\ 2 & -2 \end{bmatrix} - \begin{bmatrix} h_1 \\ h_2 \end{bmatrix} [0 \quad 1] = \begin{bmatrix} -1 & 1 & -h_1 \\ 2 & -2 & -h_2 \end{bmatrix}.$$

The characteristic polynomial of the observer thus is

$$P_B(s, \boldsymbol{h}) = Det(s\boldsymbol{I} - \boldsymbol{A} + \boldsymbol{h}\boldsymbol{c}^T) = \begin{vmatrix} s+1 & h_1 - 1 \\ -2 & s+2+h_2 \end{vmatrix} = s^2 + (h_2 + 3)s + h_2 + 2h_1$$

and with $\lambda_{B1} = \lambda_{B2} = -20$ the desired polynomial is

$$P_B(s) = s^2 + 40s + 400.$$

A comparison of coefficients yields $\boldsymbol{h}^T = [181.5\ 37]$.

The observer equation follows from 6.60:

$$\dot{\hat{x}} = \boldsymbol{A}\hat{x} + \boldsymbol{b}u + \boldsymbol{H}(m - \boldsymbol{C}^*\hat{\boldsymbol{x}}) = \begin{bmatrix} -1 & 1 \\ 2 & -2 \end{bmatrix}\hat{\boldsymbol{x}} + \begin{bmatrix} 0,25 \\ 0 \end{bmatrix} u + \begin{bmatrix} 181.5 \\ 37 \end{bmatrix}[0\ \ 1](\boldsymbol{x} - \hat{\boldsymbol{x}}),$$

$$\dot{\hat{\boldsymbol{x}}} = \begin{bmatrix} -1 & 1 \\ 2 & -2 \end{bmatrix}\hat{\boldsymbol{x}} + \begin{bmatrix} 0 & 25 \\ 0 & \end{bmatrix} u + \begin{bmatrix} 181.5 \\ 37 \end{bmatrix}(x_2 - \hat{x}_2).$$

Example 6.7

The single-track model from Example 6.1 is revisited:

The matrices $\boldsymbol{A}$ and $\boldsymbol{B}$ are (6.12)

$$\boldsymbol{A} = \begin{bmatrix} -8.0713 & -19.0000 \\ 0 & -12.2683 \end{bmatrix}, \quad \boldsymbol{b} = \begin{bmatrix} 45.43 & 0 \\ 86.33 & 7.6923 \times 10^{-4} \end{bmatrix}, \quad \boldsymbol{c} = \begin{bmatrix} 0.0526 \\ 0 \end{bmatrix}. \tag{6.68}$$

It is assumed that the yaw angular velocity $\dot{\psi}$ and the lateral acceleration $\dot{v}_y$ are available as measurements. In this case, the measurement vector contains the derivative of a state:

$$\boldsymbol{m} = \begin{bmatrix} x_2 \\ \dot{x}_1 \end{bmatrix} = \begin{bmatrix} \dot{\psi} \\ \dot{v}_y \end{bmatrix} = \begin{bmatrix} 0 & 1 \\ 0 & 0 \end{bmatrix}\boldsymbol{x} + \begin{bmatrix} 0 & 0 \\ 1 & 0 \end{bmatrix}\dot{\boldsymbol{x}} = \begin{bmatrix} 0 & 1 \\ 0 & 0 \end{bmatrix}\boldsymbol{x} + \begin{bmatrix} 0 & 0 \\ 1 & 0 \end{bmatrix}(\boldsymbol{A}\boldsymbol{x} + \boldsymbol{B}\boldsymbol{u}). \tag{6.69}$$

Using the first row vectors of $\boldsymbol{A}$ and $\boldsymbol{B}$, this leads to

$$\begin{bmatrix} m_1 \\ m_2 \end{bmatrix} = \begin{bmatrix} 0 & 1 \\ a_{11} & a_{12} \end{bmatrix}\begin{bmatrix} x_1 \\ x_2 \end{bmatrix} + \begin{bmatrix} 0 & 0 \\ b_{11} & b_{12} \end{bmatrix}\begin{bmatrix} u_1 \\ u_2 \end{bmatrix} \tag{6.70}$$

and in matrix notation

$$\boldsymbol{m} = \boldsymbol{C}^* x + \boldsymbol{D}^* u. \tag{6.71}$$

In the given example, $\boldsymbol{C}^*$ and $\boldsymbol{D}^*$ result in

$$\boldsymbol{C}^* = \begin{bmatrix} 0 & 1 \\ -8.0713 & -19 \end{bmatrix}; \quad \boldsymbol{D}^* = \begin{bmatrix} 0 & 0 \\ 45.4382 & 0 \end{bmatrix}. \tag{6.72}$$

Since the observer poles should be significantly faster than those of the closed loop, they are chosen as $\lambda_{1,2} = -30, -31$.

In the present example, the number of measurements in $\boldsymbol{m}$ is equal to the number of states so that for the determination of the elements of the gain matrix $\boldsymbol{H}$ the following strategy can be applied.

The closed-loop observer matrix $\boldsymbol{A} - \boldsymbol{HC}^*$ is chosen such that the estimation errors are decoupled, that is

$$\boldsymbol{A} - \boldsymbol{HC}^* = \begin{bmatrix} \lambda_1 & 0 \\ 0 & \lambda_2 \end{bmatrix}.$$

Solving for $\boldsymbol{H}$ leads to

$$\boldsymbol{H} = \left(\boldsymbol{A} - \begin{bmatrix} \lambda_1 & 0 \\ 0 & \lambda_2 \end{bmatrix} \right) (C^*)^{-1}. \tag{6.73}$$

For regular $n \times n$ matrices, $\boldsymbol{C}^*$ (6.73) yields a unique solution for $\boldsymbol{H}$:

$$\boldsymbol{H} = \begin{bmatrix} -70.6209 & -2.7169 \\ 18.7317 & 0 \end{bmatrix}. \tag{6.74}$$

Figures 6.7 and 6.8 show time histories of the state estimates $\dot{v}_y$ and $\hat{\dot{\psi}}$ compared to the true values. For comparison, the estimates $\hat{v}_{y,slow}$ and $\hat{\dot{\psi}}_{slow}$ from a slower observer with poles $\lambda_{1,slow}$, $\lambda_{2,slow} = 14.5, -15$ are also shown.

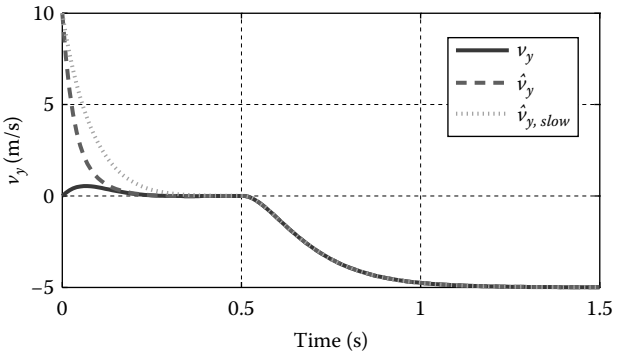

FIGURE 6.7 Time history of v_y, $\hat{v}_y$, and $\hat{v}_{y,slow}$.

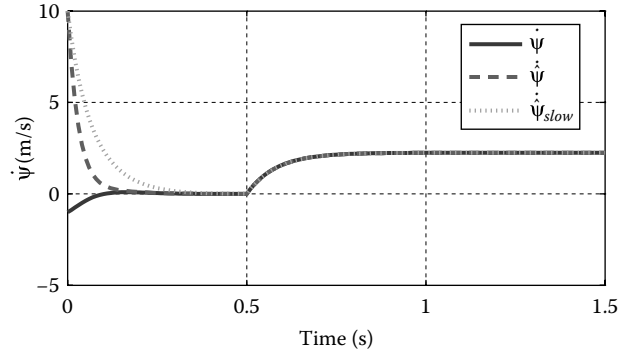

FIGURE 6.8 Time history of $\dot{\psi}$, $\hat{\dot{\psi}}$, and $\hat{\dot{\psi}}_{slow}$.

6.3 OPTIMAL CONTROL

The design of optimal control systems is an important feature of control engineering. Control systems in many different fields are designed on the basis of a performance criterion. Typical examples are

- The way different species move about
- The orientation of plants according to the position of the sun
- Fund management

Control action in the earlier examples aims at maximizing some kind of benefit or minimizing some cost.

This chapter presents the concept of optimal control for linear state-space systems. The obtained control principle is called *linear quadratic regulator* (LQR) *control*.

6.3.1 Riccati Equation

Given the linear state-space representation

$$\dot{\boldsymbol{x}} = \boldsymbol{A}\boldsymbol{x} + \boldsymbol{B}\boldsymbol{u} \qquad \boldsymbol{x}(t=0) = \boldsymbol{x}_0. \tag{6.75}$$

The following cost function will be minimized over a time horizon T:

$$V(\boldsymbol{x}(0), \boldsymbol{u}(\cdot)) = \int_0^T \frac{1}{2}(\boldsymbol{x}^T\boldsymbol{Q}\boldsymbol{x} + \boldsymbol{u}^T\boldsymbol{R}\boldsymbol{u})dt + \frac{1}{2}\boldsymbol{x}(T)^T\boldsymbol{G}\boldsymbol{x}(T). \tag{6.76}$$

The weighting matrices $\boldsymbol{Q}$, $\boldsymbol{R}$, and $\boldsymbol{G}$ must be symmetric and positive (semi)definite. The advantage of the choice of the cost function (6.76) lies in the fact that its minimization leads to a linear state feedback law of the form $\boldsymbol{u}(t) = \boldsymbol{K}(t)\boldsymbol{x}(t)$.

The minimization of 6.76 by the system 6.75 is accomplished through the following control law:

$$\boldsymbol{u}(t) = -\boldsymbol{R}^{-1}\boldsymbol{B}^T\boldsymbol{P}(t)\boldsymbol{x}(t). \tag{6.77}$$

Here, $\boldsymbol{P}(t)$ is the solution of the *Riccati* equation:

$$-\dot{\boldsymbol{P}} = \boldsymbol{P}\boldsymbol{A} + \boldsymbol{A}^T\boldsymbol{P} - \boldsymbol{P}\boldsymbol{B}\boldsymbol{R}^{-1}\boldsymbol{B}^T\boldsymbol{P} + \boldsymbol{Q} \qquad \text{with } \boldsymbol{P}(T) = \boldsymbol{G}. \tag{6.78}$$

The Ricatti equation is a differential equation for the matrix $\boldsymbol{P}(t)$, which is solved backward in time. Due to its symmetric nature, $\boldsymbol{P}(t)$ is also symmetric.

6.3.2 Riccati Equation for $T \to \infty$

In most practical applications, $T \to \infty$ is chosen for the time horizon. The cost function (6.76) now reads

$$V(\boldsymbol{x}(0), \boldsymbol{u}(\cdot)) = \int_0^\infty \frac{1}{2}(\boldsymbol{x}^T\boldsymbol{Q}\boldsymbol{x} + \boldsymbol{u}^T\boldsymbol{R}\boldsymbol{u})dt \tag{6.79}$$

whereby the terminal cost term $\frac{1}{2}\boldsymbol{x}(T)^T\boldsymbol{G}\boldsymbol{x}(T)$ has been omitted. As opposed to 6.76, the cost function (6.79) does not always have a minimum.

Theorem 6.6 (Stabilizability)

A linear state-space system

$$\dot{\boldsymbol{x}} = \boldsymbol{A}\boldsymbol{x} + \boldsymbol{B}\boldsymbol{u} \qquad \boldsymbol{x}(t=0) = \boldsymbol{x}_0$$

is stabilizable if all noncontrollable eigenmodes are asymptotically stable, that is, if the real parts of their associated eigenvalues are negative.

For $T \to \infty$ and for positive definite weighting matrices $\boldsymbol{Q}$, $\boldsymbol{R}$ the cost function (6.79) is bounded only if the underlying system is stabilizable. In this case, the Riccati equation converges toward a stationary $\boldsymbol{P}$ which can be obtained from 6.78 by setting $\dot{\boldsymbol{P}}$ to zero:

$$\boldsymbol{P}\boldsymbol{A} + \boldsymbol{A}^T\boldsymbol{P} - \boldsymbol{P}\boldsymbol{B}\boldsymbol{R}^{-1}\boldsymbol{B}^T\boldsymbol{P} + \boldsymbol{Q} = \boldsymbol{0}. \tag{6.80}$$

Equation 6.96 is called *Lyapunov equation*. The control law follows to

$$\boldsymbol{u}(t) = -\boldsymbol{R}^{-1}\boldsymbol{B}^T\boldsymbol{P}\boldsymbol{x}(t). \tag{6.81}$$

Example 6.8

The following state-space system is considered:

$$\dot{\boldsymbol{x}} = \begin{bmatrix} 2 & 1 \\ 0 & 1 \end{bmatrix}\boldsymbol{x} + \begin{bmatrix} 1 \\ 0 \end{bmatrix}u.$$

It is apparent that the second state x_2 is unstable ($\lambda_2 = 1$) and uncontrollable since $x_2(t)$ is neither directly nor indirectly affected by $u(t)$. Consequently, the system is not stabilizable. Choosing the weighting matrices to

$$\boldsymbol{Q} = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}, \quad R = 1,$$

the Riccati equation (6.78) is

$$-\dot{\boldsymbol{P}} = \boldsymbol{P}\begin{bmatrix} 2 & 1 \\ 0 & 1 \end{bmatrix} + \begin{bmatrix} 2 & 1 \\ 0 & 1 \end{bmatrix}^T\boldsymbol{P} - \boldsymbol{P}\begin{bmatrix} 1 & 0 \\ 0 & 0 \end{bmatrix}\boldsymbol{P} + \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}.$$

Figures 6.9 and 6.10 show the components $P_{11}(t)$, $P_{12}(t) = P_{21}(t)$ and $P_{22}(t)$, if the Riccati equation is solved backward in time starting from $\boldsymbol{P}(3) = \boldsymbol{0}$. While $P_{11}(t)$ and $P_{12}(t)$ quickly converge toward their steady-state equilibrium, the component $P_{22}(t)$ is obviously unbounded.

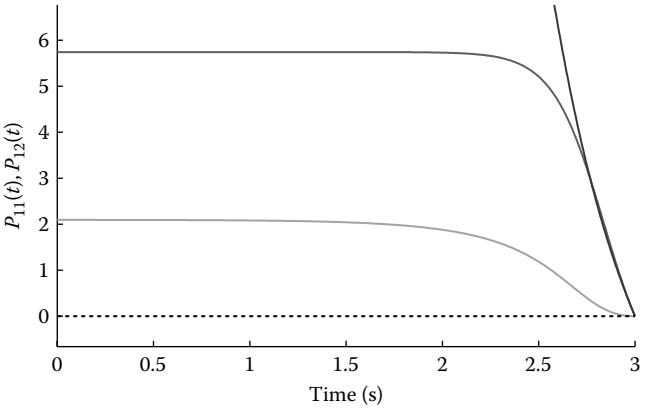

FIGURE 6.9 Example 6.8: $P_{11}(t)$ and $P_{12}(t)$.

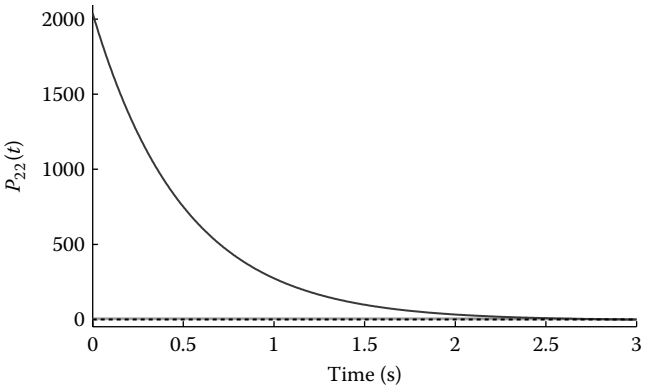

FIGURE 6.10 Example 6.8: $P_{22}(t)$.

6.3.3 *Q–R* Selection

This section will provide different criteria for the proper choice of the weighting matrices.

6.3.3.1 Basics

The elements of the state vector and the control inputs can vary significantly in size. A basic rule of thumb is to choose $\boldsymbol{Q}$ and $\boldsymbol{R}$ as diagonal matrices with

$$q_{ii} = \frac{1}{(x_{i,max})^2} \quad \text{and} \quad r_{ii} = \frac{1}{(u_{i,max})^2},$$

where $x_{i,max}$ and $u_{i,max}$ are the maximum desired amplitudes of the individual states and controls, respectively.

6.3.3.2 State Weighting versus Control Weighting

Strong state weighting. If the elements of $\boldsymbol{Q}$ are large compared to those of $\boldsymbol{R}$, there is a strong emphasis on the states in the cost function. The resulting controller will consequently aim at bringing the states to zero as fast as possible. As a result, the control effort will increase and the bandwidth of the closed loop will grow.

Strong control weighting. If the elements of $\boldsymbol{Q}$ are small compared to those of $\boldsymbol{R}$, there is a strong emphasis on the controls in the cost function. Consequently, the controller will try to reduce the control effort as much as possible. For stable systems, this will result in a control law $u \equiv 0$ and the poles of the closed loop will approach those of the open loop. For systems with unstable poles, these poles will be reflected on the imaginary axis resulting in a stable closed-loop system.

6.3.3.3 Stability

Stability of the closed loop mainly depends on the proper choice of the weighting matrix $\boldsymbol{Q}$.

Theorem 6.7 (Detectability)

*The matrices [**A**, **Q**] are called detectable, if for **A** every eigenvalue λ_i with positive real part the eigenvector $\boldsymbol{u}_i$ fulfills*

$$\boldsymbol{u}_i^T \boldsymbol{Q} \boldsymbol{u}_i \neq \boldsymbol{0}. \tag{6.82}$$

In the sense of optimal control, detectability means that unstable eigenmodes of the systems show up in the cost function.

The following conditions have to be fulfilled for the closed loop to be stable:

- Uncontrollable modes of the system $[\boldsymbol{A},\boldsymbol{B}]$ are stable, that is, $[\boldsymbol{A},\boldsymbol{B}]$ is *stabilizable* (cf. Theorem 6.6).
- Unstable modes of the system are visible in the cost function, that is, $[\boldsymbol{A},\boldsymbol{Q}]$ is detectable.

Example 6.9

The following system is considered:

$$\dot{x} = x + u.$$

If the cost function is chosen as

$$V_*(\boldsymbol{x}(t),\ \boldsymbol{u}_*(t)) = \int_0^\infty u^2 dt.$$

It is apparent that the optimal control law is $u \equiv 0$. The closed loop would then be unstable although the system is fully state controllable because the unstable mode does not show up in the cost function.

6.3.3.3.1 Assigning a Predefined Degree of Stability

Due to robustness requirements, it is often desirable to ensure a certain degree of stability, that is, the real parts of the closed-loop poles must be smaller than some predefined constant α.

The open-loop system (6.75) is

$$\dot{\boldsymbol{x}} = \boldsymbol{A}\boldsymbol{x} + \boldsymbol{B}\boldsymbol{u} \qquad \boldsymbol{x}(t=0) = \boldsymbol{x}_0\,.$$

For the cost function, new state and control variables $\hat{\boldsymbol{x}}$, $\hat{\boldsymbol{u}}$ are introduced:

$$\hat{\boldsymbol{x}} = e^{\alpha t}\boldsymbol{x} \quad \text{and} \quad \hat{\boldsymbol{u}} = e^{\alpha t}\boldsymbol{u}. \tag{6.83}$$

Differentiating and inserting $\dot{\boldsymbol{x}} = \boldsymbol{A}\boldsymbol{x} + \boldsymbol{B}\boldsymbol{u}$ gives

$$\dot{\hat{\boldsymbol{x}}} = \frac{d}{dt}(e^{\alpha t}\boldsymbol{x}) = (\boldsymbol{A} + \alpha\boldsymbol{I})\hat{\boldsymbol{x}} + \boldsymbol{B}\hat{\boldsymbol{u}}. \tag{6.84}$$

The cost function (6.76) is now expressed in terms of $\hat{\boldsymbol{x}}$ and $\hat{\boldsymbol{u}}$:

$$V(\boldsymbol{x}(0),\ \boldsymbol{u}(\cdot)) = \int_0^\infty \frac{1}{2}(\hat{\boldsymbol{x}}^T\boldsymbol{Q}\hat{\boldsymbol{x}} + \hat{\boldsymbol{u}}^T\boldsymbol{R}\hat{\boldsymbol{u}})\,dt. \tag{6.85}$$

If the closed loop should have a degree of stability α, a controller for modified system (6.84) based on the cost function (6.85) must be stable. From Theorems 6.6 and 6.7, this entails

1. $[\boldsymbol{A} + \alpha\boldsymbol{I}, \boldsymbol{B}]$ is stabilizable.
2. $[\boldsymbol{A} + \alpha\boldsymbol{I}, \boldsymbol{Q}]$ is detectable.

If $\hat{\boldsymbol{P}}$ is the solution of the Lyapunov equation associated with 6.84 and 6.85 according to

$$\hat{\boldsymbol{P}}(\boldsymbol{A}+\alpha\boldsymbol{I})+(\boldsymbol{A}+\alpha\boldsymbol{I})^T\hat{\boldsymbol{P}}-\hat{\boldsymbol{P}}\boldsymbol{B}\boldsymbol{R}^{-1}\boldsymbol{B}^T\hat{\boldsymbol{P}}+\boldsymbol{Q}=\boldsymbol{0}, \tag{6.86}$$

then the control law is

$$\boldsymbol{u}(t)=e^{-\alpha t}\hat{\boldsymbol{u}}(t)=-e^{-\alpha t}\boldsymbol{R}^{-1}\boldsymbol{B}^T\hat{\boldsymbol{P}}e^{\alpha t}\boldsymbol{x}(t)=-\boldsymbol{R}^{-1}\boldsymbol{B}^T\hat{\boldsymbol{P}}\boldsymbol{x}(t). \tag{6.87}$$

6.3.3.4 Modal Weighting

In many applications, it is useful if certain undesirable states of the system could be particularly weighted in the cost function. For example, these could be oscillations or unstable eigenmodes that could destabilize the control loop. For this purpose, the matrix $\boldsymbol{Q}$ can be designed such that these modes have a predefined effect on the cost function.

Let $\boldsymbol{s}_1 \ldots \boldsymbol{s}_n$ be the unit eigenvectors of the open-loop system. If there is a complex conjugate eigenvalue couple, then the corresponding eigenvector has to be separated into real and imaginary parts.

Next, an auxiliary matrix $\hat{\boldsymbol{Q}}$ is designed such that for every vector $\boldsymbol{s}_k$, $k = 1 \ldots n$ the following relation must hold:

$$\hat{\boldsymbol{Q}}\boldsymbol{s}_k=\boldsymbol{s}_k m_k, \quad k=1\ldots n. \tag{6.88}$$

Here, m_k is a positive real weighting factor. If all m_k are collected in a diagonal matrix $\boldsymbol{M}$ and all $\boldsymbol{s}_k$ are concatenated to a matrix $\boldsymbol{S}$, then 6.88 can be collected for all $k = 1 \ldots n$:

$$\hat{\boldsymbol{Q}}\boldsymbol{S}=\boldsymbol{S}\boldsymbol{M}. \tag{6.89}$$

The auxiliary matrix $\hat{\boldsymbol{Q}}$ is obtained from

$$\hat{\boldsymbol{Q}}=\boldsymbol{S}\boldsymbol{M}\boldsymbol{S}^{-1} \tag{6.90}$$

and the weighting matrix $\boldsymbol{Q}$ is obtained from

$$\boldsymbol{Q}=\hat{\boldsymbol{Q}}^T\hat{\boldsymbol{Q}}. \tag{6.91}$$

The last step ensures that $\boldsymbol{Q}$ is symmetric. If $\boldsymbol{s}_k$ is inserted into the cost function, one obtains

$$\boldsymbol{s}_k^T\boldsymbol{Q}\boldsymbol{s}_k=\boldsymbol{s}_k^T\hat{\boldsymbol{Q}}^T\hat{\boldsymbol{Q}}\boldsymbol{s}_k=m_k^2 \quad \text{with } \|\boldsymbol{s}_k\|=1. \tag{6.92}$$

It is apparent that the kth eigenmode contributes to the cost function proportionally to m_k^2.

Modal weighting can be successfully applied to design controllers that have to fulfill a very specific control task. Typically, m_k is chosen small for nonrelevant modes whereas large values of m_k are assigned to the undesirable modes.

6.3.3.5 Weighting of State Derivatives

Often state derivatives (e.g., accelerations) have to be considered in the cost function. This section shortly describes how this can be accomplished.

Consider the following cost function:

$$V=\int_0^\infty\frac{1}{2}(\dot{\boldsymbol{x}}^T\boldsymbol{Q}\dot{\boldsymbol{x}}+\boldsymbol{u}^T\boldsymbol{R}\boldsymbol{u})\,dt. \tag{6.93}$$

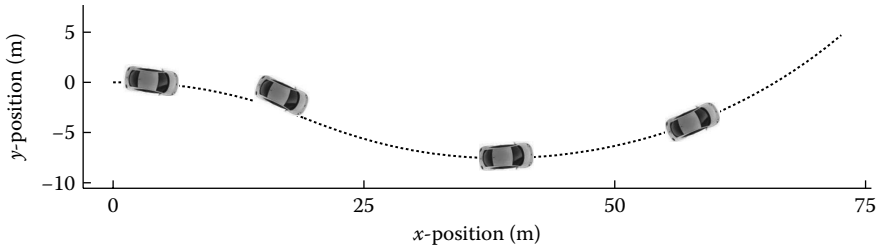

FIGURE 6.11 C/G trajectory with LQR control.

Inserting $\dot{\boldsymbol{x}} = \boldsymbol{Ax} + \boldsymbol{Bu}$ leads to

$$V = \int_0^\infty \frac{1}{2}(\boldsymbol{x}^T \bar{\boldsymbol{Q}}\boldsymbol{x} + 2\boldsymbol{x}^T \boldsymbol{N}\boldsymbol{u} + \boldsymbol{u}^T \bar{\boldsymbol{R}}\boldsymbol{u})dt \tag{6.94}$$

with $\bar{\boldsymbol{Q}} = \boldsymbol{A}^T\boldsymbol{QA}$, $\bar{\boldsymbol{R}} = \boldsymbol{B}^T\boldsymbol{QB} + \boldsymbol{R}$ and $\boldsymbol{N} = \boldsymbol{A}^T\boldsymbol{QB}$. The control law then takes the form

$$\boldsymbol{u}(t) = -\bar{\boldsymbol{R}}^{-1}(\boldsymbol{N}^T + \boldsymbol{B}^T\bar{\boldsymbol{P}})\boldsymbol{x}(t) \tag{6.95}$$

where $\bar{\boldsymbol{P}}$ is the solution of a modified Lyapunov equation:

$$\bar{\boldsymbol{P}}(\boldsymbol{A} - \boldsymbol{B}\bar{\boldsymbol{P}}^{-1}\boldsymbol{N}^T) + (\boldsymbol{A} - \boldsymbol{B}\bar{\boldsymbol{P}}\boldsymbol{N}^T)^T\bar{\boldsymbol{P}} - \bar{\boldsymbol{P}}\boldsymbol{B}\bar{\boldsymbol{R}}^{-1}\boldsymbol{B}^T\bar{\boldsymbol{P}} + (\boldsymbol{Q} - \boldsymbol{N}\bar{\boldsymbol{R}}^{-1}\boldsymbol{N}^T)\boldsymbol{0}. \tag{6.96}$$

Example 6.10

Again, the single-track model from Example 6.1 is considered.

In contrast to Example 6.5, the steering angle is now considered as an additional control input. The new control input can be considered as an additional steering wheel angle $\Delta\delta$ that is superimposed to the driver's input.

The selection of the weighting matrices $\boldsymbol{Q}$ and $\boldsymbol{R}$ is based on the simple criteria from Section 6.3.3.1.

$\boldsymbol{Q}$ is chosen as the identity matrix, the control weights are chosen as

$$\boldsymbol{R} = \begin{bmatrix} 5000 & 0 \\ 0 & 10^{-7} \end{bmatrix}. \tag{6.97}$$

Figure 6.11 shows the trajectory of the car under the respective control action. Figure 6.12 illustrates the activity of the superimposed control $\Delta\delta$ and Figure 6.13 shows a time history of the second control input (M). A comparison of Figures 6.5 and 6.11 reveals that the stabilization by the controller is now somewhat slower. However, the bandwidth LQR controller could be readily improved by increasing the entries of the $\boldsymbol{Q}$ matrix.

6.4 IDENTIFICATION—EXPERIMENTAL MODELING

6.4.1 Introduction

System identification is the art of extracting both structural and quantitative knowledge about a dynamic system from phenomenological data only. For a given model, structure methods exist to estimate a set of optimal parameters. Nevertheless, the model structure itself has to be defined a priori by the user, and optimal structure can only be shown a posteriori using validation methods. Therefore, system identification is always an iterative process.

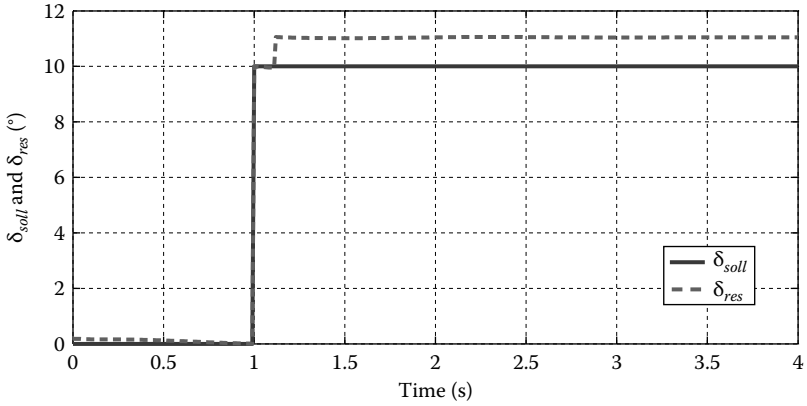

FIGURE 6.12 Time history of δ_{soll} and resultant δ_{res} ($\delta_{res} = \delta_{soll} + \Delta\delta$).

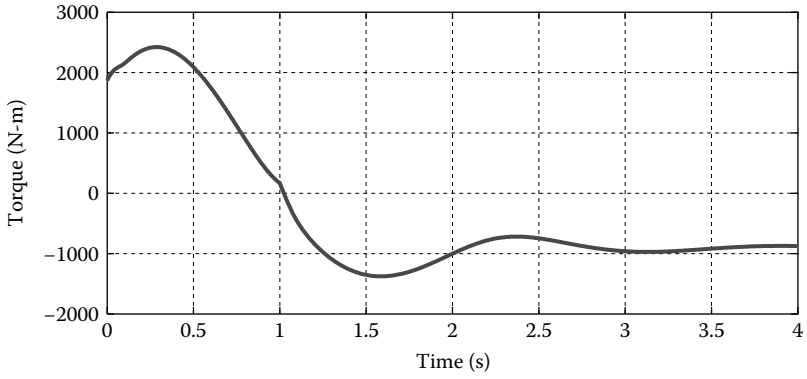

FIGURE 6.13 Time history of control input two (torque).

The components of an identification problem are

- Measured input and output signals
- General structural assumptions (e.g., linearity, certain polynomial orders, etc.)
- A number of system parameters that parameterize the model structure and uniquely define the system's behavior

The procedure of an identification is closely intertwined with the important part of model validation (see Figure 6.14). To this end, the data are divided in an identification and a validation part, respectively. Assuming a certain model structure, the model parameters can be estimated utilizing the identification

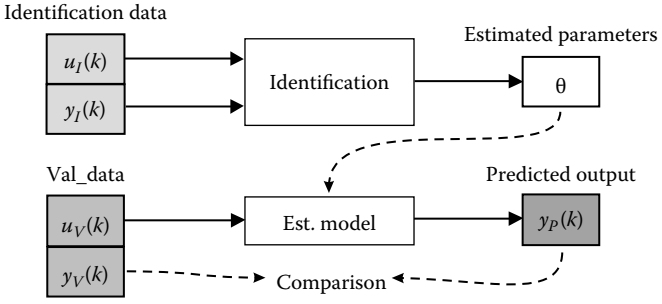

FIGURE 6.14 Identification and cross-validation of an experimental model.

data and a suitable estimation method. The quality of this model is consequently tested on the validation data, where the ability to correctly predict the measured output is an important criterion.

The remainder of this section is structured as follows: first, some basic notions on discrete-time signals and systems are introduced. This is followed by an introduction to probability and stochastics, as the treatment of random measurement noise requires some of these concepts. The core part is formed by an introduction to nonparametric and parametric estimation methods, where mainly linear systems are addressed. This is followed by short step-by-step instructions how to accomplish a successful model identification.

Because of the close affinity to identification procedures, the Kalman filter and its subsequent developments as well as alternative methods for state estimation are also included in this section.

6.4.2 Fundamentals

6.4.2.1 Reality, System, and Model

The notion of a *system* is used to describe a set of interacting elements inside a system boundary, which may exchange energy or information with the environment by means of input and output signals (Figure 6.14). A large or complex system can be divided into subsystems, where the inner interactions of the original system become visible. On the other hand, a set of subsystems can be combined in one complete system and the inner interactions are no longer explicit (Figure 6.15).

In order to represent a well-defined domain of a technical application by a system (this mapping will be called *model*), the system boundaries have to be chosen carefully. This is especially important, since the input and output signals necessary for identification are also defined with the choice of the boundary. The ability and performance of an experimental model critically rely on the choice of the system boundaries and hence the input and output signals [14].

6.4.3 Model Validation

An experimental model is only as good as its validation. The task of a model validation is a realistic performance test in order to guarantee an acceptable amount of reliability and accuracy. The method of cross-validation is the most reliable way to validate a model: measured data are split into a larger identification part and a smaller validation part (Figure 6.14). Since the model is validated with data that have not been used during identification, this test constitutes a simulation of the model's real-world application. It tests the model's ability to reproduce not only the identification data but also more general data (this ability is called *generalization* [7,13,14]).

Model validation is performed in a recursive manner (Figure 6.16). Since assumptions on model structure have to be made prior to the identification procedure, each identification has to be followed by a validation. The results of the validation indicate which alterations in the model are necessary (structure, simplifications, parameters). The iteration is stopped when the trade-off between model

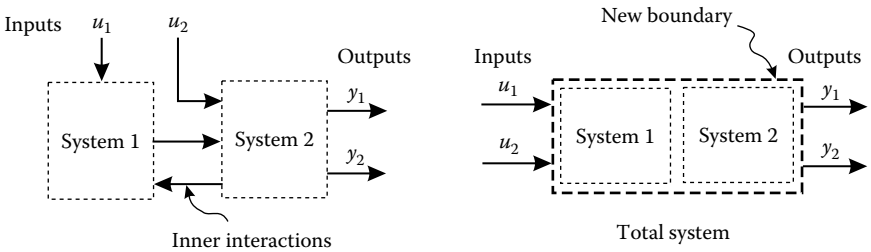

FIGURE 6.15 A complete system can be divided into a number of subsystems. The inner interactions are not explicitly visible in the original system.

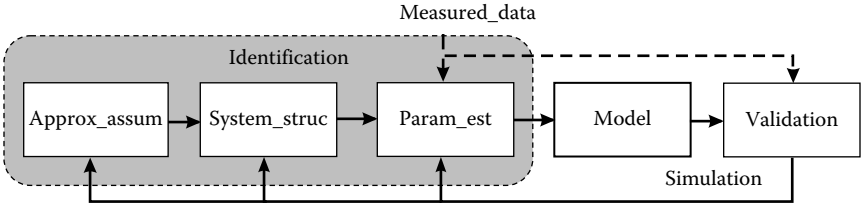

FIGURE 6.16 Identification and validation are an iterative process.

accuracy and complexity comes to an optimum. Depending on the purpose of an experimental model, accuracy may be less important than stability, simplicity, and generalization.

6.4.4 Basics of Discrete-Time Signals and Systems

Discrete-time signals are built from continuous-time signals using a procedure called "sampling" [18,19]. The time axis is divided into equidistant sections (sampling time T_s), and signal values are only stored ("sampled") at the intersections (see Figure 6.17a). Each time instant of the sampled signal $x(kT_s)$ is denoted by a dimensionless counter k:

$$x(t)\big|t = kT_s = x(kT_s) = x(k), \quad k \in Z. \tag{6.98}$$

The values of the original signal between the sampling instants can only be reconstructed up to the Nyquist frequency ω_ν [18,19], where

$$\omega_\nu = \frac{1}{2}\omega_s = \frac{1}{2}2\pi f_s = \frac{\pi}{T_s} \tag{6.99}$$

holds. An analog low-pass filter has to be employed prior to sampling in order to avoid aliasing effects. Discrete-time system descriptions consist of difference equations as opposed to differential equations for continuous-time systems. It is important to note that the sampling time T_s is inherently stored in the system parameters and acts as a scaling parameter on the time axis.

Example 6.11

The continuous-time model of a damped linear oscillator with external force F(t) is given by the differential equation:

$$\ddot{x}(t) + 1.2\dot{x}(t) + 9x(t) = F(t).$$

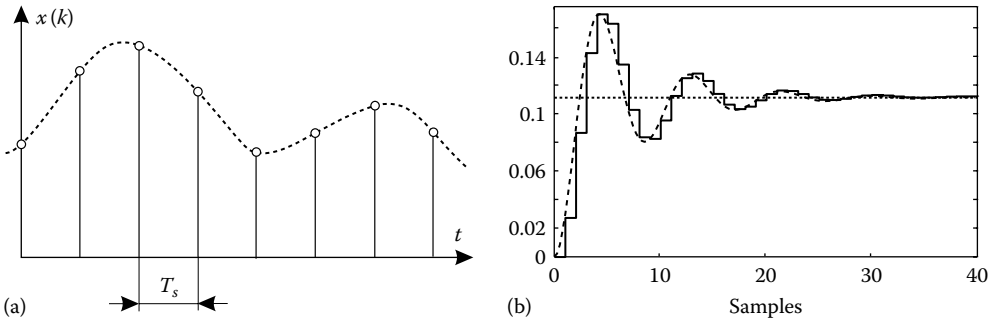

FIGURE 6.17 (a) Sampling of a continuous-time signal with a sample time of T_s. (b) Step response for continuous-time and discrete-time model of a damped oscillator.

Discretization with a sampling time of $T_s = 0.25$ s yields a difference equation:

$$x(k) - 1.2772x(k-1) + 0.7408x(k-2) = 0.0271F(k-1) + 0.0244F(k-2).$$

In Figure 6.17b, the step responses of both systems are plotted. Note that the response of the sampled system is identical to the continuous one only at the sampling instants; during the sampling interval, the output is kept constant which indicates the loss of information.

6.4.4.1 Pulse Transfer Function

A discrete-time linear dynamic SISO system is defined through a difference equation:

$$d_n y(k-n) + \cdots + d_1 y(k-1) + d_0 y(k) = c_m u(k-m) + \cdots + c_1 u(k-1) + c_0 u(k). \tag{6.100}$$

Assuming vanishing initial conditions ($u(k) = y(k) = 0, \forall k \leq 0$) and using the z-transform [18,19], the difference equation (6.100) can be transformed into

$$d_n z - {}^n Y(z) + \cdots + d_1 z^{-1} Y(z) + d_0 Y(z) = c_m z^{-m} U(z) + \cdots + c_1 z^{-1} U(z) + c_0 U(z). \tag{6.101}$$

The discrete-time pulse transfer function in the complex variable z is defined as

$$G(z) = \frac{Y(z)}{U(z)} = \frac{c_m z^{-m} + \cdots + c_1 z^{-1} + c_0}{d_m z^{-n} + \cdots + d_1 z^{-1} + d_0}. \tag{6.102}$$

The parameters c_i and d_j define the dynamic properties of the system [18,19].

6.4.5 Basics of Probability and Stochastics

6.4.5.1 Probability of an Event

An event A is a well-defined subset of all possible outcomes a of a random process.

Example 6.12

A random process has possible outcomes of $0 \leq a < 360$. One can define the events $A_1 = \{120 \leq a < 180\}$ and $A_2 = \{300 \leq a < 360\}$.

If a random process is sampled N times and the absolute frequency of the event A is given by $N[A]$, the relative frequency of the event A is defined as $n[A] = N[A]/N$. The limit

$$P[A] = \lim_{N \to \infty} n[A] = \lim_{N \to \infty} \frac{N[A]}{N} \tag{6.103}$$

empirically defines the probability of the event A.

6.4.5.2 Definition of a Random Variable

A random variable X is a real-valued function that maps all samples of a random process on the real axis or parts thereof [3]. It must not be multi-valued and can therefore be seen as a universal description of any random process.

6.4.5.2.1 Probability Density Function

Due to the earlier defined mapping, the probability of an event $P[A]$ with A given by $A = \{a \leq x < b\}$ is

$$P[A] = P[a \leq x < b] \tag{6.104}$$

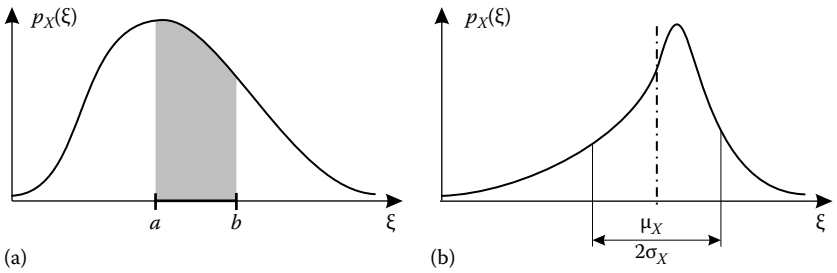

FIGURE 6.18 Continuous probability density function (PDF) $p_x(\xi)$. (a) Probability that the value of the random variable falls in an interval $a \le X \le b$. (b) Mean and standard deviation constitute the weak description of a random variable.

and can be expressed using the *probability density function* (PDF) $p_X(\xi)$ (see Figure 6.18a):

$$P[A] = P[a < X \le b] = \int_a^b p_X(\xi) d\xi. \tag{6.105}$$

Properties of the PDF $p_X(\xi)$:

$$0 \le p_X(\xi),$$

$$p_X(-\infty) = p_X(\infty) = 0,$$

$$\int_{-\infty}^{\infty} p_X(\xi)\, d\xi = 1. \tag{6.106}$$

The PDF is the strict sense description of a random variable.

6.4.5.2.2 Expectation and Moments—Mean and Variance

The *expectation* or (linear) *mean* μ_X of a random variable X is defined as the first-order moment of the WDF $p_X(\xi)$ [3],

$$\hat{\mu}_x = E\{X\} = \bar{X} = \int_{-\infty}^{\infty} \xi p_X(\xi) d\xi. \tag{6.107}$$

In Equation 6.107, the *expectation operator* $E\{\}$ assigns the deterministic expectation μ_X to the random variable X. The empirical mean $\hat{u}_x$ of a discrete-time signal $x(k)$ with N samples is given by

$$\hat{\mu}_x = \frac{1}{N} \sum_{k=1}^{N} x(k).$$

Note that the empirical mean $\hat{\mu}_x$ depends on the sample values $x(k)$ and therefore is in itself a random variable while μ_X is the true (deterministic) mean of the underlying random process. The *variance* σ_X^2 is defined as the mean quadratic deviation of the random variable X from its mean value μ_X (second centered moment),

$$\sigma_X^2 = E\{X - \mu_X)^2\} = \int_{-\infty}^{\infty} (\xi - \mu_X)^2 p_X(\xi) d\xi.$$

The empirical variance $\hat{\sigma}_x^2$ of a discrete-time signal $x(k)$ with N samples is given by

$$\hat{\sigma}_x^2 = \frac{1}{N}\sum_{k=1}^{N}(x-\hat{\mu}_x)^2(k).$$

The square root of the variance is called *standard deviation* σ_X (see Figure 6.18b). Mean and variance constitute the weak description of a random variable. Using the expectation operator, the weak description can always be computed from the PDF but not vice versa. Note that all empirical estimates are random variables in themselves; this implies that they have a mean and variance depending on the number of samples used for computation N as well as the reliability of the sampled data (measurement noise)!

6.4.5.2.3 Correlation and Covariance

If two random variables X_1, X_2 with a joint probability density function (JPDF) $p_{X_1X_2}(\xi_1, \xi_2)$ are considered simultaneously, the means μ_{X_1}, μ_{X_2} and variances $\sigma_{X_1}^2$, σ_{X2}^2 contain no information about their statistical dependency. Therefore, the *correlation* $p_{X_1X_2}^2$ and the *covariance* $\sigma_{X_1X_2}^2$ are defined [3,6]:

$$p_{X_1X_2}^2 = E\{X_1X_2\}, \quad \sigma_{X_1X_2}^2 = E\{(X_1-\mu_{X_1})(X_2-\mu_{X_2})\}. \tag{6.108}$$

Two random variables are *uncorrelated* if

$$\sigma_{X_1X_2}^2 = 0 \quad \text{or} \quad p_{X_1X_2}^2 = \mu_{X_1}, \mu_{X_2} \quad \text{or} \quad E\{X_1X_2\} = E\{X_1\}E\{X_2\}.$$

In this case, $\sigma_{X_1+X_2}^2 = \sigma_{X_1}^2 + \sigma_{X2}^2$ holds. For practical applications, the empirical correlation $\hat{p}_{xy}^2$ and covariance $\hat{\sigma}_{xy}^2$ between two discrete-time signals $x(k)$ and $y(k)$ are a measure for statistical dependence:

$$\hat{\rho}_{xy}^2 = E\{x(k)y(k)\} = \frac{1}{N}\sum_{k=1}^{N}x(k)y(k),$$

$$\hat{\sigma}_{xy}^2 = E\{[x(k)-\hat{\mu}_x][y(k)-\hat{\mu}_y]\} = \frac{1}{N}\sum_{k=1}^{N}[x(k)-\hat{\mu}_x][y(k)-\hat{\mu}_y].$$

In order to have a normalized measure for correlation, the *correlation coefficient* $\hat{r}_{xy}$ is defined as

$$\hat{r}_{xy} = \frac{\hat{\sigma}_{xy}^2}{\sqrt{\hat{\sigma}_x^2\hat{\sigma}_y^2}} = \frac{\hat{\sigma}_{xy}^2}{\hat{\sigma}_x\hat{\sigma}_y}, \quad |\hat{r}_{xy}| \le 1.$$

The strict sense description of two random variables X_1X_2 is given by the JPDF; the wide sense description is given by the means μ_{X_1}, μ_{X_2}, the variances $\sigma_{X_1}^2, \sigma_{X_2}^2$, and the covariance $\sigma_{X_1+X_2}^2$ (instead of $\sigma_{X_1+X_2}^2$, $p_{X_1X_2}^2$ can also be used).

6.4.5.3 Covariance Matrix

The covariance matrix $\hat{\boldsymbol{C}}$ is a quadratic scheme to clearly describe the statistical dependencies between n different signals [6,13]. The individual signals $x_i(k)$ are combined into a measurement

matrix $\boldsymbol{X} = [x_1 x_2 \ldots x_n]$ (each column constitutes a signal; each line corresponds to a sampling instant k). The *covariance matrix* is defined as

$$\hat{\boldsymbol{C}}(\boldsymbol{x}) = E\{[\boldsymbol{x}(k) - \hat{\boldsymbol{\mu}}_x][\boldsymbol{x}(k) - \hat{\boldsymbol{\mu}}_x]^T\} = \begin{bmatrix} \hat{\sigma}^2_{x_1 x_1} & \hat{\sigma}^2_{x_1 x_2} & \cdots & \hat{\sigma}^2_{x_1 x_n} \\ \hat{\sigma}^2_{x_2 x_1} & \hat{\sigma}^2_{x_2 x_2} & \cdots & \hat{\sigma}^2_{x_2 x_n} \\ \vdots & \vdots & \ddots & \vdots \\ \hat{\sigma}^2_{x_n x_1} & \hat{\sigma}^2_{x_n x_2} & \cdots & \hat{\sigma}^2_{x_n x_n} \end{bmatrix}$$

The vector $\hat{\boldsymbol{\mu}}_x = [\hat{\mu}_x, \hat{\mu}_2, \ldots, \hat{\mu}_n]$ contains the means of the individual signals. The covariance matrix is a quadratic, symmetric, positive (semi-)definite $n \times n$ matrix, whose elements consist of covariances and variances (in the diagonal), respectively:

$$\hat{\sigma}^2_{x_i x_j} = E\{[x_i(k) - \hat{\mu}_{x_i}][x_j(k) - \hat{\mu}_{x_j}]\}, \quad \hat{\sigma}^2_{xixi} = E\{[x_i(k) - \hat{\mu}_{x_i}]^2\}.$$

The covariance matrix $\hat{\boldsymbol{C}}$ is positive definite if and only if all signals $x_i(k)$ are linear-independent random variables.

6.4.5.4 Auto- and Cross-Correlation Functions

The correlation between two signals $x(k)$ and $y(k)$ provides scalar information about statistical dependencies. However, depending on a relative time shift τ between the two signals and the signal characteristic, the correlation may change considerably with τ. Inserting the time shift into Equation 6.108 yields

$$R_{xy}(\tau) = E\{x(k)y(k-\tau)\}, \tag{6.109}$$

the cross-correlation function (CCF) between $x(k)$ and $y(k)$. The CCF is dependent only on τ if the signals $x(k)$ and $y(k)$ are stationary (meaning that their statistical properties are invariant to a time shift). Important properties of the CCF are [2,3,19]

$$R_{xy}(\tau) = R_{yx}(-\tau), \tag{6.110}$$

$$R_{xy}(0) = E\{x(k)y(k)\} = \rho^2_{xy}. \tag{6.111}$$

The autocorrelation function (ACF) is defined as

$$R_{xx}(\tau) = E\{x(k)x(k-\tau)\}, \tag{6.112}$$

with the properties

$$R_{xx}(\tau) = R_{xx}(-\tau), \tag{6.113}$$

$$R_{xx}(0) = E\{x(k)x(k)\} = \sigma^2_x. \tag{6.114}$$

The empirical ACF and CCF for signals $x(k)$ and $y(k)$ with N samples are given by

$$\text{ACF} \qquad \hat{R}_{xx}(l) = F_s \sum_{k=1}^{N} x(k)x(k-l),$$

$$\text{CCF} \qquad \hat{R}_{xy}(l) = F_s \sum_{k=1}^{N} x(k)y(k-l),$$

where $F_s = 1/(N - |l|)$ is a scaling factor for an unbiased estimate (see Section 6.5.3.2).

6.5 IDENTIFICATION METHODS

6.5.1 Input Signals and Persistent Excitation

The choice of a proper input signal is important since the unknown system dynamics have to be excited in order to show up in the measured outputs. A Dirac-delta impulse $u(t)=\delta(t-t_0)$ will certainly excite the system's dynamics; however, energy is fed into the system only at a single time instant t_0. On the other hand, a harmonic signal $u(t) = \sin(\omega_0 t)$ will permanently excite the system but only at a single frequency ω_0. It would therefore be desirable to have a signal which combines both advantages. This signal is a purely random sequence where constant power is contained over the frequency range. It is called *white noise* [3,13].

A necessary condition for a system of order $n \leq m$ to be identifiable is that the input is *persistently exciting* (PE) of order $2m$. The Dirac-delta impulse is PE of order 0, a signal consisting of a sum of m sine functions is PE of order $2m$, and white noise is PE of order ∞ [13].

Example 6.13

The ACF of a white random signal w(k) with variance σ_w^2 is given by $R_{\omega\omega}(\tau)$. Here, δ_0 denotes the Kronecker-delta function, which is 1 at $\tau = 0$ and zero elsewhere. Two white noise sequences are given by w(k) and v(k) = w(k – d), that is, v(k) is a version of w(k) shifted by d samples. Both have the same ACF given in the earlier example and they have a CCF of $R_{wv}(\tau) = \sigma_w^2\delta_0(\tau - d)$.

6.5.2 Nonparametric Modeling

Nonparametric models utilize characteristic functions in the time and frequency domains to describe a dynamic system. They are compact and robust, but yield mostly qualitative results and are not suitable for direct simulation. One of the main advantages is that only minimal assumptions on the model order or structure are necessary: linearity, uncorrelated measurement noise (no applicability in closed loop), and PE input.

6.5.2.1 Step Response

According to the definition of the step response, a stepwise input $u(k) = \sigma(k)$ is fed into the system. The output can be seen as a nonparametric model of the process. Stationary gain, dead time, and characteristic time constants can be extracted from the output. Furthermore, for MIMO systems a quick overview over couplings between inputs and outputs is possible [13,14]. Instead of the step, an impulse can be used as an alternate excitation.

6.5.2.2 Correlation Analysis

Correlation analysis is a method for estimating the impulse or step response for nearly arbitrary input signals. Furthermore, statistical reliability is guaranteed even in the presence of measurement noise. The method is based on the Wiener–Hopf equation:

$$R_{uy}(k) = \sum_{h=0}^{\infty} g(h) R_{uu}(h+k), \tag{6.115}$$

where

R_{uy} is the CCF between input u and output y
R_{uu} is the ACF of the input
$g(h)$ is the impulse response of the system

If the input signal is white noise with variance σ_u^2, Equation 6.115 can be solved for $g(k)$:

$$g(k) = \frac{1}{\sigma_u^2} R_{uy}(k). \tag{6.116}$$

Since Equation 6.116 is only true for a white input sequence, an additional procedure is necessary for arbitrary signals. A so-called prewhitening filter is estimated such that the spectrum of the real input is equal to white noise filtered through the inverse prewhitening filter. Using the filtered versions of the measured signals, an unbiased estimate of $g(k)$ is possible [2,13,14,19].

6.5.2.3 Spectral Analysis

The spectrum $\Phi_u(i\omega)$ of a signal $u(k)$ describes the average power content depending on the frequency ω. The complex-valued estimate $\hat{\Phi}_u(i\omega)$ (periodogram) is typically computed utilizing an averaging method in order to achieve a consistent but biased (methods by Welch or Blackman–Tukey).

The nonparametric estimate of the transfer function $\hat{G}(i\omega)$ is then computed by

$$\hat{G}(i\omega) = \frac{\hat{\Phi}_{yu}(i\omega)}{\hat{\Phi}_u(i\omega)}, \tag{6.117}$$

where $\hat{\Phi}_{yu}(i\omega)$ denotes the cross-spectral density estimate between $u(k)$ and $y(k)$. Depending on the implementation, some additional numerical parameters have to be chosen. Nevertheless, there is always a dependency on a smoothing parameter. Strong smoothing will give a biased but consistent estimate, while no smoothing will yield an unbiased but very noisy estimate [2,14,19].

6.5.3 Parametric Modeling

In this section, the basic notions of linear parameter estimation will be introduced. The models will have mainly the structure of a discrete transfer function, but any other structure, which is linear in the parameters, can be treated in the same way.

6.5.3.1 Problem Formulation

In parametric models, the presence of measurement noise (see Figure 6.19) has to be explicitly addressed by the estimation procedure. The measured output is given by

$$y(k) = y_0(k) + n(k).$$

A parametric model in the formulation of a discrete-time linear difference equation is defined by

$$d_n y(k-n) + \cdots + d_1 y(k-1) + d_0 y(k) = c_m u(k-m) + \cdots + c_1 u(k-1) + c_0 u(k).$$

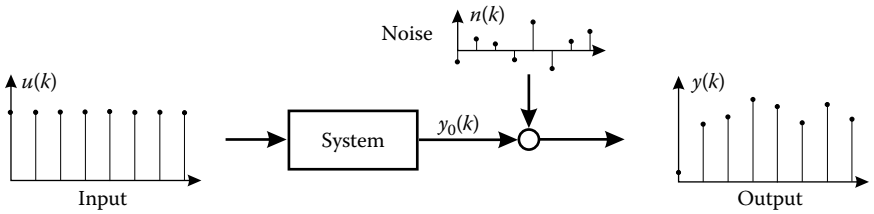

FIGURE 6.19 The measured output $y(k)$ is composed of the deterministic output $y_0(k)$ plus the measurement noise $n(k)$.

Rearranging for the current output $y(k)$ given by past outputs $y(k-i)$ and inputs $u(k-j)$ yields

$$y(k) = a_n y(k-n) + \cdots + a_1 y(k-1) + \beta_m u(k-m) + \cdots + \beta_1 u(k-1) + \beta_0 u(k). \tag{6.118}$$

Changing into matrix-vector representation gives

$$y(k) = [y(k-n)\ldots y(k-1)u(k-m)\ldots u(k-1)u(k)] \begin{bmatrix} \alpha_n \\ \vdots \\ \alpha_1 \\ \beta_m \\ \vdots \\ \beta_1 \\ \beta_0 \end{bmatrix}, \tag{6.119}$$

which can be augmented for all time instances k:

$$\begin{bmatrix} y(k) \\ y(k+1) \\ \vdots \\ y(k+N) \end{bmatrix} = \begin{bmatrix} y(k-n) & \cdots y(k-1) & u(k-m) & \cdots u(k-1) & u(k) \\ y(k-n+1) & \cdots y(k) & u(k-m)+1 & \cdots u(k) & u(k+1) \\ \vdots & \vdots & \vdots & \vdots & \vdots \\ y(k-n+N) & \cdots y(k-1+N) & u(k-m+N) & \cdots u(k-1+N) & u(k+N) \end{bmatrix} \begin{bmatrix} \alpha_n \\ \vdots \\ \alpha_1 \\ \beta_m \\ \vdots \\ \beta_1 \\ \beta_0 \end{bmatrix}. \tag{6.120}$$

Writing 6.120 in symbolic form yields

$$\boldsymbol{y} = \boldsymbol{X}\boldsymbol{\theta}. \tag{6.121}$$

where

- $\boldsymbol{y}$ denotes the output vector
- $\boldsymbol{X}$ is the regressor matrix
- $\boldsymbol{\theta}$ is the parameter vector

It should be observed that the system order (n and m, respectively) has to be chosen prior to constructing the regressor matrix. This means that the optimal system order has to be found iteratively, since each solution to 6.121 is only valid for a dedicated combination of n and m, respectively.

Remark:

A dead time of d samples can be easily incorporated by replacing the arguments (k) of y in the regressor matrix (6.120) by ($k-d$).

Equation 6.121 defines a system of linear equations; solving for $\boldsymbol{\theta}$ would give the desired solution to the parameter estimation problem. A formal requirement for (6.121) to have a solution is a quadratic non-singular regressor matrix $\boldsymbol{X}$. However, the regressor matrix in general has many more lines (number of samples) than columns (number of parameters). Obviously, some alternate method has to be employed in order to solve the overdetermined system of equations. This leads to the following section.

6.5.3.2 Least-Squares Algorithm

Considering the presence of measurement noise, the output vector $\boldsymbol{y}$ can be expressed using the regression matrix $\boldsymbol{X}$, the parameter vector $\boldsymbol{\theta}$, and the equation error $\boldsymbol{e}$:

$$\boldsymbol{y} = \boldsymbol{X}\boldsymbol{\theta} + \boldsymbol{e}. \tag{6.122}$$

The equation error $\boldsymbol{e}$ can also be seen as the difference between filtered input $u(k)$ and output $y(k)$, respectively (see Figure 6.20). The central concept of the least-squares (LS) algorithm is to minimize the equation error with respect to θ. Therefore, the criterion

$$J = \sum_{i=k}^{k+N} e^2(i) = e^T e \rightarrow \min. \tag{6.123}$$

is defined. Inserting 6.122 in the criterion 6.123 yields

$$J = (\boldsymbol{y} - \boldsymbol{X}\boldsymbol{\theta})^T(\boldsymbol{y} - \boldsymbol{X}\boldsymbol{\theta}) = \boldsymbol{y}^T\boldsymbol{y} - \boldsymbol{\theta}^T\boldsymbol{X}^T\boldsymbol{y} - \boldsymbol{y}^T\boldsymbol{X}\boldsymbol{\theta} + \boldsymbol{\theta}^T\boldsymbol{X}^T\boldsymbol{X}\boldsymbol{\theta} \rightarrow \min. \tag{6.124}$$

Differentiating 6.124 with respect to the parameter estimate $\hat{\theta}$ and setting equal to zero

$$\frac{\partial \boldsymbol{J}}{\partial \boldsymbol{\theta}}\bigg|_{\theta=\hat{\theta}} = -2\boldsymbol{X}^T\boldsymbol{y} + 2\boldsymbol{X}^T\boldsymbol{X}\hat{\boldsymbol{\theta}} = 0 \tag{6.125}$$

results in an equation for the parameter estimate. The LS estimate is therefore defined as

$$\hat{\boldsymbol{\theta}} = (\boldsymbol{X}^T\boldsymbol{X})^{-1}\boldsymbol{X}^T \cdot \boldsymbol{y}. \tag{6.126}$$

The expression $(\boldsymbol{X}^T\boldsymbol{X})^{-1}\boldsymbol{X}^T$ is called pseudo-inverse or Moore–Penrose inverse of $\boldsymbol{X}$. The non-singularity of $\boldsymbol{X}^T\boldsymbol{X}$ and the existence of the pseudo-inverse is guaranteed if the input signal is PE [6,13]. From Figure 6.20, the z-transform of the equation error $E(z)$ follows as

$$E(z) = -\boldsymbol{B}z^{-d}U(z) + \boldsymbol{A}Y(z) = -\boldsymbol{B}z^{-d}U(z) + \frac{\boldsymbol{A}}{\boldsymbol{A}_P}V(z) + \boldsymbol{A}\frac{\boldsymbol{B}_P z^{-d}}{\boldsymbol{A}_P}U(z). \tag{6.127}$$

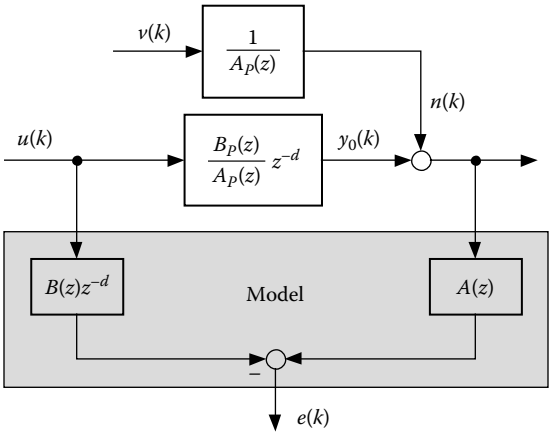

FIGURE 6.20 Noise filter for LS method (ARX model): measurement noise is generated by white noise filtered through a noise filter $1/A_p(z-1)$.

The identity $E(z) = V(z)$ in Equation 6.127 is fulfilled only if

$$\hat{\theta} = \theta, \quad \boldsymbol{A} = \boldsymbol{A}_P, \quad \boldsymbol{B} = \boldsymbol{B}_P \tag{6.128}$$

holds. Only in this case, the equation error is independent of the parameters and consists of a purely random signal (white noise).

The necessary assumptions for a LS estimator are as follows [13]:

- The LS method identifies an ARX model (see Equation 6.129), that is, a noise filter $\frac{1}{\boldsymbol{A}_p(z-1)}$ is assumed.
- The system order n (and dead time d) must be known.
- The input signal $u(k)$ must be known exactly.
- The input signal $u(k)$ must be PE of order $2n$.
- The noise signal $n(k)$ must be stationary with zero mean.

If these assumptions are fulfilled, the following statements will hold [13,14]:

1. The estimate is *unbiased*, that is, the mean estimation error is zero.
2. The estimate is *consistent*, that is, the parameter variance converges to zero if the number of samples approaches infinity.

In practical applications, the assumptions are verified by the model validation.

6.5.3.2.1 Model Structures

Apparently, the estimation of a noise filter is necessary in order to yield unbiased estimates. The following model structures differ only in their noise filter [13,14].

The *ARX model* has already been introduced:

$$Y(z) = \frac{B(z^{-1})}{A(z^{-1})}U(z) + \frac{1}{A(z^{-1})}V(z). \tag{6.129}$$

Only two polynomials A and B have to be estimated using the LS estimator. The ARX model is efficient and robust; but, since the noise transfer function is determined by the plant's denominator, it is not flexible for different noise spectra. In this case, it will yield biased estimates or a high model order.

The simplest structure is called *output-error model* (*OE model*), where the transfer function of the noise filter is 1.

$$Y(z) = \frac{B(z^{-1})}{A(z^{-1})}U(z) + \frac{1}{A(z^{-1})}V(z). \tag{6.130}$$

Although this structure looks even simpler than the ARX model, the parameters of the polynomials must be estimated using nonlinear prediction error methods (PEM).

The *Auto Regression with Moving Average and eXtra input* (ARMAX) *model* has a common denominator but a dedicated numerator for the noise filter:

$$Y(z) = \frac{B(z-1)}{A(z-1)}U(z) + \frac{D(z^{-1})}{A(z^{-1})}V(z). \tag{6.131}$$

The number of polynomials to estimate is three, but linear estimation methods may be employed. This model is the extension of the ARX model with added flexibility due to the numerator of the noise filter.

The most general model structure is the *Box–Jenkins model* (*BJ model*) with completely independent transfer functions for plant and noise filter:

$$Y(z) = \frac{B(z-1)}{A(z-1)}U(z) + \frac{D(z^{-1})}{A(z^{-1})}V(z). \tag{6.132}$$

It is capable of representing any dynamics and noise spectra, respectively, but with the highest computational effort.

6.5.3.3 Recursive Least-Squares Algorithm

In Equation 6.126, the parameter estimate is computed in a single step from all measured data. How can this estimate be improved when an additional measurement becomes available? Apparently, it would be very inefficient to repeat the computation with an augmented regressor matrix. Instead, a recursive formulation is sought for, where the current estimate $\hat{\boldsymbol{\theta}}(k+1)$ is computed using the previous estimate $\hat{\boldsymbol{\theta}}(k)$.

A derivation of recursive least squares (RLS) can be found in [6,13]. The resulting formulation is

$$\hat{\boldsymbol{\theta}}(k+1) = \hat{\boldsymbol{\theta}}(k) + \boldsymbol{P}(k+1)x(k)\cdot[y(k+1) - \boldsymbol{x}^T(k+1)\hat{\boldsymbol{\theta}}(k)], \tag{6.133}$$

where $\boldsymbol{P}$ is defined as

$$\boldsymbol{P}(k) = (\boldsymbol{X}^T(k)\boldsymbol{X}(k))^{-1}. \tag{6.134}$$

Note that $\boldsymbol{P}$ is proportional to a covariance matrix of the parameter estimates (see Section 6.5.3.3). Equation 6.133 can be read as

$$\begin{aligned}\text{Current estimate} = {} & \text{previous estimate} + \text{correction vector} \\ & \times\big[\text{current measurement} - \text{prediction of the new measurement}\big].\end{aligned} \tag{6.135}$$

In this interpretation, the expression $\boldsymbol{x}^T(k+1)\hat{\boldsymbol{\theta}}(k)$ is the prediction of the new output. Although the current measurement $\boldsymbol{x}(k+1)$ is already available, the previous estimate $\hat{\boldsymbol{\theta}}(k)$ must be used for computation. This estimate is called a priori prediction (see Section 6.7.1.6).

The computation of 6.133 is problematic, since it requires a matrix inversion at each time step. Using a matrix inversion lemma [13], the correction vector $\gamma(k)$ can be computed according to

$$\gamma(k) = \frac{\boldsymbol{P}(k)\boldsymbol{x}(k+1)}{1 + \boldsymbol{x}^T(k+1)\boldsymbol{P}(k)\boldsymbol{x}(k+1)} \tag{6.136}$$

and the current parameter estimate is given by

$$\hat{\boldsymbol{\theta}}(k+1) = \hat{\boldsymbol{\theta}}(k) + \gamma(k)[y(k+1) - \boldsymbol{x}^T(k+1)\hat{\boldsymbol{\theta}}(k)], \tag{6.137}$$

with $\boldsymbol{P}(k+1)$ recursively defined by

$$\boldsymbol{P}(k+1) = [\boldsymbol{I} - \gamma(k)\boldsymbol{x}^T(k+1)]\boldsymbol{P}(k). \tag{6.138}$$

Evaluating Equations 6.136 through 6.138 in this order allows for an efficient computation of the online estimate.

Example 6.14

The output of a process with discrete-time transfer function of

$$G(z^{-1}) = \frac{0.1^{z-1}}{1-0.9z^{-1}+0.5^{z-2}} \tag{6.139}$$

is corrupted by measurement noise (ARX structure). The input is white noise with a variance of $\sigma^2 u = 1$*, the noise source has a variance of* $\sigma^2 v = 0.14$*.*

The initial values for an RLS identification are $\boldsymbol{\theta}_0 = [0\ 0\ 0]'$ *and the main diagonal of* $\boldsymbol{P}_0$ *is* $10^6[1\ 1\ 1]'$*. After 150 samples, the estimated parameter values are* $\hat{\boldsymbol{\theta}} = [-0.95\ 0.52\ 0.13]'$ *and the corresponding entries of the* $\boldsymbol{P}$ *matrix are [0.027 0.027 0.0064]. The development of the parameter estimates as well as the diagonal entries of the* $\boldsymbol{P}$ *matrix can be seen in* Figures 6.21a,b*, respectively.*

Choice of initial values $\hat{\boldsymbol{\theta}}(0)$ *and* $\boldsymbol{P}(0)$

There are three possibilities for the choice of initial values [6,13]:

- Using an a priori estimate (rarely possible)
- Computing the LS estimate $\hat{\boldsymbol{\theta}} = (\boldsymbol{X}^T\boldsymbol{X})^{-1}\boldsymbol{X}^T\boldsymbol{y}$ and $\boldsymbol{P} = (\boldsymbol{X}^T\boldsymbol{X})^{-1}$ from the first m data and starting the RLS algorithm at $m + 1$
- Choosing a random initial parameter vector $\hat{\boldsymbol{\theta}}(0)$ and $\boldsymbol{P}(0) = \alpha\boldsymbol{I}$, where α is a large scalar

The choice of $P(0) = \alpha\boldsymbol{I}$, $\alpha \gg 1$ (reflecting an uncertain initial estimate) can be motivated as follows. Since

$$\hat{\boldsymbol{\theta}}(k) = \boldsymbol{P}(k)[\boldsymbol{X}^T(k)\boldsymbol{y}(k) + \boldsymbol{P}^{-1}(0)\hat{\boldsymbol{\theta}}(0)] \tag{6.140}$$

is valid for RLS, for $\alpha \to \infty$ and arbitrary $\hat{\boldsymbol{\theta}}(0)$ the LS estimator (Equation 6.126) will result.

The covariance of the parameter estimation error $cov(\hat{\boldsymbol{\theta}} - \boldsymbol{\theta})$ is defined by [13]

$$cov(\boldsymbol{\theta} - \boldsymbol{\theta}) = \sigma_e^2\boldsymbol{P}, \tag{6.141}$$

where σ_e^2 is the variance of the residual. A covariance matrix $\boldsymbol{P}$ with large entries in the diagonal reflects the lack of information on the true parameter values.

6.5.3.4 Algorithms for the ARMAX Model

The parameter estimation of an ARMAX model poses a more complex problem: Since the inputs to the noise transfer function (white noise) are not known, they have to be reconstructed from measured data and current parameter estimates. Utilizing a recursive formulation, the parameters of the plant transfer function, the numerator polynomial of the noise transfer function, and the sequence of white noise entering the noise filter are estimated. Another method is the instrumental variable (IV) method [13].

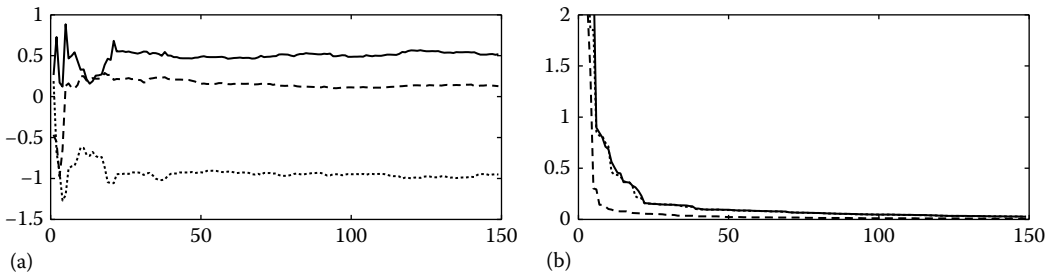

FIGURE 6.21 RLS identification. (a) The parameters show fast convergence from their initial values to the true ones. (b) The corresponding diagonal entries of the $\boldsymbol{P}$ matrix decrease rapidly.

6.5.3.5 RLS for Time-Varying Systems

In time-varying systems, the inherent memory of the parameter estimates should be limited in order to allow unbiased adaptation to new parameter values. A straightforward way to achieve this is given by applying a decaying exponential weight to the data such that the current measurement is most important and older measurements are neglected (weighted recursive least squares [WRLS]) [6,13]. The criterion for minimization J_k is defined as

$$J_k = \sum_{i=k}^{k} \lambda^{k-i} e^2(i) = e_k{}^T e_k, \quad 0 < \lambda < 1, \tag{6.142}$$

where λ is the so-called *forgetting factor*. Ordinary RLS is obtained with $\lambda = 1$.

The resulting recursive estimation algorithm consists of three formulas:

$$\gamma(k) = \frac{1}{\boldsymbol{x}^T(k+1)\boldsymbol{P}(k)\boldsymbol{x}(k+1) + \lambda} \boldsymbol{P}(k)\boldsymbol{x}(k+1), \tag{6.143}$$

$$\hat{\theta}(k+1) = \hat{\theta}(k) + \gamma(k)\,[y(k+1) - \boldsymbol{x}^T(k+1)\hat{\theta}(k)], \tag{6.144}$$

$$\boldsymbol{P}(k+1) = [\boldsymbol{I} - \gamma(k)\boldsymbol{x}^T(k+1)]\boldsymbol{P}(k)\frac{1}{\lambda}. \tag{6.145}$$

Choice of the forgetting factor λ

- Choose λ small (e.g., $\lambda = 0, 9$), if the parameters change quickly. In this case, measurement noise strongly affects the estimates (large estimation error covariance).
- Choose λ large (e.g., $\lambda = 0, 999$), if the parameters change slowly. Measurement noise is attenuated (small estimation error covariance).

A time-varying forgetting factor can also be utilized to achieve a good estimate [6,13].

Example 6.15

The forgetting factor λ acts as a low-pass filter. For values of λ close to 1, a smooth but slow response to a stepwise parameter change follows. For smaller λ, the variance increases but the estimate reacts more quickly (see Figure 6.22). For $\lambda = 1$, a biased estimate results, since the measurements before the parameter change corrupt the estimate.

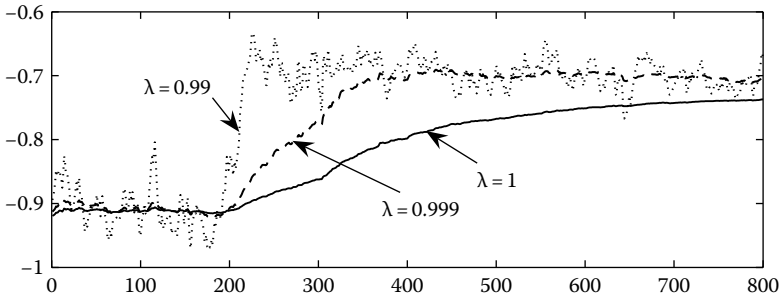

FIGURE 6.22 WRLS identification: for $\lambda = 0.999$ a compromise can be achieved, $\lambda = 0.99$ shows large variance, and $\lambda = 1$ is far too slow in reaching the new value. In this case, a biased estimate results.

6.5.3.6 Prediction Error Method

In the case of ARX and ARMAX model, the parameter estimate $\hat{\boldsymbol{\theta}}$ can be computed using linear methods. However, BJ and OE model require nonlinear estimation methods, since minimization of a quadratic criterion using the prediction error $\varepsilon(k|\boldsymbol{\theta}) = y(k) - \hat{y}(k|\boldsymbol{\theta})$ leads to a nonlinear optimization problem for the parameter vector $\hat{\boldsymbol{\theta}}$. Therefore, general optimization methods like Gauss–Newton or Levenberg–Marquard have to be employed. The drawback of these methods is their dependency on initial conditions, optimization parameters and possibly convergence problems [13].

6.5.3.7 Identification of a State-Space Model

Identification of a state-space model (6.1, 6.2) requires estimation of a higher number of parameters, and the additional problem of generating a nonunique sequence of state vectors has to be solved. Nevertheless, algorithms for direct identification of MIMO state-space systems exist [13,15] and can be applied especially to systems with high number of inputs and outputs.

6.5.4 Black-Box versus Gray-Box Models

Until now, the model structure consists of the assumption of linearity, the model orders (dead time), and the noise filter. Usually, these features have to be chosen a priori and after an appropriate identification step the validation results indicate whether these assumptions were justified or not. Since no information is available at the beginning of the identification, these models are called black-box models.

In the case of physical models, however, the model structure is already known due to analytical or empirical information and only the parameter values of this model have to be found. To indicate that some structural information already exists, these models are called gray-box models.

Example 6.16

The relation between spring force F and compression s in a linear spring is given by the expression $F(s) = ks$, where k is the linear spring constant (measured, e.g., in N/mm). A nonlinear spring characteristic is often desired in automotive suspensions. Typical equation for such a progressive spring is

$$F(s) = ks + hs^3, \tag{6.146}$$

where h is an additional coefficient in N/mm^3. In Figure 6.23, the original characteristic with $k = 50$ N/mm and $h = 0.0015$ N/mm^3 is plotted as solid line. Note that this model is nonlinear but linear in the parameters.

Assuming that 25 data (s_i, F_i) have been measured (circles in Figure 6.23), the parameters k *and* h will be identified. By building a regression vector $[s_i \quad s_i^3]$ together with the corresponding output value F_i, the least-squares solution 6.126 can be computed leading to the estimates $\hat{k} = 59.3$ N/mm and $\hat{h} = 0.0010$ N/mm^3. The model prediction is plotted as dashed line in Figure 6.23. The identified model lies close to the true one despite the small number of measurements. Observe that the identified model starts exactly in the origin since this is required by the model structure.

6.5.5 Nonlinear Modeling

Nonlinear models provide an abundance of structures, and the choice of a distinct structure is always motivated by the individual application. Only a short and incomplete introduction can be given here.

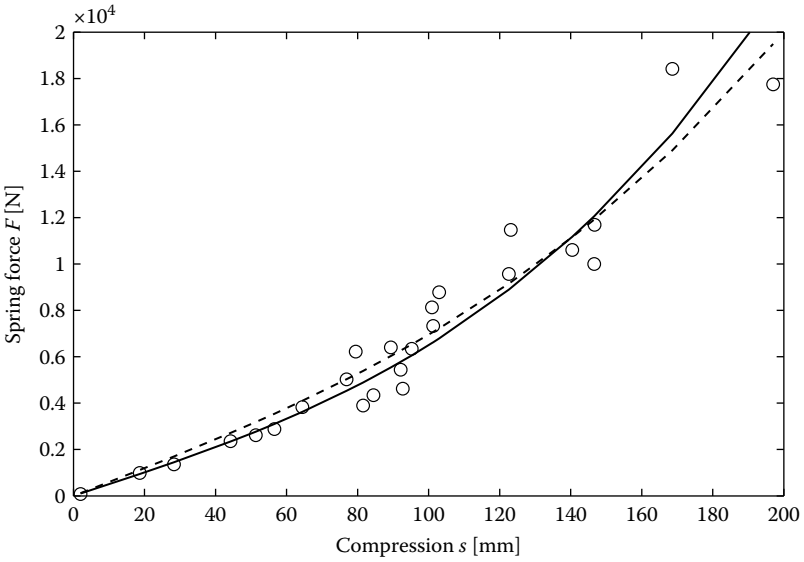

FIGURE 6.23 Gray-box identification of a progressive spring. Measured data (circles), true model (solid line), and identified model (dashed line).

6.5.5.1 Models that are Linear in the Parameters

This important class of models can be described by

$$y_i = f_1(\boldsymbol{y}, \boldsymbol{u})\theta_1 + \cdots + f_n(\boldsymbol{y}, \boldsymbol{u})\theta_n = [f_1(\boldsymbol{y}, \boldsymbol{u}) \cdots f_n(\boldsymbol{y}, \boldsymbol{u})]\boldsymbol{\theta}, \tag{6.147}$$

where

y_i is an output value
$\boldsymbol{u}$ and $\boldsymbol{y}$ are the input and output vectors, respectively
$\boldsymbol{\theta}$ is the parameter vector
f_i are n nonlinear functions on the input and output vectors, respectively

In the case of vanishing $\boldsymbol{y}$ in the arguments of the f_i, the output directly depends on the inputs and a moving average (MA) model results. In the case of past inputs and outputs in the arguments of the f_i, a nonlinear autoregressive model with moving average and exogenous input (NARMAX) is given. It is important to notice that 6.147 is of the same structure as 6.119; hence, a regressor matrix with nonlinear function values can be constructed and the pseudo-inverse (6.126) can be applied [13].

Polynomial models or cubic splines exploit this structure, which combines computational efficiency with extended flexibility compared to linear models.

6.5.5.2 Local Linear Models

The quality of an approximation of a global nonlinear function using local linear models critically depends on the regions of validity for each local model. The main focus of these methods is therefore the partitioning of the input space, which is a nonlinear optimization problem. Several model structures like LOLIMOT, INN, RBF have been proposed [16] and are state of the art in automotive applications like ECU mappings.

6.5.5.3 Artificial Neural Networks

An artificial neural network (ANN) is a nonlinear structure that is capable of approximating arbitrary nonlinearities; but, since the solution is not unique, many different network structures are possible. On the one hand, the choice of the network topology, the activation functions, and the

(nonlinear) training algorithm constitute a flexible tool, which is sometimes capable of representing a complex nonlinear behavior in compact formulation. On the other hand, it requires expert knowledge to efficiently utilize these tools and not get lost in the numerous possibilities [7].

6.5.6 Stepwise Identification Procedure

6.5.6.1 Gathering Information

The first and most important step to an experimental model is measuring the inputs and outputs of the process. Defining the system borders, keeping in mind the purpose of the model, and choosing appropriate excitation signals are of fundamental importance to any identification. The most important issues for a successful identification are listed as follows [14]:

- The system borders should be chosen such that the complexity of the unknown model is minimal; all significant inputs and outputs can be measured; and the dynamics of interest are contained.
- Data recording must be performed according to correct measurement procedures, sampling frequency and any filters must be chosen to match the expected model characteristic.
- The input signals must fulfill the condition of being PE (optimal: white noise).
- The input signals must feed enough energy into the system in order to achieve an acceptable signal-to-noise ratio in the outputs.
- The input signals must be generated according to the operating point of the process. This could include consecutive stepwise changes in order to cover a wide dynamic range (possibly nonlinear) with local models. Also ramps can be used.

Careful planning resulting in a measuring protocol and a complete and comprehensive documentation is essential.

6.5.6.2 Pre-Processing of Data

All data must be plotted at least in the time domain in order to recognize outliers, artefacts, offsets, drifts, and significant changes in the system dynamics. Many of these defects can be filtered automatically; however, manual control of these procedures is highly recommended. In the case of much higher sampling rates than necessary for the system dynamics, a correct downsampling improves the efficiency of the algorithms.

All data should be split into a larger identification part and a smaller validation part (necessary for cross-validation, see Section 6.4.3). Care should be taken to have the same energy and frequency content in both data sets.

6.5.6.3 Nonparametric Models

If no correlation between measurement noise and input exists (as in closed loop), the impulse response and the frequency response are important tools. Both provide the first information on the absolute and relative degree of the model, time constants, stationary gain, and damping. The impulse response estimate is especially useful for estimating the dead time of a system. Using confidence intervals for the zero line, a quantitative conclusion on the probability of a certain dead time is possible (Figure 6.24a).

6.5.6.4 Parametric models

Parametric linear models should be estimated beginning with the ARX structure and ending with the most complex BJ model. For the purpose of dead-time estimation, a low-order (third- or fourth-order) ARX model can be identified for different dead times. The model with the correct dead time usually yields a significantly better prediction performance than the others. Once the dead time has been ascertained, it is fixed for all consecutive models.

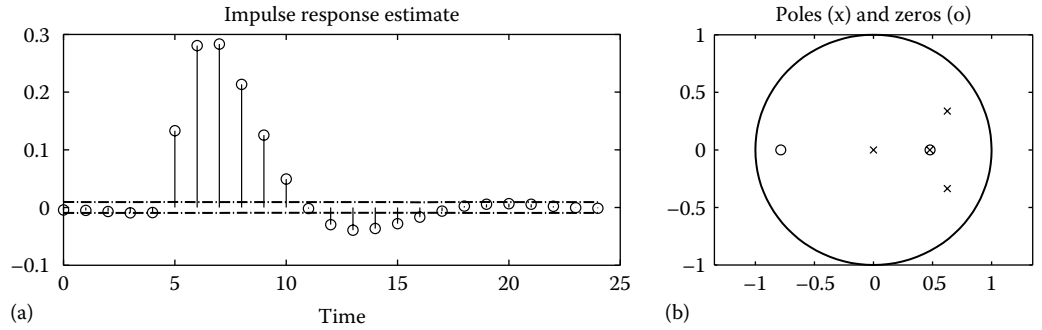

FIGURE 6.24 (a) Estimate of the impulse response by a correlation analysis; a dead time of five samples is observable. (b) Pole-zero plot; a cancellation occurs at (0.5/0).

Utilizing the validation methods outlined later, the model orders for numerator and denominator polynomials of plant and noise model are increased in an iterative manner. For each model structure, the model with the best trade-off between complexity and performance is saved, and finally, the overall best linear model is chosen between them.

6.5.6.5 Model Validation

The following procedures have to be carried out for each model and form the basis of a fair comparison in order to find the optimal model.

6.5.6.5.1 Model Performance

By means of a numerical simulation, the output of a certain model is computed from the validation input. This predicted output is compared to the measured validation output (model fit). In general, a good model will have a good fit; however, due to the measurement noise a perfect fit is not desirable. Models with very high order tend to reproduce the measurement noise in the identification data, but due to cross-validation they will yield a smaller performance on the validation data compared to a lower-order model.

6.5.6.5.2 Residual Analysis

The residual analysis computes the ACF and CCF between the residual and the input, respectively. The residual due to measurement noise should be purely stochastic and therefore not correlated with itself or the input signal [13]. Its autocorrelation should therefore be a Kronecker-delta function.

The correlation functions are sensitive tools for detecting significant correlations by showing signal values significantly different from zero as indicated by 99% confidence intervals (Figure 6.25). In this case, either the model order or the model structure is not correct, or the general assumptions are not fulfilled (e.g., by nonlinear dynamics or closed-loop data).

6.5.6.5.3 Model Order

The optimal model order is found applying the procedure outlined earlier. For too low orders, both performance and residual analysis will show poor results. Right above the optimal model order, the performance will hardly increase or even decrease. The residual analysis will not detect too high model orders, but a simple pole-zero plot can detect near cancellations, which are caused by redundant poles and zeros (Figure 6.24b). Small models typically show a better ability to generalize, that is, to achieve a good model fit on data not available for identification.

6.5.6.5.4 Model Structure

In order to have unbiased estimates, the correct noise filter has to be found. The most important tool for this purpose is again the correlation analysis. If a wrong model structure has been chosen,

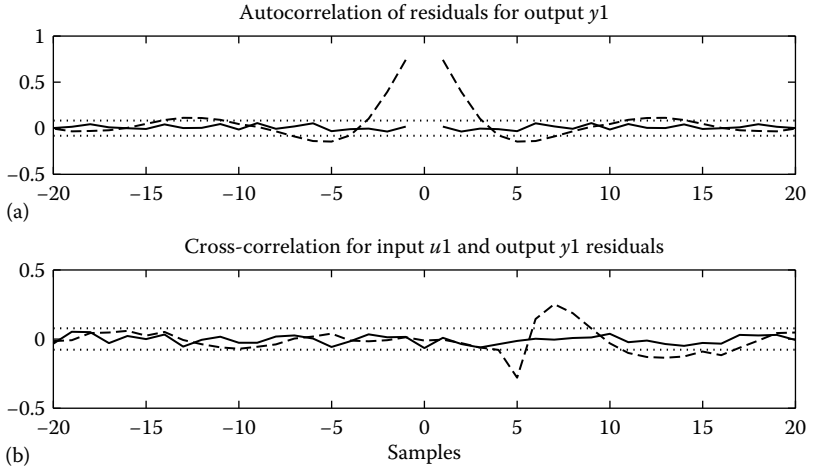

FIGURE 6.25 Residual analysis: (a) ACF of the residual and (b) CCF between residual and input show satisfactory results for an ARX model (solid line) while a low-order OE model (dashed line) exceeds the 99% confidence intervals.

a satisfactory result is only possible for very high orders. Furthermore, an adequate ACF of the residual but significant cross-correlations between input and residual indicate a wrong (too low) order of the numerator, and vice versa.

As opposed to linear system theory, nonlinear control concepts cannot be covered by a general approach. The theory covering nonlinear systems is also complex and mathematically involved. Textbooks covering the general concepts and may be used for an introduction are [8,9,11]. Therefore, the optimal strategy is to find a matching design for a specific nonlinear control problem. Following is a listing of some important techniques [9], which may be applied to particular control problems:

Trial and error: Using nonlinear analysis methods and considering the special structure of a given control problem, a custom-tailored control concept is designed and verified by simulations. If the complexity of the problem becomes too large, this approach will most likely fail.

Linearization: A straightforward method for applying the well-known and powerful linear design tools is to linearize a given nonlinear system model around an operating point. Obviously, the system states are required to stay within a vicinity of this operating point; otherwise, the linearization may no longer be valid. In this case, poor closed-loop performance and even unstable system behavior can result. Nevertheless, since this approach utilizes linear controller design methods, it is widely used and therefore elaborated on in the remainder of this chapter.

Gain scheduling: Gain scheduling is the extension to linearization around only one operating point by selecting a number of operating points which cover the whole operating range. By computing a linear controller for each operating point, discrete sets of controller parameters will result. Between operating points, the controller parameters will be interpolated or scheduled in order to have a smooth change in parameters.

Robust control: Most model-based design technique assumes a valid nominal model and model uncertainties are not explicitly incorporated into the design process. In robust control, these uncertainties are quantitatively considered during the controller design and a guaranteed performance is obtained as long as the assumptions on the uncertainties apply. A linearized model is often the starting point for a robust controller design, and the nonlinearities are then regarded as uncertainties of the nominal linear model.

Adaptive control: Another approach to deal with nonlinear or time-varying systems is adaptive control. Basically, the dynamic structure of the system has to be known but the unknown or slowly varying parameters are identified online. The resulting overall control system is inherently nonlinear.

6.6 NONLINEAR CONTROL DESIGN

6.6.1 Linearization

A time-invariant MIMO system is generally described by a nonlinear state-space differential equation and an associated output equation:

$$\dot{\boldsymbol{x}} = \boldsymbol{f}(\boldsymbol{x}, \boldsymbol{u}, \boldsymbol{z}); \qquad \boldsymbol{x}(t_o) = \boldsymbol{x}_o \tag{6.148}$$

$$\boldsymbol{y} = \boldsymbol{g}(\boldsymbol{x}, \boldsymbol{u}, \boldsymbol{z}) \tag{6.149}$$

where

$\boldsymbol{x}$ der $(n \times 1)$ is the state vector
$\boldsymbol{u}$ der $(r \times 1)$ is the input vector
$\boldsymbol{z}$ der $(q \times 1)$ is a vector of disturbance inputs
$\boldsymbol{y}$ der $(m \times 1)$ is the vector of outputs

6.6.1.1 Linearization about an Equilibrium Point

An equilibrium point $\boldsymbol{x}_R$ of the system (6.148) can be determined by setting the state derivative to zero:

$$\dot{\boldsymbol{x}} = \boldsymbol{f}(\boldsymbol{x}_R, \boldsymbol{u}_R, \boldsymbol{z}_R) = \boldsymbol{0}. \tag{6.150}$$

The equilibrium output $\boldsymbol{y}_R$ is determined from

$$\boldsymbol{y}_R = \boldsymbol{g}(\boldsymbol{x}_R, \boldsymbol{u}_R, \boldsymbol{z}_R). \tag{6.151}$$

The linearized dynamics of 6.150 about $\boldsymbol{x}_R$ are then described by

$$\Delta\dot{\boldsymbol{x}} = A\Delta\boldsymbol{x} + B\Delta\boldsymbol{u} + E\Delta\boldsymbol{z} \tag{6.152}$$

and

$$\Delta y = C\Delta x + D\Delta u + F\Delta z. \tag{6.153}$$

Here, $\Delta\boldsymbol{x} = \boldsymbol{x} - \boldsymbol{x}_R$, $\Delta\boldsymbol{u} = \boldsymbol{u} - \boldsymbol{u}_R$, $\Delta\boldsymbol{z} = \boldsymbol{z} - \boldsymbol{z}_R$ and $\Delta\boldsymbol{y} = \boldsymbol{y} - \boldsymbol{y}_R$ are used to describe deviations from the equilibrium point.

The matrices $\boldsymbol{A}$, $\boldsymbol{B}$, $\boldsymbol{C}$, $\boldsymbol{D}$, $\boldsymbol{E}$, and $\boldsymbol{F}$ are obtained from

$$\boldsymbol{A} = \begin{bmatrix} \frac{\partial f_1}{\partial x_1} & \frac{\partial f_1}{\partial x_2} & \cdots & \frac{\partial f_1}{\partial x_n} \\ \frac{\partial f_2}{\partial x_1} & \frac{\partial f_2}{\partial x_2} & \cdots & \frac{\partial f_2}{\partial x_n} \\ \vdots & \vdots & & \vdots \\ \frac{\partial f_n}{\partial x_1} & \frac{\partial f_n}{\partial x_2} & \cdots & \frac{\partial f_n}{\partial x_n} \end{bmatrix}_R \quad \boldsymbol{B} = \begin{bmatrix} \frac{\partial f_1}{\partial u_1} & \frac{\partial f_1}{\partial u_2} & \cdots & \frac{\partial f_1}{\partial u_r} \\ \frac{\partial f_2}{\partial u_1} & \frac{\partial f_2}{\partial u_2} & \cdots & \frac{\partial f_2}{\partial u_r} \\ \vdots & \vdots & & \vdots \\ \frac{\partial f_n}{\partial u_1} & \frac{\partial f_n}{\partial u_2} & \cdots & \frac{\partial f_n}{\partial u_r} \end{bmatrix}_R$$

$$\boldsymbol{E}=\left[\begin{array}{cccc}\frac{\partial f_1}{\partial z_1} & \frac{\partial f_1}{\partial z_2} & \cdots & \frac{\partial f_1}{\partial z_q}\\ \frac{\partial f_2}{\partial z_1} & \frac{\partial f_2}{\partial z_2} & \cdots & \frac{\partial f_2}{\partial z_q}\\ \cdot & \cdot & \cdot & \cdot\\ \cdot & \cdot & \cdot & \cdot\\ \frac{\partial f_n}{\partial z_1} & \frac{\partial f_n}{\partial z_2} & \cdots & \frac{\partial f_n}{\partial z_q}\end{array}\right]_R \quad \boldsymbol{C}=\left[\begin{array}{cccc}\frac{\partial g_1}{\partial x_1} & \frac{\partial g_1}{\partial x_2} & \cdots & \frac{\partial g_1}{\partial x_n}\\ \frac{\partial g_2}{\partial x_1} & \frac{\partial g_2}{\partial x_2} & \cdots & \frac{\partial g_2}{\partial x_n}\\ \cdot & \cdot & \cdot & \cdot\\ \cdot & \cdot & \cdot & \cdot\\ \frac{\partial g_m}{\partial x_1} & \frac{\partial g_m}{\partial x_2} & \cdots & \frac{\partial g_m}{\partial x_n}\end{array}\right]_R$$

$$\boldsymbol{D}=\left[\begin{array}{cccc}\frac{\partial g_1}{\partial u_1} & \frac{\partial g_1}{\partial u_2} & \cdots & \frac{\partial g_1}{\partial u_r}\\ \frac{\partial g_2}{\partial u_1} & \frac{\partial g_2}{\partial u_2} & \cdots & \frac{\partial g_2}{\partial u_r}\\ \cdot & \cdot & \cdot & \cdot\\ \cdot & \cdot & \cdot & \cdot\\ \frac{\partial g_m}{\partial u_1} & \frac{\partial g_m}{\partial u_2} & \cdots & \frac{\partial g_m}{\partial u_r}\end{array}\right]_R \quad \boldsymbol{F}=\left[\begin{array}{cccc}\frac{\partial g_1}{\partial z_1} & \frac{\partial g_1}{\partial z_2} & \cdots & \frac{\partial g_1}{\partial z_q}\\ \frac{\partial g_2}{\partial z_1} & \frac{\partial g_2}{\partial z_2} & \cdots & \frac{\partial g_2}{\partial z_q}\\ \cdot & \cdot & \cdot & \cdot\\ \cdot & \cdot & \cdot & \cdot\\ \frac{\partial g_m}{\partial z_1} & \frac{\partial g_m}{\partial z_2} & \cdots & \frac{\partial g_m}{\partial z_q}\end{array}\right]_R$$

or in short notation

$$\boldsymbol{A}=\left.\frac{\partial \boldsymbol{f}(\boldsymbol{x},\boldsymbol{u},\boldsymbol{z})}{\partial \boldsymbol{x}}\right|_R \qquad B=\left.\frac{\partial \boldsymbol{f}(\boldsymbol{x},\boldsymbol{u},\boldsymbol{z})}{\partial \boldsymbol{u}}\right|_R$$

$$E=\left.\frac{\partial \boldsymbol{f}(\boldsymbol{x},\boldsymbol{u},\boldsymbol{z})}{\partial \boldsymbol{z}}\right|_R \qquad C=\left.\frac{\partial \boldsymbol{g}(\boldsymbol{x},\boldsymbol{u},\boldsymbol{z})}{\partial \boldsymbol{x}}\right|_R$$

$$D=\left.\frac{\partial \boldsymbol{g}(\boldsymbol{x},\boldsymbol{u},\boldsymbol{z})}{\partial \boldsymbol{u}}\right|_R \qquad F=\left.\frac{\partial \boldsymbol{g}(\boldsymbol{x},\boldsymbol{u},\boldsymbol{z})}{\partial \boldsymbol{z}}\right|_R .$$

6.6.2 Feedback Linearization

Using control authority to transform nonlinear models into linear ones is one of the most commonly used ideas of practical nonlinear control design. Feedback linearization is a versatile control technique for nonlinear systems, which converts a nonlinear system into a linear system using a nonlinear coordinate transformation and feedback control.

It is noteworthy that feedback linearization relies on access to accurate information about the control system in terms of its parameters. While in some cases one can extend the benefits of feedback linearization to approximately known and imperfectly observed models, information flow constraints remain a serious obstacle when applying feedback linearization.

For the sake of simplicity, the explanation is restricted to nonlinear time-invariant SISO systems of the form:

$$\dot{\boldsymbol{x}}=\boldsymbol{f}(\boldsymbol{x}(t))+\boldsymbol{g}(\boldsymbol{x}(t))u(t) \quad \boldsymbol{x}\in\mathbb{R}^n, \tag{6.154}$$

$$y(t) = h(x(t)). \tag{6.155}$$

Feedback linearization now aims at finding a (generally nonlinear) state-space transformation $z = \Phi(x)$ and a feedback law that transforms the original nonlinear system (6.154) into a linear one so that linear control theory can be applied subsequently.

6.6.2.1 Zero Dynamics—Output Zeroing

Definition 6.4

Zero dynamics: The term zero dynamics is used to describe the internal dynamics of a system when the output y(t) is identical zero for a certain input signal u(t) and initial conditions $\boldsymbol{x}$*(0).*

For the computation of the zero dynamics, initial conditions and an input signal have to be found such that

$$y(t) = \dot{y}(t) = \ddot{y}(t) = \cdots = 0 \tag{6.156}$$

holds for all $t \geq 0$. This immediately leads to the first requirement:

$$y(t) = h(x(t)) = 0. \tag{6.157}$$

The requirement (6.157) is independent of the system input $u(t)$ and can thus only be fulfilled by proper selection of the initial conditions.

Differentiating the output equation (6.155) yields

$$\dot{y}(t) = \left[\frac{\partial h(\boldsymbol{x}(t))}{\partial \boldsymbol{x}}\right]^T \dot{\boldsymbol{x}}(t) = \left[\frac{\partial h(\boldsymbol{x}(t))}{\partial \boldsymbol{x}}\right]^T [f(\boldsymbol{x}(t)) + \boldsymbol{g}(\boldsymbol{x}(t))u(t)] \tag{6.158}$$

and setting $\dot{y}(t) = 0$ yields

$$\dot{y}(t) = L_f h(\boldsymbol{x}(t)) + L_g h(\boldsymbol{x}(t))u(t) = 0. \tag{6.159}$$

The expressions $L_f h(\boldsymbol{x}(t))$ and $L_g h(\boldsymbol{x}(t))$ are the so-called *Lie derivatives* or directional derivatives of $h(\boldsymbol{x})$ along $\boldsymbol{f}(\boldsymbol{x})$ and $\boldsymbol{g}(\boldsymbol{x})$, respectively.

If $L_g h(\boldsymbol{x}(t)) = 0$ in 6.159, then $\dot{y}$ is also independent of $u(t)$ and one proceeds with the second derivative:

$$\ddot{y}(t) = \frac{\partial y(t)}{\partial t} = \left[\frac{\partial L_f h(\boldsymbol{x}(t))}{\partial \boldsymbol{x}}\right]^T \dot{\boldsymbol{x}}(t) = \left[\frac{\partial L_f h(\boldsymbol{x}(t))}{\partial \boldsymbol{x}}\right]^T [\boldsymbol{f}(\boldsymbol{x}(t)) + \boldsymbol{g}(\boldsymbol{x}(t))u(t)] \tag{6.160}$$

and setting $\ddot{y}(t) = 0$ yields

$$\ddot{y}(t) = L_f^2 h(\boldsymbol{x}(t)) + L_g L_f h(\boldsymbol{x}(t))u(t) = 0. \tag{6.161}$$

If $L_g L_f h(\boldsymbol{x}(t)) = 0$, then $u(t)$ has nondirect influence on the second derivative of the output as well. In this case, the third derivative of the output is obtained as

$$y^{(3)}(t) = L_f^3 h(\boldsymbol{x}(t)) + L_g L_f^2 h(\boldsymbol{x}(t))u(t). \tag{6.162}$$

Derivatives of the output are computed consecutively until the input $u(t)$ explicitly appears in the rth derivative $y^{(r)}(t)$:

$$L_g L_f^{r-1} h(\boldsymbol{x}(t)) \neq 0 \tag{6.163}$$

which implies that

$$y^{(r)}(t) = L_f^r h(\boldsymbol{x}(t)) + L_g L_f^{r-1} h(\boldsymbol{x}(t)) u(t). \tag{6.164}$$

The number r is then called the *relative degree* of the system. Zeroing the output $y(t)$ at all times $t \geq 0$ according to 6.156 implies that the initial conditions $\boldsymbol{x}(t = 0)$ have to be selected such that

$$h(\boldsymbol{x}) = L_f h(\boldsymbol{x}(t)) = L_f^2 h(\boldsymbol{x}(t)) = \cdots = L_f^{r-1} h(\boldsymbol{x}(t)) = 0 \tag{6.165}$$

holds.

A suitable state-space transformation for feedback linearization is now obtained through

$$\begin{aligned} z_1 &= \Phi_1(\boldsymbol{x}) = h(\boldsymbol{x}) \\ z_2 &= \Phi_2(\boldsymbol{x}) = L_f h(\boldsymbol{x}(t) \\ &\vdots \quad \vdots \\ z_r &= \Phi_r(\boldsymbol{x}) = L_f^{r-1} h(\boldsymbol{x}(t)). \end{aligned} \tag{6.166}$$

The remaining transformations $\Phi_{r+1}(\boldsymbol{x})$ through $\Phi_n(\boldsymbol{x})$ have to be found such that the Jacobian $\partial\Phi/\partial x \neq 0$ and that $L_g \Phi_i(\boldsymbol{x}) = 0$ holds.

In the new coordinates, the first r equations of the state-space system now read

$$\begin{aligned} \dot{z}_1 &= z_2 \\ \dot{z}_2 &= z_3 \\ &\vdots \quad \vdots \\ \dot{z}_{\mathrm{r}-1} &= z_r \\ \dot{z}_r &= L_f^r h(\boldsymbol{x}(t)) + L_g L_f^{r-1} h(\boldsymbol{x}(t)) u(t) = a(\boldsymbol{x}) + b(\boldsymbol{x}) u. \end{aligned} \tag{6.167}$$

Next, the linearizing feedback law is defined as

$$u(t) = \frac{-a(\boldsymbol{x}) + v(t)}{b(\boldsymbol{x})}, \tag{6.168}$$

where $v(t)$ is the control input associated with the linear system. Application of $u(t)$ requires that $b(\boldsymbol{x}) \neq 0$. Inserting into the last derivative (6.167) leads to

$$\dot{z}_{\mathrm{r}} = v(t). \tag{6.169}$$

The structure of the feedback-linearized system is illustrated in Figure 6.26.

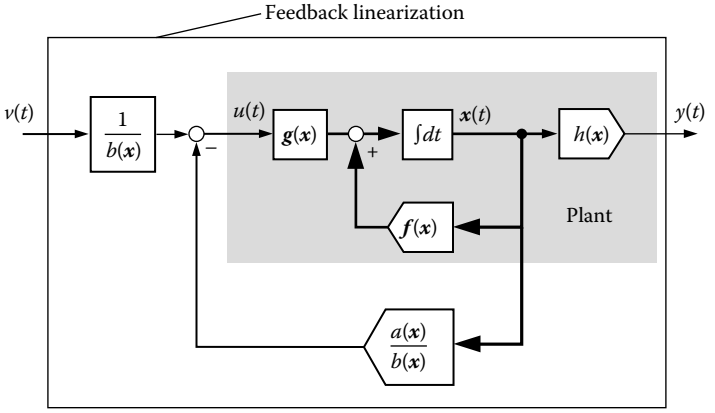

FIGURE 6.26 Block diagram of a feedback-linearized system.

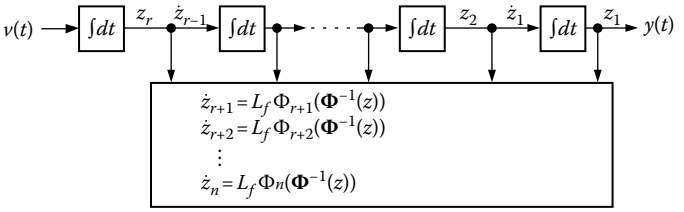

FIGURE 6.27 Resulting structure of a feedback-linearized system.

If the remaining transformations are chosen such that $L_g\Phi_i(\boldsymbol{x}) = 0$, then

$$\begin{aligned}
\dot{z}_{r+1} &= q_{r+1}(z) = \mathrm{L}_f\Phi_{r+1}(\boldsymbol{\Phi}^{-1}(z)) \\
\dot{z}_{r+2} &= q_{r+2}(z) = \mathrm{L}_f\Phi_{r+2}(\boldsymbol{\Phi}^{-1}(z)) \\
&\vdots \quad \vdots \\
\dot{z}_n &= q_n(z) = \mathrm{L}_f\Phi_n(\boldsymbol{\Phi}^{-1}(z)).
\end{aligned} \tag{6.170}$$

The transformed system now consists of two parts: first, there is a sequence of r integrators, described by 6.167 with $v(t)$ as input to the rth integrator according to 6.169. This subsystem is linear and fully controllable and observable. The second part, described by 6.170, is generally nonlinear and has no influence on the output $y(t)$. It is therefore also understood as the *unobservable* part of the transformed system. The situation is illustrated in Figure 6.27. If $v(t) \equiv 0$ and if all conditions (6.165) are met, then the unobservable part of the system (6.170) is commonly called *zero dynamics*.

For a subsequent controller design for the linear part $z_1, \ldots, z_r$, it is essential that the zero dynamics $z_{r+1}, \ldots, z_n$ are stable.

Example 6.17

Feedback linearization

Consider the system

$$\dot{x} = \begin{bmatrix} -x_1 \\ x_1x_2 \\ x_2 \end{bmatrix} + \begin{bmatrix} \exp(x_2) \\ 1 \\ 0 \end{bmatrix} u(t) \quad \text{and} \quad y = h(x) = x_3. \tag{6.171}$$

From 6.157, one gets

$$y = h(x) = x_3 = 0 \qquad z_1 = \Phi_1(x) = x_3.$$

Next, 6.159 is evaluated:

$$\dot{y} = L_f h(\boldsymbol{x}(t) + L_g h(\boldsymbol{x}(t) u(t) = x_2 = 0 \qquad z_2 = \Phi_2(\boldsymbol{x}) = x_2.$$

Then, 6.161 gives

$$\ddot{y} = L_f^2 h(\boldsymbol{x}(t)) + L_g L_f h(\boldsymbol{x}(t)) u(t) = x_1 x_2 + u = 0.$$

Apparently, the relative degree of the system is $r = 2$ and the control law (6.168) now reads

$$u(t) = -x_1 x_2 + v(t).$$

Next, $\Phi_3(\boldsymbol{x})$ has to be found such that

$$L_g \Phi_3(\boldsymbol{x}) = \left[\frac{\partial \Phi_3(\boldsymbol{x})}{\partial \boldsymbol{x}} \right]^T \boldsymbol{g}(\boldsymbol{x}) = \frac{\partial \Phi_3}{\partial x} \exp(x_2) + \frac{\partial \Phi_3}{\partial x_1} 1 = 0.$$

One possible solution is $\Phi_3(\boldsymbol{x}) = 1 + x_1 - \exp(x_2)$. The Jacobian then becomes

$$\frac{\partial \boldsymbol{\Phi}}{\partial \boldsymbol{x}} = \begin{bmatrix} 0 & 0 & 1 \\ 0 & 1 & 0 \\ 1 & -\exp(x_2) & 0 \end{bmatrix}.$$

Accordingly, the feedback-linearized system is described by

$$\begin{bmatrix} \dot{z}_1 \\ \dot{z}_2 \\ \dot{z}_3 \end{bmatrix} = \begin{bmatrix} z_2 \\ v(t) \\ (1 - z_3 - \exp(z_2))(1 + z_2 \exp(z_2)) \end{bmatrix}. \tag{6.172}$$

The zeroing initial conditions (6.165) become

$$h(x) = z_1 = x_3 = 0, \quad L_f h(\boldsymbol{x}(t)) = z_2 = x_2 = 0, \quad \text{and thus } u = 0$$

Inserting into the last equation (6.172) shows that the zero dynamics for $u = 0$ are described by $\dot{z}_3 = -z_3$. In this case, the zeros dynamics are linear and stable.

6.6.3 Robust Control

The robust control concept most widely used is H_∞ control. This is due to the seamless fit in the framework of optimal control and versatile design parameters which allow for the incorporation of different types of model uncertainties. In this section, only a short overview will be given and thorough coverage is given in [21].

The definition of the H_∞ norm is given by

$$\left\| \mathbf{G} \right\|_\infty = \sup_w \frac{\left\| \mathbf{y} \right\|_2^2}{\left\| \mathbf{u} \right\|_2^2}, \tag{6.173}$$

where $\mathbf{G}$ is the closed-loop transfer function between the input $\mathbf{u}$ and the output $\mathbf{y}$.

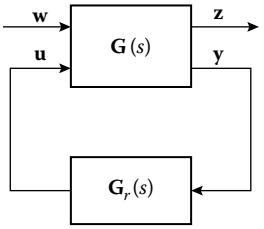

FIGURE 6.28 Basic structure of the H_∞-control problem.

The formulation of the H_∞-control problem is based on the structure in Figure 6.28. The system input is now **w** whereas the output is some arbitrary performance variable **z**. An obvious and important differentiation to LQR design is that disturbance and control inputs as well as measured and performance outputs need not be identical. They all will, however, be explicitly incorporated into the controller design. This fact enables the designer to achieve a predefined controller performance (defined only in the performance variable **z**) in spite of measuring other output variables **y**. Nevertheless, the fundamental principle behind H_∞ design is also an optimization procedure.

The transfer-function matrix **G** in Figure 6.28 can be partitioned into four appropriate submatrices $\mathbf{G}_{ij}$, which constitute the following equations for the variables **z** and **y**:

$$\mathbf{z} = \mathbf{G}_{zw}\mathbf{w} + \mathbf{G}_{zu}\mathbf{u}, \tag{6.174}$$

$$\mathbf{y} = \mathbf{G}_{yw}\mathbf{w} + \mathbf{G}_{yu}\,\mathbf{u}, \tag{6.175}$$

where the $\mathbf{G}_{ij}$ are the respective components of the plants transfer-function matrix. Combining Equations 6.174 and 6.175, the input/output characteristic of the plant **G** and of the controller $\mathbf{G}_r$ are obtained by

$$\begin{bmatrix}\mathbf{z}\\ \mathbf{y}\end{bmatrix} = \begin{bmatrix}\mathbf{G}_{zw} & \mathbf{G}_{zu}\\ \mathbf{G}_{yw} & \mathbf{G}_{yu}\end{bmatrix}\begin{bmatrix}\mathbf{w}\\ \mathbf{u}\end{bmatrix} \tag{6.176}$$

and

$$\mathbf{u} = \mathbf{G}_r\mathbf{y}. \tag{6.177}$$

The transfer function of the overall closed-loop system is given by

$$\mathbf{T}_{zw} = \frac{\mathbf{z}}{\mathbf{w}} \tag{6.178}$$

and by inserting Equation 6.176 into Equation 6.175 it is transformed to

$$\mathbf{T}_{zw} = \mathbf{G}_{zw} + \mathbf{G}_{zu}\mathbf{G}_r(1-\mathbf{G}_{yu}\mathbf{G}_r)^{-1}\mathbf{G}_{yw}. \tag{6.179}$$

The result of 6.179 is termed as lower fractional transform (LFT). This description is unique and can be directly computed from Equation 6.176. Using Equation 6.179, the transfer zeros of the closed loop can be affected by an appropriate choice of $\mathbf{G}_{zw}$ and $\mathbf{G}_{zu}$. The minimization of the LFT with respect to the ∞ norm is the H_∞-design problem and can be recasted as

$$\min_{\mathbf{G}_r(s)} \left\|\mathbf{T}_{zw}\right\|_\infty = \min_{\mathbf{G}_r(s)} \sup_{w\in R} \bar{\sigma}\{\mathbf{T}_{zw}\}. \tag{6.180}$$

In the case of a SISO system, the minimization of the largest singular value $\bar{\sigma}$ is identical to minimizing the maximal value of the gain response of $\mathbf{T}_{zw}$. In contrast to LQ optimization, where the integral criterion averages over the frequency range, H_∞ design aims to limit the gain response only in the direction of the worst case.

Some advantages and disadvantages of the H_∞-control design method are outlined in the following:

Advantages:

- A controller design explicitly incorporating all disturbances is possible.
- An assumption of uncorrelated (and possibly white) disturbances and control inputs is not necessary.
- Arbitrary performance variables can be defined and the control performance is guaranteed.
- Frequency weighting of the inputs and outputs is easily implemented.
- The effects of neglected structural or actuator dynamics can be counteracted.
- Standard method for robust control, many numerical tools available.

Disadvantages:

- The design of the controller is mathematically involved and especially scaling issues of the plant model can be cumbersome.
- Inherent coupling of an observer and controller design ⇒ the optimization has to be solved iteratively. However, software tools considerably ease this situation.

6.7 STATE ESTIMATION REVISITED

The basic state observer has already been introduced in Section 6.2.2 (Luenberger observer). However, the Luenberger observer has been derived under the assumption of both deterministic inputs and perfect knowledge of the stationary plant. If these conditions are not met, the performance of the observer may be poor or it may even become unstable. In this chapter, two concepts are introduced, which are able to deal with the earlier outlined problems: the Kalman filter for systems with stochastic inputs, and the sliding mode observer (SMO) for systems with parameter variations.

6.7.1 Kalman Filter

6.7.1.1 Motivation

The Kalman filter problem is fundamentally different from the previous system configurations. Not only measurement noise $\boldsymbol{\nu}(t)$ corrupts the output measurement, but also an additional stochastic input called process noise $\boldsymbol{w}(t)$ is fed into the system (see also Figure 6.29):

$$\dot{\boldsymbol{x}} = \boldsymbol{A}\boldsymbol{x} + \boldsymbol{B}\boldsymbol{u} + \boldsymbol{G}\boldsymbol{w}; \quad \boldsymbol{x}(t_0) = \boldsymbol{x}_0, \tag{6.181}$$

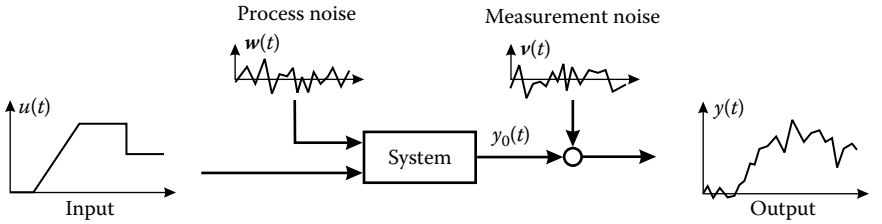

FIGURE 6.29 Kalman filter problem: the linear system has a deterministic known input $u(t)$, a stochastic unknown input $\boldsymbol{w}(t)$ (process noise), and measurement noise $\boldsymbol{\nu}(t)$ added to the system output $y_0(t)$.

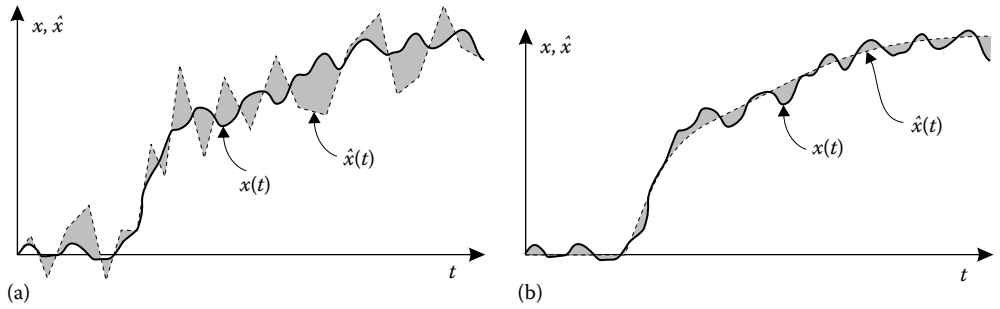

FIGURE 6.30 The problem of state estimation with measurement and process noise. (a) The measured output is a poor estimate. (b) The deterministic output is also a poor estimate.

$$\boldsymbol{y} = \boldsymbol{C}\boldsymbol{x} + \boldsymbol{v}. \tag{6.182}$$

Therefore, stochastic components of the measured output are partly actual system characteristic and partly noise. The objective is to design an observer such that the estimation error covariance is minimal. This task is not trivial, since taking the measurement as an estimate produces an estimation error equal to measurement noise, and taking the deterministic prediction as an estimate completely neglects the effects of process noise (Figure 6.30). Consequently, the optimal observer must consist of some form of compromise, which quantitatively incorporates the effects of both noise sources.

6.7.1.2 Analysis of Covariance

Since the process noise enters the system (6.181) as an input, the propagation and effect of its stochastic nature on the states must be described [1,5]. The goal is, therefore, to compute the covariance of the state vector in the presence of a stochastic system input $\boldsymbol{w}(t)$. The assumptions on the noise signals are uncorrelated zero mean ($\boldsymbol{\mu}_{\boldsymbol{w}(t)} = 0$, $\boldsymbol{\mu}_{\boldsymbol{v}(t)} = 0$) white noise sequences:

$$E\{\boldsymbol{w}(t)\boldsymbol{w}^T(\tau)\} = \boldsymbol{Q}_w\delta(t-\tau), \tag{6.183}$$

$$E\{\boldsymbol{v}(t)\boldsymbol{v}^T(\tau)\} = \boldsymbol{R}_v\delta(t-\tau), \tag{6.184}$$

$$E\{\boldsymbol{w}(t)\boldsymbol{v}^T(\tau)\} = \boldsymbol{R}_v\delta(t-\tau). \tag{6.185}$$

The definition for the covariance of the state vector x is

$$\boldsymbol{P}_x(t) = E\{\boldsymbol{x}(t)\boldsymbol{x}^T(t)\}. \tag{6.186}$$

A possible approach would be the direct computation of the integral; however, this would lead to a stochastic integration. Therefore, a differential equation for $\boldsymbol{P}_x(t)$ will be used instead. Direct differentiation of 6.186 gives

$$\begin{aligned}\dot{\boldsymbol{P}}_x &= E\left\{\dot{\boldsymbol{x}}\boldsymbol{x}^T + \boldsymbol{x}\dot{\boldsymbol{x}}^T\right\}\\ &= E\left\{\boldsymbol{A}\,\boldsymbol{x}\boldsymbol{x}^T + \boldsymbol{x}\boldsymbol{x}^T\boldsymbol{A}^T + \boldsymbol{G}\boldsymbol{w}\boldsymbol{x}^T + \boldsymbol{x}\boldsymbol{w}^T\boldsymbol{G}^T\right\}\\ &= \boldsymbol{A}\boldsymbol{P}_x + \boldsymbol{P}_x\boldsymbol{A}^T + \boldsymbol{S} + \boldsymbol{S}^T,\end{aligned} \tag{6.187}$$

where the matrix $\boldsymbol{S}$ can be computed as

$$\begin{aligned}\boldsymbol{S} &= \boldsymbol{G}\int_{t_0}^{t} E\{\boldsymbol{w}(t)\boldsymbol{w}^T(t)\}\boldsymbol{G}^T\Phi^T(t-\tau)d\tau \\ &= \frac{1}{2}\boldsymbol{G}\boldsymbol{Q}_w\boldsymbol{G}^T\end{aligned} \tag{6.188}$$

due to the Dirac-delta function in 6.183. Hence, 6.187 can be written as

$$\dot{\boldsymbol{P}}_x = \boldsymbol{A}\boldsymbol{P}_x + \boldsymbol{P}_x\boldsymbol{A}^T + \boldsymbol{G}\boldsymbol{Q}_w\boldsymbol{G}^T; \qquad \boldsymbol{P}_x(t_0) = \boldsymbol{P}_{x0}. \tag{6.189}$$

This deterministic ordinary linear differential equation is the so-called Gauss–Markov equation. For a given initial condition $\boldsymbol{P}_{x0}$, the covariance matrix of the system states $P_x(t)$ can be computed. The stationary solution $\overline{\boldsymbol{P}_x}$ of 6.187 is given by

$$\boldsymbol{A}\overline{\boldsymbol{P}_x} + \overline{\boldsymbol{P}_x}\boldsymbol{A}^T = -\boldsymbol{G}\boldsymbol{Q}_w\boldsymbol{G}^T, \tag{6.190}$$

the so-called Lyapunov equation.

6.7.1.3 Derivation of the Filter Equations

The basic structure of the Kalman filter is identical to a Luenberger observer as introduced in 6.60:

$$\dot{\hat{\boldsymbol{x}}} = \boldsymbol{A}\hat{\boldsymbol{x}} + \boldsymbol{B}\boldsymbol{u} + \boldsymbol{H}(\boldsymbol{y} - \boldsymbol{C}\hat{\boldsymbol{x}}), \tag{6.191}$$

where the state estimation error is given by

$$\dot{\tilde{\boldsymbol{x}}} = (\boldsymbol{A} - \boldsymbol{H}\boldsymbol{C})\tilde{\boldsymbol{x}} + \boldsymbol{G}\boldsymbol{w} - \boldsymbol{H}\boldsymbol{v}. \tag{6.192}$$

In both formulations (6.191) and (6.192), the so-called Kalman gain matrix H is the only unknown. The Kalman gain matrix H should now be chosen such that the error covariance matrix

$$\boldsymbol{P}(t) = E\{\tilde{\boldsymbol{x}}(t)\tilde{\boldsymbol{x}}^T(t)\} \tag{6.193}$$

will be minimal. Using 6.183, the Gauss–Markov equation for the error covariance is given by

$$\dot{\boldsymbol{P}} = (\boldsymbol{A} - \boldsymbol{H}\boldsymbol{C})\boldsymbol{P} + \boldsymbol{P}(\boldsymbol{A} - \boldsymbol{H}\boldsymbol{C})^T + \boldsymbol{G}\boldsymbol{Q}_w\boldsymbol{G}^T + \boldsymbol{H}\boldsymbol{R}_v\boldsymbol{H}^T. \tag{6.194}$$

The minimal error covariance can be found by minimizing the trace of $\dot{\boldsymbol{P}}$ with respect to $\boldsymbol{H}$:

$$\frac{\partial Tr(\dot{\boldsymbol{P}})}{\partial \boldsymbol{H}} = -2\boldsymbol{P}\boldsymbol{C}^T + 2\boldsymbol{H}\boldsymbol{R}_v = 0. \tag{6.195}$$

The resulting optimal Kalman gain $\boldsymbol{H}$ is then given by

$$\boldsymbol{H} = \boldsymbol{P}\boldsymbol{C}^T\boldsymbol{R}_v^{-1} \tag{6.196}$$

and 6.194 can be written as

$$\dot{\boldsymbol{P}} = \boldsymbol{A}\boldsymbol{P} + \boldsymbol{P}\boldsymbol{A}^T + \boldsymbol{G}\boldsymbol{Q}_w\boldsymbol{G}^T - \boldsymbol{H}\boldsymbol{R}_v\boldsymbol{H}^T. \tag{6.197}$$

Equations 6.196 and 6.197 constitute the continuous-time Kalman filter. Together, they represent a Riccati equation structurally identical to 6.78, which was the solution for optimal control. This is not surprising since the Kalman filter is also the solution to a quadratic minimization problem with a linear side condition.

6.7.1.4 Properties of the Kalman Filter

The conditions for the existence and optimality of the Kalman filter are [1,5]

- Measurement and process noise are white stochastic processes.
- $\boldsymbol{R}_v$ must be positive definite (inversion in 6.196).
- $(\boldsymbol{A}, \boldsymbol{C})$ must be observable.
- $(\boldsymbol{A}, \boldsymbol{G})$ must be controllable.

If these preconditions are met, the Kalman filter has the following properties:

- The estimate is unbiased:

$$E\{\hat{\boldsymbol{x}}\} \rightarrow E\{\boldsymbol{x}\}. \tag{6.198}$$

- The estimate is optimal with respect to minimal error covariance:

$$E\{\tilde{\boldsymbol{x}}^T(t)\tilde{\boldsymbol{x}}(t)\} = min. \tag{6.199}$$

Therefore, each $E\{\tilde{x}_i(t)^2\}$, $i = 1, \ldots, n$ is minimal.

- The error covariance can be computed off-line using 6.197, without knowledge of actual measurements.
- The solution $\boldsymbol{P}(t)$ constitutes a self-diagnosis for the accuracy of the filter.

The Kalman gain is in general a time-dependent quantity. It should be noted that a stationary solution for the covariance matrix $\bar{\boldsymbol{P}}$ and the Kalman gain $\bar{\boldsymbol{H}}$ can be computed and a stationary Kalman filter can be implemented. In many practical problems, the stationary Kalman filter will be sufficient.

It can be shown [1,13] that the Kalman filter can also be applied to parameter estimation problems. Under certain conditions, it is equivalent to the RLS estimator but it can be used for combined state and parameter estimation. In this case, the original state vector x is augmented with the unknown parameters, the original system matrix $\boldsymbol{A}$ is augmented with an identity matrix block, and the output matrix $\boldsymbol{C}$ is left unaltered. Of course, observability and controllability of the augmented system must exist.

Example 6.18

A second-order continuous-time linear state-space system is given by

$$\dot{\boldsymbol{x}} = \begin{bmatrix} -1 & 0.2 \\ 0.1 & -1.5 \end{bmatrix}\boldsymbol{x} + \begin{bmatrix} 1 \\ 0 \end{bmatrix}\boldsymbol{u} + \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}\boldsymbol{w}, \quad \boldsymbol{y} = [0 \quad 1]\boldsymbol{x} + \boldsymbol{v}$$

and the covariance matrices are

$$\boldsymbol{Q} = \begin{bmatrix} 0.3 & 0 \\ 0 & 0.0001 \end{bmatrix}, \quad \boldsymbol{R} = 1 \times 10^{-5},$$

respectively. A stationary Kalman filter is to be designed and compared with two Luenberger observers.

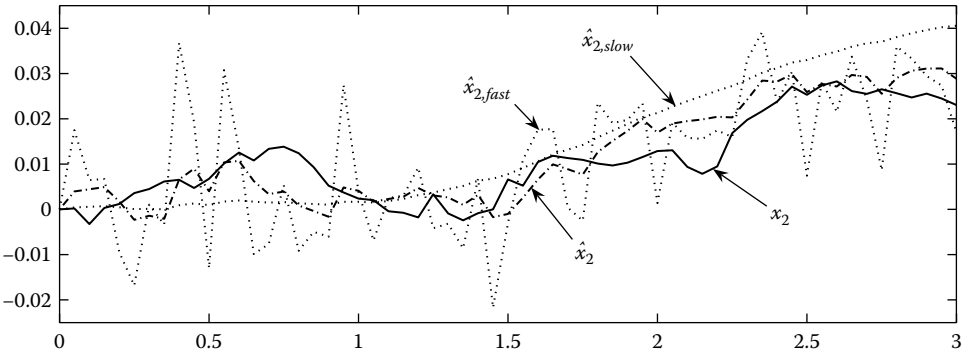

FIGURE 6.31 True state x_2 and estimations from Kalman filter ($\tilde{x}_2$), fast ($\tilde{x}_{2,fast}$), and slow ($\tilde{x}_{2,slow}$) Luenberger observers.

The stationary solution of the Riccati equation (6.197) yields the constant Kalman gain (6.196):

$$\boldsymbol{H} = [117.0 \quad 4.47]^T.$$

In a numerical simulation, the Kalman filter is compared to two Luenberger observers: one with a tenfold larger feedback gain (subscript "fast") and one with only one-tenth of the Kalman gain (subscript "slow"). The results are plotted in Figure 6.31. From the figure, it is clear that the fast observer is strongly compromised by the measurement noise while the slow observer is basically a deterministic prediction that mostly ignores the process noise. The optimality of the Kalman filter is reflected in the estimation error variances:

$$\sigma^2_{e_2} = 0.41.10^{-4}, \quad \sigma^2_{e_2,fast} = 1.41.10^{-4}, \quad \sigma^2_{e_2,slow} = 1.54.10^{-4}.$$

6.7.1.5 Stochastic Separation Principle

A stochastic separation is valid in analogy to the deterministic separation principle (see Equation 6.67). If the Kalman filter is combined, for example, with an optimal state-space controller, the resulting closed-loop system will minimize a criterion similar to 6.76, where the expectation operator has to be used additionally in order to incorporate the stochastic nature of the state vector. This result implies that for any given linear controller (which was designed using the deterministic assumptions of Section 6.3.3), the Kalman filter constitutes the observer which guarantees a minimal criterion (6.76) under the influence of noise.

6.7.1.6 Discrete-Time Kalman Filter

The discrete-time Kalman filter is an important formulation for real-time implementations. Based on the discrete-time representation of a state-space system

$$\boldsymbol{x}(k+1) = \boldsymbol{A}\boldsymbol{x}(k) + \boldsymbol{B}\boldsymbol{u}(k) + \boldsymbol{G}\boldsymbol{w}(k); \quad \boldsymbol{x}(k=0) = \boldsymbol{x}_0, \tag{6.200}$$

$$\boldsymbol{y}(k) = \boldsymbol{C}\boldsymbol{x}(k) + \boldsymbol{v}(k) \tag{6.201}$$

the recursive equations for the Kalman filter are

$$\boldsymbol{x}^*(k+1) = \boldsymbol{A}\hat{\boldsymbol{x}}(k) + \boldsymbol{B}\boldsymbol{u}(k), \tag{6.202}$$

$$\boldsymbol{P}^*(k+1) = \boldsymbol{A}\boldsymbol{P}(k)\boldsymbol{A}^T + \boldsymbol{G}\boldsymbol{Q}(k)\boldsymbol{G}^T, \tag{6.203}$$

$$\boldsymbol{K}(k+1) = \boldsymbol{P}^*(k+1)\boldsymbol{C}^T[\boldsymbol{C}\boldsymbol{P}^*(k+1)\boldsymbol{C}^T + \boldsymbol{R}(k+1)]^{-1}, \tag{6.204}$$

$$\hat{\boldsymbol{x}}(k+1) = \boldsymbol{x}^*(k+1) + \boldsymbol{K}(k+1)[\boldsymbol{y}(k+1) - \boldsymbol{C}\boldsymbol{x}^*(k+1)], \tag{6.205}$$

$$\boldsymbol{P}(k+1) = [\boldsymbol{I} - \boldsymbol{K}(k+1)\boldsymbol{C}]\boldsymbol{P}^*(k+1). \tag{6.206}$$

$\boldsymbol{P}^*(k + 1)$ and $\boldsymbol{x}^*(k + 1)$ are the a priori predictions of the error covariance and the state vector at sampling instant k, respectively [5].

6.7.1.7 Stability Problems and Divergence

The Kalman filter can be impaired by many problems: the process noise may not be white; measurement noise may be correlated; controllablility of $(\boldsymbol{A}, \boldsymbol{G})$ may be given but poor; and the process model may be inaccurate. In these cases, the Kalman filter may not converge or the error covariance estimate is biased. Remedies do exist [1,5], but in most cases a suboptimal filter is the result.

6.7.1.8 Related Filters for Nonlinear Systems

For nonlinear systems, the extended Kalman filter (EKF) can be applied to both state and parameter estimation. For a nonlinear system representation,

$$\dot{\boldsymbol{x}}(t) = \boldsymbol{f}(\boldsymbol{x}(t), t) + \boldsymbol{G}\boldsymbol{w}(t),$$

$$\boldsymbol{y}(t) = \boldsymbol{g}(\boldsymbol{x}(t)) + \boldsymbol{v}(t). \tag{6.207}$$

a local (state-dependent) approximation of the system is given by the Jacobians

$$\boldsymbol{A}(\hat{\boldsymbol{x}}, t) = \frac{\partial \boldsymbol{f}(\boldsymbol{x}(t), (t)}{\partial \boldsymbol{x}(t)}\Big\|_{\boldsymbol{x}(t)=\hat{\boldsymbol{x}}(t)}, \tag{6.208}$$

$$\boldsymbol{C}(\hat{\boldsymbol{x}}, (t)) = \frac{\partial \boldsymbol{g}(\boldsymbol{x}(t))}{\partial \boldsymbol{x}(t)}\Big\|_{\boldsymbol{x}(t)=\hat{\boldsymbol{x}}(t)},$$

which are evaluated at the current state estimate $\hat{\boldsymbol{x}}$. Using the Jacobians (6.209), the same equations as given for the ordinary Kalman filter are utilized [5,6].

Obviously, the EKF makes use of a local first-order approximation of the nonlinear functions $\boldsymbol{f}$ and $\boldsymbol{g}$. However, this may introduce large errors and due to the local linearization the Kalman gain itself is now a stochastic variable. The performance of the EKF is therefore strongly dependent on the type of the nonlinearities, and modeling errors easily lead to convergence problems (note that the observability of $(A(\hat{\boldsymbol{x}}, t), C(\hat{\boldsymbol{x}}, (t)))$ and the controllability of $(A(\hat{\boldsymbol{x}}, t), G)$, is now state dependent).

To overcome these problems, more advanced techniques have been proposed, like the unscented Kalman filter (UKF) [10] or the DD2 filter [17], where without the necessity of partial derivatives a more accurate and robust higher-order approximation is achieved. Another approach is the SMO, which is introduced in Section 6.7.2.

6.7.2 Sliding Mode Observer

6.7.2.1 Motivation

The structure and parameters of the model necessary for an observer are almost always uncertain. This may be due to unknown parameter values, nonlinearities, or time-varying systems. However, the Luenberger observer and the Kalman filter critically rely on a good prediction model. It is therefore desirable to have an estimation tool, which delivers unbiased state or parameter estimates even in the presence of unknown but bounded parameter uncertainties.

6.7.2.2 Principle of the SMO

The design of a SMO is structured in two parts:

1. A so-called sliding surface (a manifold whose dimension is less than that of the original system) is designed in order to assure the desired system properties (dynamics, stability).
2. A switched feedback signal is designed which steers the states (i.e., the estimation errors) to the manifold and keeps all subsequent motion on it.

6.7.2.3 Structure of a SMO

Observers based on the sliding mode concept can have a variety of structures [4,20]. Here, a Lyapunov-based observer for uncertain systems is presented. Consider a system given by

$$\dot{\boldsymbol{x}} = \boldsymbol{A}\boldsymbol{x} + \boldsymbol{B}\boldsymbol{u} + \boldsymbol{f}(\boldsymbol{x}, \boldsymbol{u}, t), \tag{6.209}$$

$$\boldsymbol{y} = \boldsymbol{C}\boldsymbol{x}, \tag{6.210}$$

where $\boldsymbol{A}$, $\boldsymbol{B}$, and $\boldsymbol{C}$ are constant matrices assumed to be known, and the unknown but bounded function $\boldsymbol{f}(\boldsymbol{x}, \boldsymbol{u}, t)$ represents nonlinearities, time-varying terms, and disturbances (e.g., unknown inputs, uncertain parameters). The pair $(\boldsymbol{A}, \boldsymbol{C})$ is assumed to be observable.

Defining the output error $\boldsymbol{e} = \boldsymbol{y} - \hat{\boldsymbol{y}}$ with $\hat{\boldsymbol{y}} = \boldsymbol{C}\hat{\boldsymbol{x}}$, a SMO for the earlier defined system is given by

$$\dot{\hat{\boldsymbol{x}}} = \boldsymbol{A}\hat{\boldsymbol{x}} + \boldsymbol{B}\boldsymbol{u} + \boldsymbol{H}\boldsymbol{e} + \boldsymbol{S}(\boldsymbol{x}, \boldsymbol{u}, t), \tag{6.211}$$

where the switching function $\boldsymbol{S}(\boldsymbol{x}, \boldsymbol{u}, t)$ is defined as

$$\boldsymbol{S}(\boldsymbol{x}, \boldsymbol{u}, t) = \rho \boldsymbol{P}^{-1}\boldsymbol{C}^T \frac{\boldsymbol{e}}{\|\boldsymbol{e}\|} \tag{6.212}$$

and in the case of a scalar output y and output error e:

$$\boldsymbol{S}(\boldsymbol{x}, \boldsymbol{u}, t) = \rho \boldsymbol{P}^{-1}\boldsymbol{C}^T sign(e). \tag{6.213}$$

The gain matrix $\boldsymbol{H}$ and an arbitrary symmetric positive definite matrix $\boldsymbol{Q}$ must be chosen so that the following conditions are satisfied [4]: $\boldsymbol{A}_0 = \boldsymbol{A} - \boldsymbol{H}\boldsymbol{C}$ must be stable and $PA_0 + A_0^T P = -Q$. If ρ is chosen according to

$$\rho > \left\|\boldsymbol{h}(\boldsymbol{x}, \boldsymbol{u}, t)\right\|, \quad \boldsymbol{f}(\boldsymbol{x}, \boldsymbol{u}, t) = \boldsymbol{P}^{-1}\boldsymbol{C}^T\boldsymbol{h}(\boldsymbol{x}, \boldsymbol{u}, t), \tag{6.214}$$

quadratic stability of the observer is guaranteed. In practical problems, the value of ρ is often chosen as a compromise between robustness and noise attenuation.

An ideal sliding mode requires infinite switching frequency. Whenever the switching frequency is limited "chattering" occurs, that is, the switched feedback signal is visible in the state estimates.

Example 6.19

A second-order continuous-time nonlinear state-space system is given by

$$\dot{\boldsymbol{x}} = \begin{bmatrix} -1 & 0.2 \\ 0.1 & -0.3 \end{bmatrix}\boldsymbol{x} + \begin{bmatrix} 1 \\ 0 \end{bmatrix}u + \begin{bmatrix} 0 \\ -1.2atan(x_2) \end{bmatrix}, \quad y = [0 \quad 1]\boldsymbol{x}.$$

Linearization around $\boldsymbol{x} = [0\ 0]^T$ yields the deterministic part of the system given in Example 6.18. An SMO is to be designed and compared with a Luenberger observer (LO) for a nonstationary input.

The feedback gain matrix $\boldsymbol{H}$ and the symmetric positive definite matrix $\boldsymbol{Q}$ from Equation 6.211 are chosen as

$$\boldsymbol{H} = [117.0 \quad 4.47]^T, \quad \boldsymbol{Q} = \begin{bmatrix} 120 & 3.45 \\ -0.03 & -0.182 \end{bmatrix}$$

and the switched signal according to Equation 6.213 is given by

$$\boldsymbol{S}(\boldsymbol{x}) = [57.2 \quad 10.3]^T \, sign(e).$$

In a numerical simulation, the SMO is compared to the LO with a feedback gain of $\boldsymbol{H} = [117.0 \quad 4.47]^T$. The results are plotted in Figure 6.32. The LO produces a biased estimate in both state variables, while the SMO is capable of reconstructing $\hat{x}_1$ within a small error bound and $\hat{x}_2$ with an error only due to chattering.

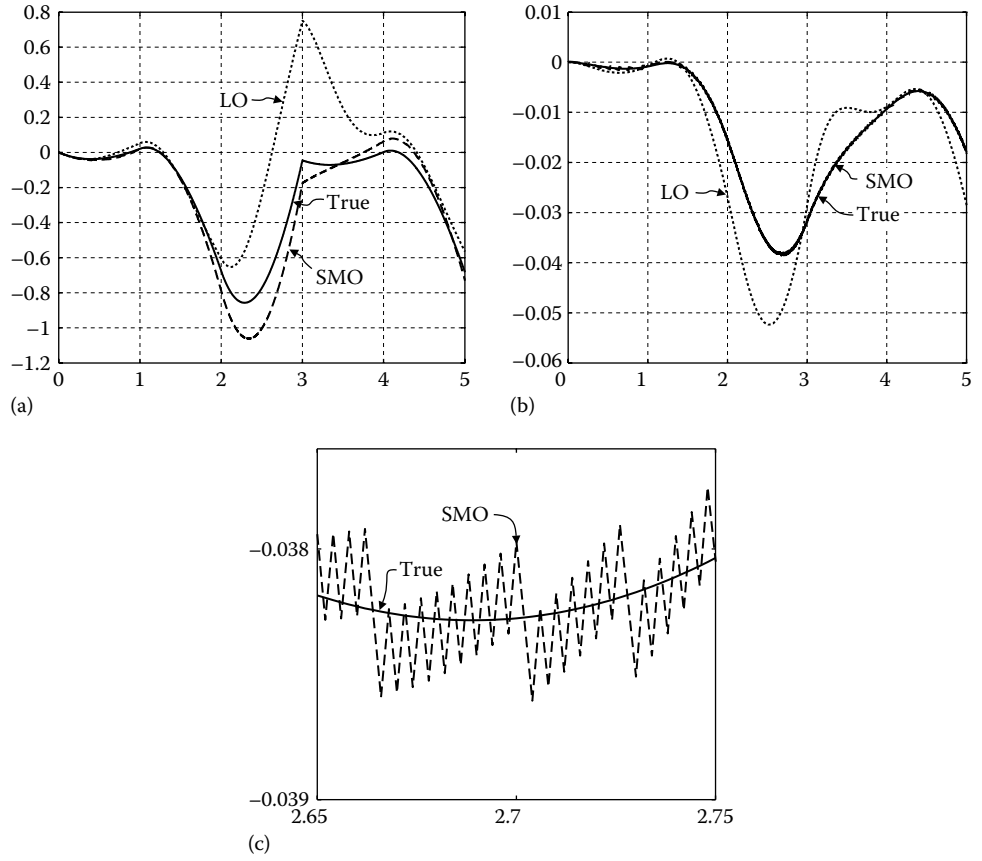

FIGURE 6.32 (a) True state x_1 and estimations from SMO and LO. (b) True state x_2 and estimations from SMO and LO. (c) Chattering in the SMO estimate $\hat{x}_2$ due to finite switching frequency.

7.1 INTRODUCTION

Actuators and sensors are important devices for vehicle dynamic control (VDC). In the usual feedback control system, it is important to detect the controlled values, such as vehicle motions, velocities, and yaw rate. The output of control system should be applied the force or torque in the dynamic system. In the vehicle system, dynamic experiments are valuable methods for research and development. In that time, the vehicle motion must be detected without any control system. Sensor system is necessary in that case.

For the design of controller and modeling of vehicle, the simple model is used as the first step of examination. In that case, we assume that the controlled value is ideally measured and the output of controller also ideally transmits to the dynamic system. However, the actuator and sensors are dynamic system themselves. They have dynamic properties. It is important to consider such dynamic properties in the detailed examination of the VDC and measurements.

In this chapter, at first, the vehicle dynamics and control are explained to understand the actuators and sensors. Next, the modeling of actuator is shown. Some applications of actuators for vehicle system are also shown. For sensors, some remarks of sensing system are decried. Finally, some applications of sensors in vehicle control, vehicle measurements, and vehicle environment measurements are shown.

7.2 VEHICLE DYNAMICS AND CONTROL

7.2.1 Classification of Controls

In the design of automobiles, various electric devices have been developed for realizing further safety, comfort, and availability of vehicle. Control systems composed with these devices can be roughly categorized as the power train control, the electro-communication, the vehicle body control, and the chassis control. The chassis control is also called as vehicle dynamics control. In this chapter, the control is treated for surveying recent actuator and sensor system technologies (Figure 7.1).

VDCs fundamentally aim to control the automobile basic motion (i.e., running, curving, and braking), and improves further handling stability, riding comfort, and safety. The control of the vehicle dynamics can also be classified in detail as the suspension control, the steering control, and the drive control. The suspension control, which control vertical, rolling, and pitching motion of vehicle, aims to improve riding quality and wheel tracking ability along road. The steering control aims to improve handling and stability on curving and controls yawing and lateral motion of vehicle. Drive control aims vehicle longitudinal motion control.

7.2.2 Suspension Control

Automobile suspension has two functions: one is absorbing vibration for improving riding comfort and the other is transmitting traction and braking force aroused between wheel and road for improving handling stability. From the view point of riding comfort, soft spring, which isolate severe stimulus from road, is necessary. On the other hand, hard suspension is necessary for realizing excellent handling stability. The compatibility for both requirements is quite crucial problem to be solved in the design of suspension.

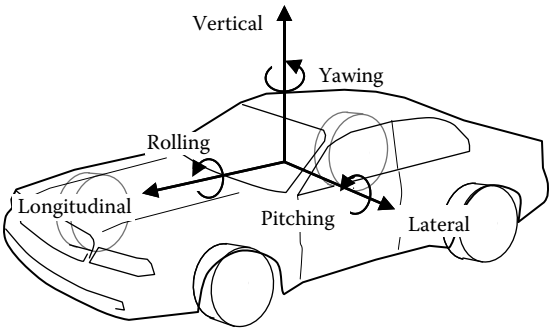

FIGURE 7.1 Controlled degree of freedom of automobile with vehicle dynamics control systems.

The definition of the active suspension is shown from the points of the power source and control function according to the road condition. The semi-active suspension is also defined as the suspension which does not have power source but has control function according to the road condition. These controlled suspensions are realized by utilizing hydraulic and pneumatic actuators. Control method of suspension has started with skyhook control which is useful for both active and semi-active suspensions control algorithm. In the control of suspensions, many researches have been reported such as optimal control, robust control, and adaptive control.

Even though the hydraulic actuators had been mainly used in the suspension control of the vehicle, the electromagnetic suspension has also been developed. The electromagnetic suspension gives many benefits in simplicity for damping tuning, maintenance, and high precision control and response. Furthermore, the possibility of self-powered control, which utilizes vibration energy regenerated by suspension and stored in capacitor for using active control, has been studied.

7.2.3 Steering Control

The control of four-wheel steering (4WS) [1] had been developed from the early 1970s. In the first step of the control algorithm for rear steering angles, simple feedback controls regarding such as front steering angle, steering force, and yaw-late were considered. As the relation between control theory and vehicle dynamics had been gradually clarified, more effective feedback control algorithm was developed. For example, the control where the output signal with sideslip angle of center of gravity is used for output zeroing was considered. Model following control, where the error signal between reference model and the output signal composed with vehicle lateral acceleration and yaw-late sensors, was also proposed. Previously mentioned 4WS controls are distinct from what is chosen as controlled output, and lead great difference for stability factor, handling stability, and disturbance response. The more control algorithm becomes complicated, the more sensors are required to be equipped. The work of 4WS had theoretically summarized by the end of 1980, and leads vehicle stability control (VSC) and direct yaw-moment control (DYC) [2–5].

In recent years, the application of fly-by-wire (FBW) in aerospace category has been positively introduced into the steering control of automobiles. The steer-by-wire (SBW) [6,7], which is capable of flexible change of the relation between vehicle and driver, gives great possibility on vehicle handling control such as variable gear ratio control.

7.2.4 Drive Control

The basic function of the drive control is longitudinal control such as braking, acceleration, and keeping constant velocity. These controls are realized by anti-lock brake system (ABS), traction control system (TCS), and adaptive cruise control (ACC) [8,9], respectively. Initially, the ABS control mainly aimed to keep handling stability during full braking while wheels are locked. The state of locking of wheel is indirectly measured by comparing vehicle velocity and wheel rotational velocity. In the estimation of absolute vehicle velocity from wheel rotational velocity, the accuracy of the measurement is still problem to be solved. If the brake pressure induced by the driver is such that the wheels lock, then the brake pressure must be reduced to regain steer ability. For this task, ABS uses a hydraulic unit, which has electromagnetic valves to keep the pressure in the wheel brakes.

If the driven wheels spin due to excess engine drive torque, handling becomes difficult. This has led then to the introduction of TCS which also preserve a high level of handling performance during driving with excess engine drive torque. The main task of the control algorithm is to keep a high level of traction force while at the same time keeping a sufficient level of lateral force generation by

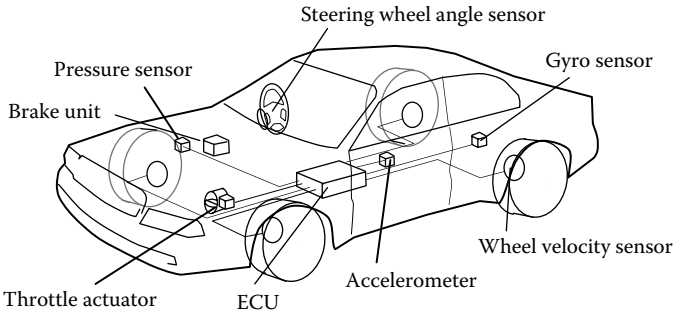

FIGURE 7.2 An example of sensor and actuator systems on ESP.

steering to preserve a high level of handling performance. Fortunately, for single axle-driven cars, the speeds of the non-driven wheels may be used to compute the free rolling speed of the driven wheels. Therefore, slip control of the driven wheels becomes possible.

Crouse control system adjusts the engine drive torque using throttle valve to keep the vehicle velocity to the desired value. As an example of vehicle velocity sensors used here, magnetic rotary encoder mounted on transmission is used.

The control of yaw momentum of vehicle is realized by controlling each wheel slip with longitudinal tire forces. This control leads stable vehicle yawing and lateral motion and improves steer ability in large region of slipping. The control is called "Electric Stability Program" (ESP; sometimes called as VDC, VSC, and so on, depending on car manufactures) and nowadays widely implemented on automobiles. Feedback control of the vehicle motion is possible by extending the TCS and ABS with additional sensors. As shown in Figure 7.2, ESP consists of many sensors as yaw-late sensors, accelerometer, steering wheel angle sensor, brake pressure sensor, and tachometer. Steering wheel angle sensor detect the curving trajectory on which driver desires to trace, then comparing the error between measured vehicle trajectory using yaw-late sensor and accelerometer, and controls the sideslip with feedback control.

Direct Yaw Control (DYC) also gives yaw-late and lateral acceleration control with longitudinal tire force. The purpose of DYC is almost same as ESP, where the difference of traction of each wheel aroused by electrically controlled Limited Slip Differential (LSD) or other differential torque devices allows more sufficient force generation than that of ESP. In recent years, electric vehicle with in-wheel drive motor is considered. The vehicle is essentially capable of high performance of DYC with motor torque control.

As in the case of SBW, throttle-by-wire (TBW) is also developed and allows cooperative use with stability controls (ESP, DYC, and so on). The cooperative use of drive control and steering control is also considered for realizing further high performance of steer ability of vehicle. Since both of control realize yaw-late and lateral acceleration control, the dynamics coupling, which results from connection of each interactive subsystem, becomes problem to be solved. In order to solve the problem, integrated vehicle control is proposed and is the latest topic of the vehicle dynamics control [10,11].

7.2.5 Sensors and Actuators in Vehicle Dynamics Controls

Some example of sensors used in previously mentioned controls are steering sensor, vehicle velocity sensor, tachometer, accelerometer, yaw-late sensors, and so on. Some of these sensors are used in more than two controls. These devices are selected along with control performance such as time-response and frequency characteristics. Furthermore, vehicles have special actuators such as ABS, LSD engine drive torque, and so on. Table 7.1 gives the classified according to controls, controlled variables, actuators, and sensors.

TABLE 7.1
Scope of Control System and Corresponding Controlled Variable

	Control	Variable	Actuator	Sensor
Suspension control	Vibration control, height control, antiroll control, etc.	Vertical, rolling, pitching motion	Hydraulic, pneumatic, electromagnetic	Accelerometer, stroke sensor, etc.
Steering control	EPS, 4WS, SBW (AFS, ARS)	Lateral, yawing motion	Hydraulic, pneumatic, electric actuator	Yaw-rate sensor, steering wheel angle, accelerometer, tachometer, etc.
Drive control	ABS, TCS, adaptive cruise control, vehicle stability control, direct yaw control	Longitudinal, yawing motion	Engine drive torque, LSD, ABS, etc.	Yaw-rate sensor, tachometer, steering wheel angle, brake pressure, throttle sensor, etc.

7.3 MODELING OF ACTUATORS

7.3.1 Classification of Electric Motors

As mentioned earlier, several kinds of actuators are utilized in automobiles. They improve running performance, ride comfort, and operate many other equipments. Major actuators utilized in the automobiles are electric motors and hydraulic actuators. Electric motors are transducers that convert electric energy into mechanical energy. The electric motors are divided into three categories: direct current (DC), alternative current (AC), and stepping motors [12].

7.3.2 DC Motors

Torque of the DC motors originates from electromagnetic force acting on a current-carrying conductor in a developed magnetic field. A typical DC motor produces torque τ_r, when the electric current passes in its armature coil:

$$\tau_r = \phi_\tau i_r. \tag{7.1}$$

To the contrary, when the rotor rotates at the angular speed of ω_r, voltage e_b is induced in the coil as

$$e_b = -\phi_e \omega_r. \tag{7.2}$$

This voltage is called back electromotive force (emf). The constants ϕ_τ and ϕ_e have the same values, since consistency of mechanical and electrical work must be maintained. Then we symbol them by ϕ ($= \phi_\tau = \phi_e$) [13].

The magnetic field of a DC motor is produced by permanent magnets (PMs) or field windings. According to the methods to produce the magnetic field, DC motors are mainly classified to three categories: PM motors, series motors, and shunt motors. Since a PM motor develops the magnetic field with a PM, it can operate with high efficiency and has a linear characteristic, which makes it control-friendly. A PM motor is mainly utilized for a servomotor in automobiles [14]; therefore, only DC motors with PM are treated in this section.

Figure 7.3 shows a model of a geared PM-type DC motor.

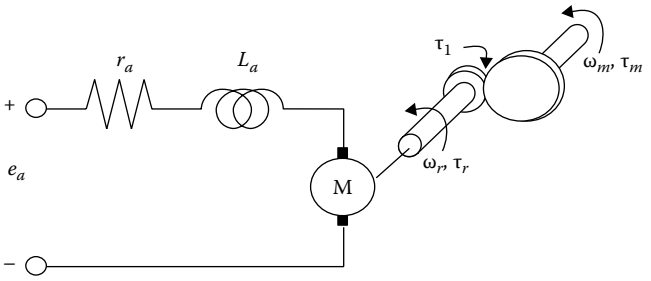

FIGURE 7.3 Model of a PM DC motor.

The parameters are defined as

i_a is the current of the armature
e_a is the applied voltage
e_b is the back emf
r_a is the resistance of the armature
L_a is the inductance of the armature
ω_r is the angular velocity of the rotor
τ_r is the torque resulted from electromagnetic force
τ_1 is the load torque of the rotor
τ_m is the load torque of the output shaft
ω_m is the angular velocity of the shaft
G is the gear ratio
J_r is the inertia of the rotor
J_m is the inertia of the output shaft

A circuit equation is

$$L\frac{di_a}{dt} + r_a i_a = e_a - e_b. \tag{7.3}$$

Moment equations of the rotor and the output shaft are

$$J_r \frac{d\omega_r}{dt} = \tau_r - \tau_1 \tag{7.4}$$

$$J_m \frac{d\omega_m}{dt} = G\tau_1 - \tau_m. \tag{7.5}$$

The relationship between τ_r and τ_m is

$$\omega_m = \frac{\omega_r}{G}. \tag{7.6}$$

Then the moment equations derived as

$$\left(J_m + G^2 J_r\right)\frac{d\omega_m}{dt} = G\tau_r - \tau_m. \tag{7.7}$$

From Equations 7.1 through 7.3, 7.6, and 7.7, the state equations are written in vector-matrix form:

$$\begin{bmatrix} \dfrac{di_a}{dt} \\ \dfrac{d\omega_m}{dt} \end{bmatrix} = \begin{bmatrix} -\dfrac{r_a}{L_a} & -\dfrac{G\phi}{L_a} \\ \dfrac{G\phi}{J_m + G^2 J_r} & -\dfrac{G^2\phi}{J_m + G^2 J_r} \end{bmatrix} \begin{bmatrix} i_a \\ \omega_m \end{bmatrix} + \begin{bmatrix} \dfrac{1}{L_a} \\ 0 \end{bmatrix} e_a + \begin{bmatrix} 0 \\ \dfrac{-1}{J_m + G^2 J_r} \end{bmatrix} \tau_m. \tag{7.8}$$

7.3.3 AC Motors

Majority of AC motors utilized as servomotors in automobile systems are synchronous motors whose magnetic field is produced by PMs [14]. The main difference between this type of AC motors and DC motors is that they do not have brushes, which commutate the armature current mechanically; therefore, they are also called brushless DC motors. Although the commutations need to be done electrically, they do not need a brush to wear out and this makes the motor maintenance-free. Figure 7.4 shows basic operational principles of the motor. In the brushless motor, the rotor consists of PMs and windings are located external to the rotating part. Hall-element sensors are placed near the rotor and measure the magnetic flux to estimate the rotor angle. According to the output of the Hall element, the circuit is changed by some kinds of transistors and the current is commutated. Although the brushless DC requires additional energy to operate sensors and transistors, it is maintenance-free and its rotor inertia is small compared with that of brushed motors. Recently, brushless DC motors have become popular electric motors and have been utilized for drive motors of a hybrid car as well as servomotors [15].

7.3.4 Stepping Motors

Stepping motors convert digital pulses into mechanical rotation. The amount of rotation is proportional to the number of pulses and the speed of rotation is relative to the frequency of those pulses. Since position error is limited and known, stepping motor has high reliability for position control.

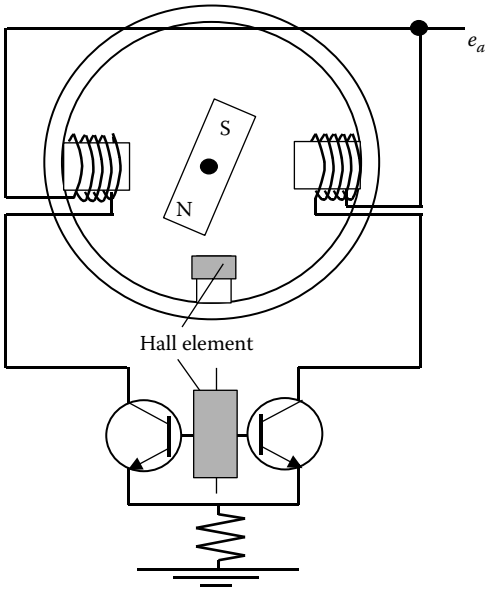

FIGURE 7.4 Basic operational principles of synchronous AC motors.

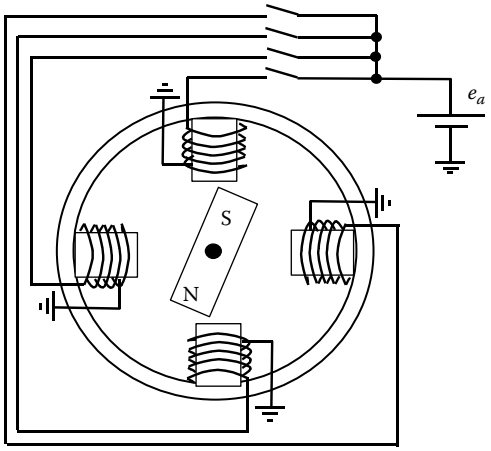

FIGURE 7.5 Basic operational principles of step motors.

In automobile system, they are utilized for meters on instrument panels, throttle valve control systems, and so on. Basic operational principles are shown in Figure 7.5. It consists of PM rotor and stator coils. Rotation is achieved by switching the voltage source to each winding in turn.

7.3.5 Conversion of Rotational to Transversal Motion

The majority of electric actuators utilized in automobiles are powered by rotary motors. Then, it is often necessary to convert rotational motion to transversal motion when we use them to produce the translational forces. One of the major converters is a ball-screw-and-nut [16]. Figure 7.6 shows one of the possible configurations of the electric motor assembled with a ball-screw-and-nut. By this mechanism, output torque of the rotary motor τ_m is converted to output force f as

$$f = \frac{2\pi}{l}\left(\tau_m - J_s \frac{d\omega_m}{dt}\right) \tag{7.9}$$

where J_s and l are inertia moment of the screw and lead of the screw. And when the speed of transversal motion is $\dot{z}$, angular speed of the screw ω_m is obtained by

$$\omega_m = \frac{2\pi}{l}\dot{z}. \tag{7.10}$$

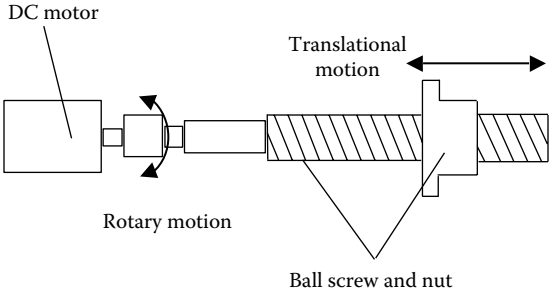

FIGURE 7.6 Configuration of an electric motor assembled with a ball-screw-and-nut.

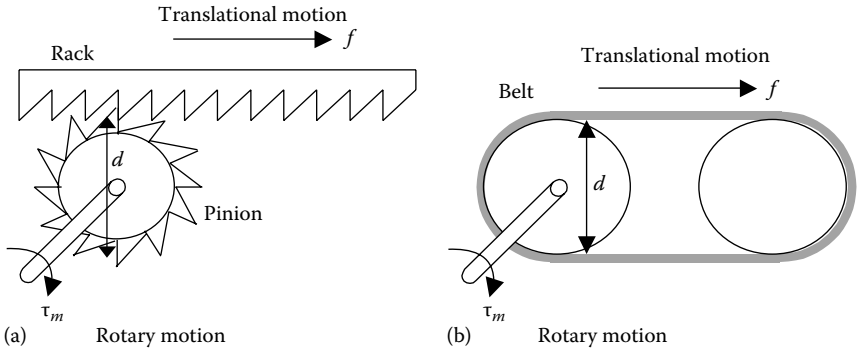

FIGURE 7.7 Conversion mechanisms: (a) a rack-and-pinion-gear and (b) a belt-and-pulley system.

Other conversion mechanisms are a rack-and-pinion-gear and belt-and-pulley system as shown in Figure 7.7. When the inertia moment and the diameter of a pinion or a pulley are J_p and d, respectively, the output force is obtained by

$$f = \frac{2}{d}\left(\tau_m - J_p \frac{d\omega_m}{dt}\right). \tag{7.11}$$

When the speed of transversal motion is $\dot{z}$, the angular speed of the motor shaft ω_m is derived as

$$\omega_m = \frac{2}{d}\dot{z}. \tag{7.12}$$

Using electric linear motors is also the possible way to produce translation forces. Figure 7.8 shows the configuration of a typical linear DC motor. This motor can produce the translational force proportional to the electric current in the motor coil without effects of friction and inertia forces of the conversion mechanism; therefore it is suitable for the actuator of the speaker, which needs high responsibility and preciseness. However, the power produced by the linear motor is small compared with the rotary motor of the same mass. The application of the linear motor in the automobile system is limited, although the innovation might change the situation.

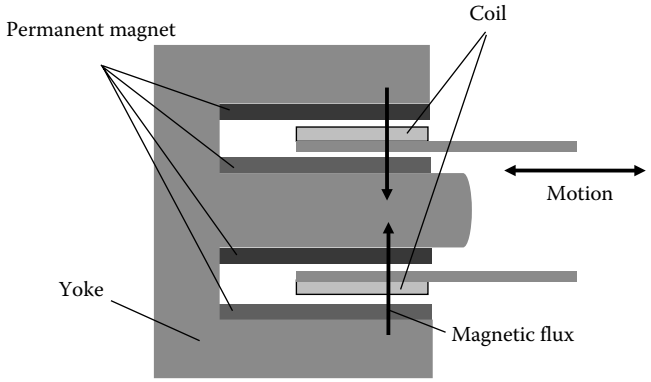

FIGURE 7.8 One of the configurations of linear DC motors.

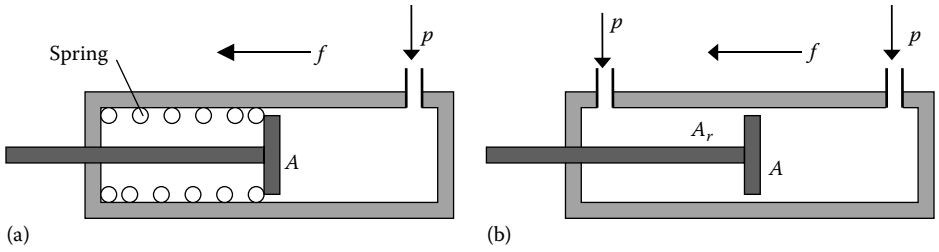

FIGURE 7.9 Configuration of a hydraulic actuator (a) is a single acting hydraulic actuator and (b) is a double acting hydraulic actuator.

7.3.6 Hydraulic Actuators

Hydraulic actuators are normally used when a large amount of force is required. Although there are several kinds of hydraulic actuators, such as a hydraulic cylinder, a rotary actuator, and a hydraulic motor, we concentrate on a hydraulic cylinder, which produces transversal motion and is frequently utilized as an actuator of an automotive system. Figure 7.9 shows configurations of the hydraulic cylinders. Figure 7.9a represents a single acting cylinder. Pressured oil is supplied to one side of the cylinder and output force f is obtained as

$$f = A\,p - f_{spring} \tag{7.13}$$

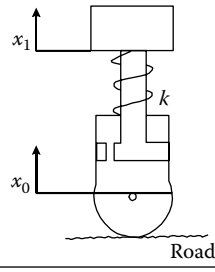
where p, A, and f_{spring} are pressure of the supplied oil, sectional area of the piston, and spring force. However, this type of the cylinder cannot produce force in the opposite direction. Usually, the piston is returned to its initial position by returning force produced by an internal spring. Figure 7.9b illustrates a double acting cylinder. This type of the cylinder has ports of the pressured oil in both sides of the cylinder; therefore, it can produce force in both directions. When the pressured oil is supplied to the left port, output force f is derived as

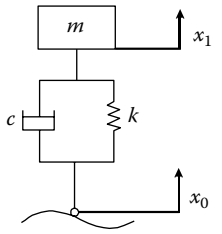
$$f = A\,p. \tag{7.14}$$

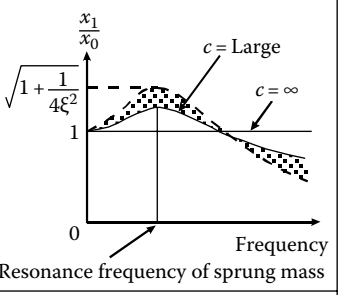
As the oil is supplied to the right port, the output becomes

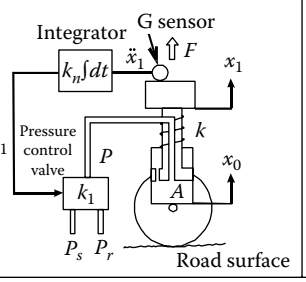
$$f = -\left(A - A_r\right)p, \tag{7.15}$$

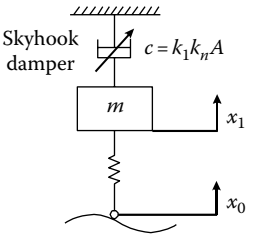
where A_r is sectional space of the rod.

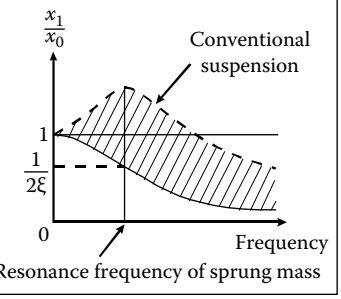












7.4 APPLICATIONS OF ACTUATORS

7.4.1 Vibration Control

In a conventional suspension of an automobile consisted of springs and dampers, it is a well-known fact that higher damping ratio of damper improves the vibration isolation around resonance frequency; however, it worsen the ride quality in high frequency range at the same time.

Active suspension gives a solution to this conflicting problem. Table 7.2 indicates the constitution and the performances of a conventional suspension and an active suspension, and it is shown that vibration isolation can be achieved both in resonance frequency and in high frequency range simultaneously by active suspension. The active suspension is considered to be effective for the vibration up to 30 Hz.

TABLE 7.2
Comparison between Conventional and Active Suspensions

	Structure	Equivalent model	Transfer characteristic
Conventional suspension			
Hydraulic active suspension			

As a control theory of the active suspension, skyhook damping theorem proposed by Karnopp et al. [17] is frequently used; in addition, other control theories such as optimal control theory, *H*-infinity control theory, and sliding mode theory are also applied in order to obtain higher performance.

In commercialized active suspension system, hydraulic actuator and pneumatic actuator are used. Figure 7.10 shows the layout of actuators and sensors for active suspension system with hydraulic system. Hydraulic system is consisted with an oil pump, a reserve tank, accumulators, controlled valve units, and actuators. As for sensing system, a certain number of three-axes accelerometers are located in both sprung mass (car body) and unsprung mass (knuckle, suspension arms, damper tube, etc.), and yaw-rate sensor, stroke sensor, and load cells are also used. Other information such as steering angle and velocity are also used for active control.

The active suspension system is also used for purposes other than vibration control. Attitude control is one of the applications. Roll and pitch motion of an automobile can be controlled by same active suspension units. In addition, vehicle height can be also controlled with same devices, so that the clearance to the ground can be generated. It is efficient especially in rough road.

Disadvantage of the active suspension system is energy consumption. It requires considerable amount of energy. Semi-active suspension is also developed from this point of view, which changes damping characteristics of damper, not generating vertical forces directly. Semi-active suspension also has a merit that control system is rather simple in comparison with active suspension.

7.4.2 Steering Control

Electric Power Steering (abbreviated as EPS, Figure 7.11) system with steering assistance power supplied from an electric motor has been recently developed and mass-produced instead of the conventional hydraulic power steering system, since it has advantages concerning environmental preservation, energy conservation, and expanded degree of freedom of steering system layout

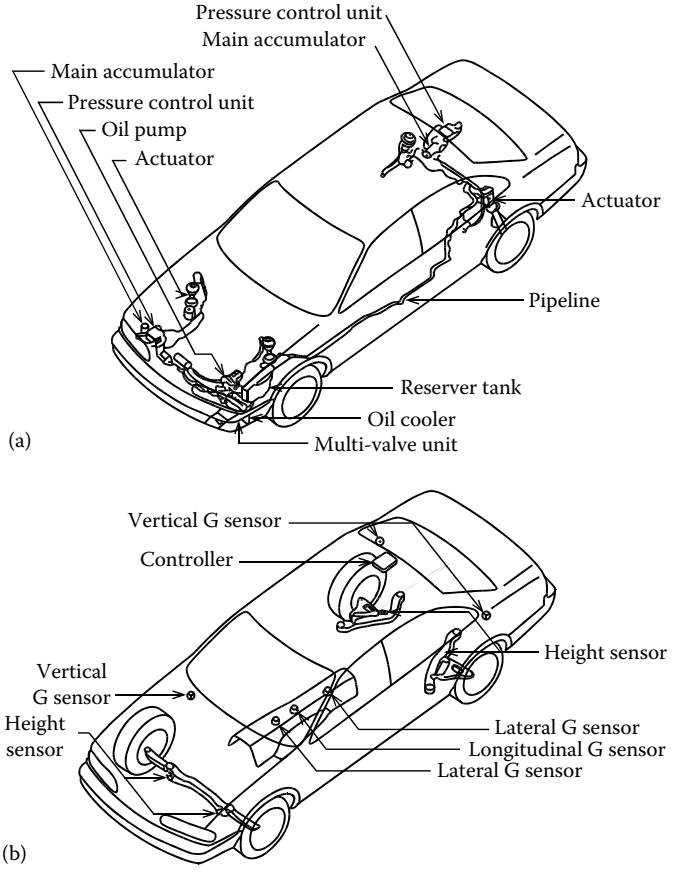


FIGURE 7.10 Layout of (a) actuators and (b) sensors.

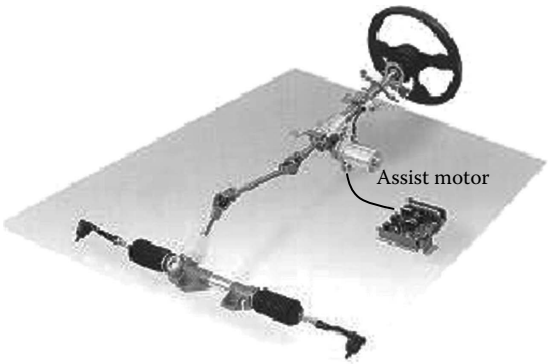

FIGURE 7.11 Column assist type EPS.

without hydraulic pump and pipes. In addition, the reduction of driver workload, and the grasping of vehicle situations and driving conditions by using EPS can contribute to the improvement of driving safety and the comfort in maneuvering [18]. However, a mechanical linkage existing between front tires and steering wheel makes the steering dynamics and vehicle dynamics unable to be designed independently. Therefore, to improve both the vehicle maneuverability and the steering feeling in maneuvering characteristics is very difficult.

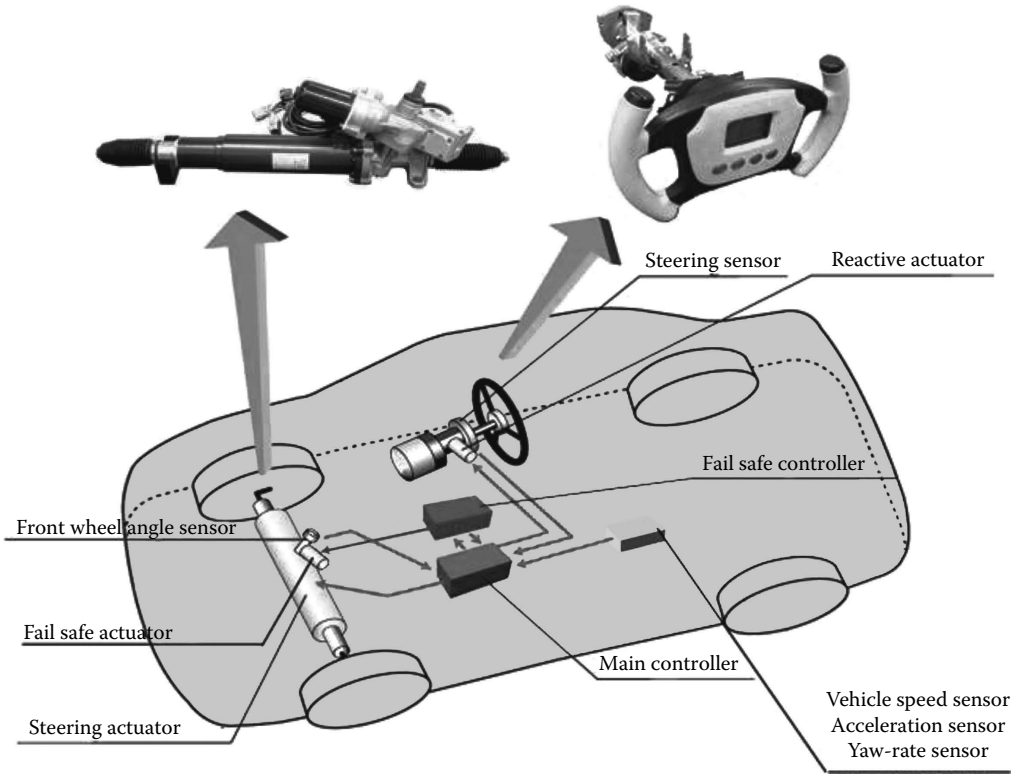

FIGURE 7.12 An example of steer-by-wire system. (From Segawa, M. et al., *JSAE Rev.*, 22, 383, 2001.)

To overcome this problem, SBW system becomes one of the solutions since the mechanical linkage does not exist as shown in Figure 7.12 [19]. Typically, SBW system has several merits as follows: (1) avoiding steering column shaft collision to driver, (2) flexibility of interior layout and steering situation, (3) flexibility of steering configuration design: for example, joystick, wheel, ellipse [19–21]. Moreover, SBW can control steering angle automatically to stabilize vehicle behavior and, can control steering characteristics such as decreasing the physical workload and transmitting the information of vehicle motion and road condition via a steering reaction torque back to the driver, without the mutual interference between the vehicle dynamics and the steering dynamics [22–24]. From the viewpoint of human–machine interface, SBW has structure merits in avoiding interference between the driver and steering wheel since the mechanical linkage between steering wheel and tire is replaced by electric wire system, consisting of sensors, steering actuators, and controllers [19,22].

As shown in Figure 7.12, the vehicle with SBW system consists of a reaction torque actuator for adjusting steering feeling and a front-tire steering actuator for steering the front tires.

7.4.3 Active Front Steering Angle Control System

For enhancing handling and stability of vehicle, the yaw rate and the lateral acceleration of vehicle are controlled to trace the desired value by using SBW system. The controlled variables are yaw rate and lateral acceleration, and the control input is front steering angle. On the other hand, to clarify the effect of the front steering angle controller, the reaction torque for adjusting steering feeling is set to be proportional to the steering wheel angle, with velocity-dependent gain, instead of a complicated vehicle motion feedback reaction torque [19,22].

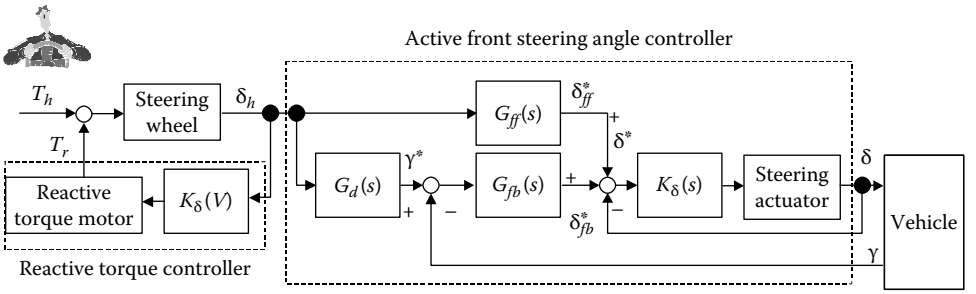

FIGURE 7.13 Block diagram of steer-by-wire control system.

The control system consists of a feedforward compensator, $G_{ff}(s)$ with respect to the steering angle, δ_h, and a feedback compensator, $G_{fb}(s)$ depending on the state deviation as shown in Figure 7.13 [22].

The desired yaw-rate model is determined to be the yaw-rate response of the zero-sideslip 4WS vehicle. To realize this characteristic, the relationship between steering wheel and front steering angle must be dependent on vehicle velocity. Moreover, to enhance stability against disturbance, steering control algorithm of feedback compensator is proposed by using theory of disturbance observer. The steering control laws of the feedforward compensator and feedback compensator can be expressed, respectively, as follows:

Feedforward compensator:

$$G_{ff}(s) = \frac{\delta^*_{ff}(s)}{\delta_h(s)} = \frac{k_{\gamma d}(V)}{k_\gamma(V)}\left[1 + \frac{\tau_\gamma(V) - \tau_{\gamma d}(V)}{\tau_{\gamma d}(V)s + 1}s\right] \tag{7.16}$$

Feedback compensator:

$$\delta^*_{fb} = \frac{1}{\tau_{fb}s + 1}\left[\frac{\tau_\gamma(V)s + 1}{k_\gamma(V)}\gamma - \delta_h\right] \tag{7.17}$$

where

$k_{\gamma d}$ and $\tau_{\gamma d}$ are the steady-state gain and the time constant of desired yaw-rate response, respectively

V indicates the chassis velocity

From earlier equations, the front steering angle can be expressed as follows:

$$\delta^* = \frac{k_{\gamma d}(V)}{k_\gamma(V)}\left[1 + \frac{\tau_\gamma(V) - \tau_{\gamma d}(V)}{\tau_{\gamma d}(V)s + 1}s\right]\delta_h(s) + \frac{1}{\tau_{fb}s + 1}\left[\frac{\tau_\gamma(V)s + 1}{k_\gamma(V)}\gamma - \delta_h\right]. \tag{7.18}$$

The other system was also proposed the alternative design of SBW control system by utilizing the combination of lateral acceleration and yaw rate, which is called D^* [19], for improving the vehicle stability, and examined the effectiveness of the control system by using experimental vehicle as shown in Figure 7.14.

7.5 SENSORS FOR AUTOMOBILE CONTROL

7.5.1 Sensing

The selection and the use of sensors are important matter for control and experiments. Sensors can translate status and attributes of physical world into values [25]. Appropriate sensors should be selected according to the observation objects, that is, required performance such as accuracy, response characteristics and also required frequency bandwidth. For example, the upper frequency of vehicle maneuver is ∼5 Hz for motion control. Then, the bandwidth of the sensors should be over 8 Hz.

In general, most sensors fall into analog and digital sensors [25]. Output signal from the sensors are gathered, processed, and handled using processors today [26]. Consequently, signal processing techniques are applied, that is, analog digital conversion and filtering [25]. Otherwise, in case of digital signal processing, analog data with sufficient sampling rate should be required to prevent an aliasing problem. An anti-aliasing filter is used in various types of digital signal processing methods. The flow of the sensing process is shown in Figure 7.15.

In the following section of this chapter, characteristics and the principle of sensing in several sensors for vehicle control and experiments are shown from the viewpoint of detecting own vehicle motion and vehicle surrounding condition.

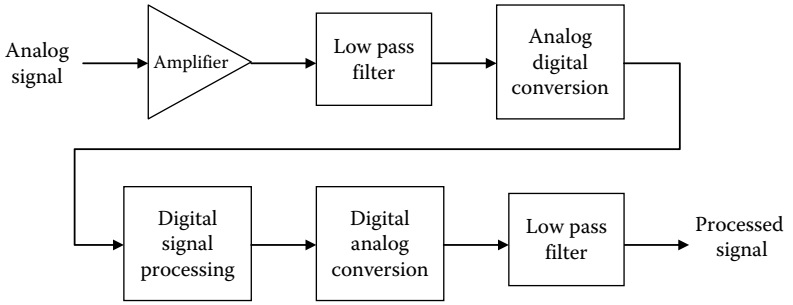

FIGURE 7.15 Sensing process.

7.5.2 Sensors for Detecting Own Vehicle Condition

7.5.2.1 Acceleration Sensor

For the vehicle control such as ABS and active suspension system, the detection of own vehicle condition is necessary. The acceleration sensors are classified to several types by the detecting theory as follows. Piezoelectric-type sensor consists of a PZT (lead zirconium titanate) or quartz as a piezoelectric element, a mass, and a housing. The PZT or quartz is sandwiched in the mass and housing. When it has displacement, the voltage can detect according to the piezoelectric effect. The features of this type sensor are compact, lightweight, and high sensitivity (Figure 7.16).

Strain gauge–type sensor's basic structure is same as the piezoelectric-type sensor. The piezoelectric element can be replaced to the strain gauge. It can measure the static acceleration [27]. If the beam is more rigid by spread the upper limit of measurement frequency, displacement will be reduced and sensitivity will be decreased.

Servo-type sensor has developed for inertial guidance of rockets. In the magnetic field, the moving coil moves according to the acceleration and measures the displacement. Current is sent to keep the displacement zero and that current is in proportional to the acceleration. The bandwidth is from DC to several hundred hertz. Resolution is very precise.

Oscillating-type sensor consists of a mass, which is supported by two strings. When acceleration a is given to the mass m, the tension of the left-side string will increase $\Delta T = ma$ and right-side one will decrease. Both strings are self-induced, vibrated, and mixing measured output frequency and natural frequency. Beat frequency is measured as the following formula:

$$f = \frac{1}{dL}\left(\sqrt{\frac{T+\Delta T}{\rho}} - \sqrt{\frac{T-\Delta T}{\rho}}\right) \tag{7.19}$$

where

dL is length of the string

ρ is the mass per unit length

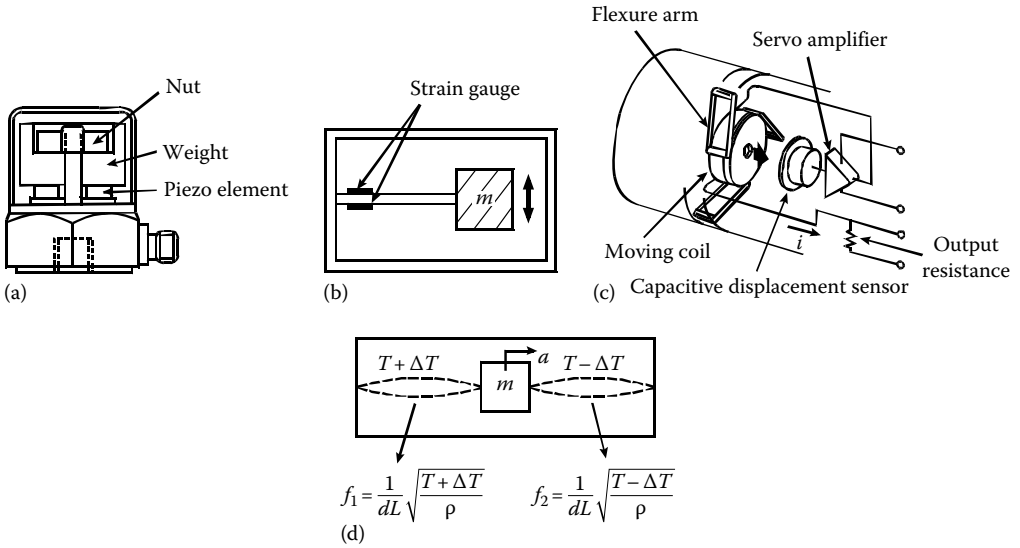

FIGURE 7.16 Acceleration sensors. (a) Piezoelectric-type sensor, (b) strain gauge–type sensor, (c) servo-type sensor, (d) oscillating-type sensor.

7.5.2.2 Yaw-Rate Sensor

For the VSC system, it is required to detect yaw motion of the vehicle, as well as the lateral and longitudinal acceleration and wheel rotating speed. The yaw-rate sensor has various methods, that is, gyro type, optical type, gas rate type, and so on [27]. One of the commonly utilized types is the vibrating structure type gyro, which is known as an inexpensive, small, and durable device. Figure 7.17 shows the basic principle of the vibrating structure type gyro. The arm inside the sensor is vibrated by a small sensor like a piezoelectric actuator. The vibrating object tends to keep vibrating in the same plane, when the sensor is rotated; therefore, the force on the object is produced according to the Coriolis effect. The sensor output voltage is in proportion to the force; therefore, it is possible to detect yaw rate by measuring the Coriolis force [27].

For the other type of gyro sensor, the ring laser gyro and optical fiber gyro are used. This type has higher performance in the stability and accuracy.

7.5.2.3 Force and Torque Sensor

For vehicle control and experiments, the measurements of force and torque are important. In the force sensor, there is a way of conversion to force from the elastic deformation, the amount of the electromagnetism, etc. [25]. Therefore, the force sensor is widely used as a basic element of other physical amount sensors like weight, pressure, and so on. The wheel force dynamometers can be used on test vehicles, servo-hydraulic and roller test stand. The piezoelectric-type sensor is used for a force sensor. It produces electric charges by the force applied. The piezoelectric elements are layered to detect the different directional forces and moments separately [28].

Steering torque is detected by the torsion angle of the torsion bar, which is located on the steering shaft differential transmission, and potentiometer and variable inductance methods are proposed [25].

7.5.3 Sensors for Detecting Vehicle Environment

7.5.3.1 Millimeter-Wave Radar

Laser radar has been in the market since 1995; however, it was not so robust in the rain condition. Radio wave radar has been developed to solve this problem, although it has problems about downsizing and reliability. The millimeter-wave radar measures a distance, a relative velocity, and direction between the sensor and the object.

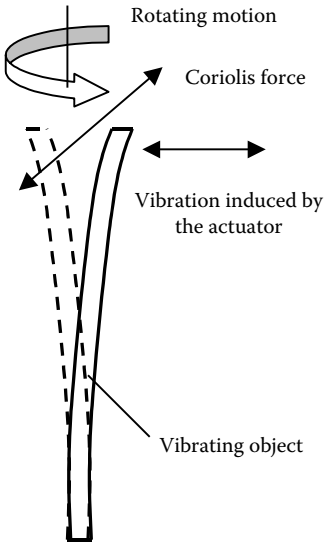

FIGURE 7.17 Principle of a vibrating structure type gyro.

The radar device consists of an antenna, a module, and a signal processing unit. The radar beam is generated and transmitted by the radio frequency (RF) module and the antenna. Frequency modulation (FM), pulse Doppler modulation, frequency-modulated continuous wave (FM-CW), spread spectrum radar wave system were used. The signal processing unit measures the delay of the transmitted and received wave. It also uses the FFT processing to find the beat frequency. To detect the direction of the object, the radar beam is scanned mechanically and electrically.

7.5.3.2 Laser Radar

Laser radar consists of a laser diode, a polygon mirror that is to scan the laser beam, and a photodiode which is to detect the reflect laser beam from the object and a CPU. It measures the flight time of the laser beam reflected from another vehicle's reflector. The CPU calculates the relative distance, velocity and estimates whether the vehicle is on the same lane or not. The rotation of the polygon mirror and pan-tilt angles is controlled by the DC motor.

7.5.3.3 Sonar

Sonar sensor uses ultrasonic wave to measure the distance. When transmitting the ultrasonic wave from the sensor, if there is some object, the sensor can receive the reflected wave. The distance is calculated by the flight time of the ultrasonic wave. The sensor consists of a ultrasonic microphone which has piezoelectric element and an amplifier. To transmit the ultrasonic wave, ultrasonic frequency AC voltage is sent to the microphone. The microphone vibrates according to the frequency of AC input. When the microphone receives the reflected wave, microphone generates the voltage according to the frequency of ultrasonic wave. The microphone uses as both transmitter and receiver.

7.5.3.4 Vision Sensor

Vision system consists of a camera and an image processor. Charge-coupled device (CCD) or complementary metal oxide semiconductor (CMOS) camera is used [25]. To realize the real-time processing, high-performance image processor is used. High frame rate, 25 fps or more, is required.

It is used to detect the feature object, for example, lane marking, signboard and human shape for lane curvature prediction, collision avoidance, and so on [29]. However, it is difficult to use in poor light and bad weather condition. Then, the robust algorism development is the most important issue. It makes an attempt to use with the range finder and develop a sensor fusion system.

ACKNOWLEDGMENTS

Prof. Shigeyuki Nakadai (Chiba Institute of Technology), Prof. Taichi Shiiba (Meiji University), Prof. Kimihiko Nakano (The University of Tokyo), Prof. Motoki Shino (The University of Tokyo), Prof. Yohei Michitsuji (Tokyo University for Agriculture and Technology), Prof. Yoshiyuki Takahashi (Toyo University), and Dr. Shoichiro Takehara (The University of Tokyo) gave a lot of help for this chapter. The author would like to thank them for their great help.

8.1 INTRODUCTION

The design process is and will always be based on the designer intuition. However, optimization techniques can permit significant improvement in the process itself. The designer activity undergoes iterations between an analysis stage, in which the relationships between parameters, performance indices, and design constraints are assessed, and a synthesis stage, in which the possible and desired performances are obtained by a proper parameter setting. The inherently iterative nature of the design process makes it particularly difficult to keep it under control.

The application of optimization in automotive engineering is increasing as more powerful computers become available. Today, calculations can be performed in a fraction of the time it took a few years ago. Therefore, the applications for numerical optimization have increased.

It is assumed in the following that an accurate (validated) mathematical model of the system under optimization is available. Successful optimization requires availability of appropriate

analysis models and knowledge of the capabilities and limitations of the mathematical optimization techniques [6,79,88,95].

In real-world applications, problems with a single, well-defined objective function tend to be the exception rather than the rule. In engineering, most optimization problems are multi-objective in their nature. In a problem with multiple objectives, it is generally impossible to obtain a ranking of all of the alternative solutions, without using further rules or assumptions. In this situation, the decision of the better solution may become subjective, or must rely on additional information, such as the importance of each objective. The most common and rigorous approach to overcome this limitation is to define the efficient solutions set [9,43,81]. If possible, the designer has to identify hierarchical levels in the complex system under study so the system can be divided into subsystems that can be further subdivided. Analytical target cascading (ATC) is a methodology for optimal design of hierarchical multilevel systems where outputs of lower-level elements are the inputs to higher-level elements [67,70,97]. In any case, optimization of complex systems may require a prohibitive simulation effort, even with the most efficient techniques. In this case, the relationship between design variables and objective functions is expressed by means of a global approximation approach. The physical model is substituted by another purely mathematical model, which is able to give computational results very quickly [33,49,82]. The inclusion of uncertainty in the problem formulations is a relatively recent development in optimization [8,10,34,36,113]. The approach allows the designer to minimize the objective function while accounting for the influence of stochastic variations of some parameters and/or variables. Typically, this involves trading (deterministic) optimality for robustness, whether in the value of the objective (robust design) or in the satisfaction of the constraints (reliable design). After the optimal solutions have been computed [12,49,81,105], the designer can make a choice and select from this set the preferred solution featuring the desired compromise among objective functions [22].

A brief outline of optimal design methods generally used for vehicle design problems is given later. Some examples of design optimizations will be given in the field of vehicle system dynamics, active safety and ride comfort, vehicle system design and lightweight structures, and advanced automotive electronics [9,27,31,43,67,83,100].

8.2 BASICS

In this section, some basic concepts of optimization theory are reviewed. The interested reader may refer to [6,79,88,95,96] for an in-depth documentation on these topics. It is assumed that an accurate (validated) mathematical model of the system under optimization is available.

8.2.1 Formulation of the Optimization Problem

The majority of engineering problems involve a constrained optimization formulation, that is, the task of minimizing (or maximizing) a vector of k objective functions (performance indices) subject to different types of constraints. Objective functions and constraints must be quantifiably expressed as functions (f, g) of the design variables x.

Find

$$\begin{aligned} &\min_{x\in R^n} f(x) \\ &h_j(x) = 0, \quad j = 1, \ldots, m_1 \\ &g_j(x) \le 0, \quad j = 1, \ldots, m_2 \\ &x \in X \end{aligned} \tag{8.1}$$

where

f is the objective function vector
x is the vector of the design variables
X is the definition domain of x
h_j and g_j are equality and inequality constraints, respectively

The set X can represent certain ranges of real values or certain types, such as integer or "standard" values, which are very often used in design specifications [88,95]. Should a maximization problem occur (i.e., max $f(x)$), the vector function $f(x)$ could be rewritten as $-f(x)$ or $1/f(x)$ and formulation 8.1 could be still used [6].

The most common and rigorous approach to solve a multi-objective optimization problem is to define *efficient solutions* (and then select) as those (and only those) solutions that improve at least one objective function and worsen at least one of the others. Under this assumption, the set of efficient solutions constitutes the pareto-optimal set [72,75,79]. The disadvantage of this approach is that generating pareto-optimal sets is generally computationally expensive.

The pareto-optimal set is the set of the non-dominated solutions, that is, the thick line in Figure 8.1 for a problem with two design variables and two objective functions. In this case, the set still represents a trade-off between the two objectives f_1 and f_2. Each point in the rectangle on the plane $x_1 - x_2$ (design variables domain) corresponds to a point in the manifold on the plane $f_1 - f_2$ (objective functions domain). The rectangular manifold on the plane $x_1 - x_2$ is transformed into the manifold on the plane $f_1 - f_2$ by the function $f(x_1, x_2)$. As all the possible combinations of design variables x_1 and x_2 have been used to generate $f_1(x_1, x_2)$, $f_2(x_1, x_2)$ (if the solution is compatible with the design constraints). Referring to Figure 8.1, point A is said to be dominated by B and C, that is, B and C dominate A. A is also dominated by all the design solutions between B and C on the bold line, that is, the solutions on the bold line between B and C are better at least in one objective function than A. Given a (wrong) solution A, there exist solutions that are better than A at least in one objective function. All the solutions corresponding to points in Figure 8.1, which do not lie on the pareto-optimal set, shown as bold line in Figure 8.1, have to be discarded by the designer. The pareto-optimal set for a biobjective problem is limited by the minima for the two scalar objective functions f_1 and f_2.

The pareto-optimal solutions are defined mathematically as follows. Given the minimization problem (8.1) with k objective functions and n design variables, a solution x_i is pareto-optimal, if there is no solution x_j such that

$$\begin{cases} f_m(x_j) \le f_m(x_i) \quad m = 1, 2, 3, \ldots, k \\ \exists l: f_l(x_j) < f_l(x_i) \end{cases} \tag{8.2}$$

This definition can be used to find the pareto-optimal solutions directly (pareto filtering, see Table 8.1) [81].

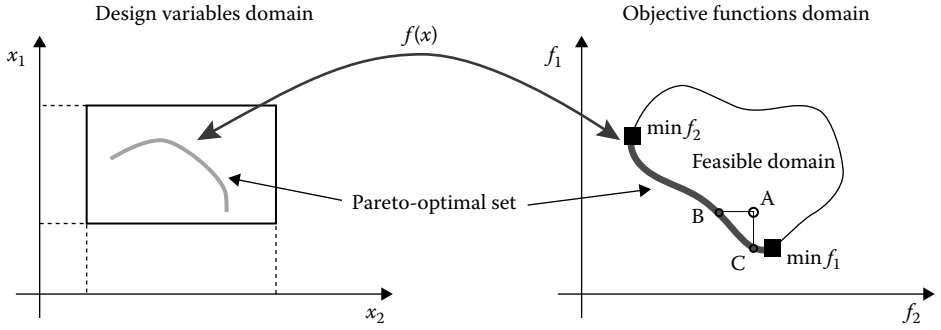

FIGURE 8.1 Multi-objective optimization problem with two design variables x_1, x_2 and two objective functions f_1, f_2. Feasible set and pareto-optimal set in the design variables and objective functions domains.

TABLE 8.1
Overview of Multi-Objective Optimization Methods

Scalarization Methods	Pareto Methods
Weighted sum (linear and nonlinear)	Pareto filtering
Constraints method	Adaptive weighted sum method
Multi-attribute utility analysis	Normal boundary intersection
Goal programming	Multi-objective evolutionary algorithms

Several methods exist for converting the multi-objective formulation into one with a scalar objective function that can be solved with the usual single-objective optimization methods, typically using some sort of weighting function. The shortcoming of such scalarization is that the designer must include subjective information and preferences a priori. Additionally, some optimal solutions can be unattainable for non-convex problems (see [88,95]).

Table 8.1 provides a list of multi-objective optimization methods. An overview of these methods can be found in [19,79]. Some scalarization methods can also be used to generate the pareto-optimal set [20].

The multi-objective optimization problem (Equation 8.1) can be reformulated ("weighted sum method") as a single-objective problem where the weighted sum of the objective functions has to be minimized. By changing the weight settings, different pareto-optimal points can be generated. This approach is usable only if the pareto-optimal set is convex.

By applying the "constraints method," the multi-objective optimization problem (Equation 8.1) with k objective functions can be converted into a single-objective problem by minimizing one objective function and adding inequality constraints (upper bounds) to the remaining $(k - 1)$ objective functions.

8.2.2 Solution Methods

The problem in Equation 8.1 is formally a mathematical programming problem [6,88,95,96]. The functions f and g in Equation 8.1 can be expressed with algebraic equations or computer simulations. If the functions f and g are all linear, the problem is a linear programming one. Otherwise, the problem is a nonlinear programming one. Discrete programming refers to problems where all the design variables have only discrete values. A large class of design problem comprises mixed-discrete/continuous design variables values [96]. This type of problems is usually a challenge for the standard methods of nonlinear programming. In Table 8.2, some of the methods for solving optimization problems are presented and compared [77,79]. This topic is further discussed in the following subsections.

TABLE 8.2
Methods for Solving Optimization Problems

Method	Type	Efficiency	Accuracy		Discrete Design Variables
Exhaustive	Nonderivative	– –	++ (Discrete variables)	– (Continuous variables)	Yes
Uniformly distributed sequences	Nonderivative	–		–	Yes
Evolutionary strategies	Nonderivative	+		+	Yes
Sequential quadratic programming	Derivative	+ +		+	No

Note: – –, very bad; –, poor; +, good; + +, very good.

8.2.2.1 Nonlinear Programming

Nonlinear programming algorithms have been extensively studied in the literature.

These algorithms are able to solve single-objective optimizations by means of an iterative procedure starting from an initial guess.

On the basis of the order of the method, three main classes can be considered:

- *Zero-order methods*: The new solution is computed without using any information about the first derivatives. Among the others, there are the random walk, the pattern search, and the simplex method [96].
- *First-order methods*: The iteration step is computed by using the gradient that identifies the steepest descent direction. In this way, a reduction in the objective function is guaranteed at each step. The steepest descent method and the conjugate gradient method [95] belong to this class.
- *Second-order methods*: The curvature (Hessian matrix) is used along with the gradient. These methods are also known as Newton's methods [6].

The zero-order methods may be useful when the functions are not differentiable. In the other cases, gradient-based methods are widely used as the Hessian computation might be too demanding. By numerical differentiation (finite differences), the computational cost needed to estimate the gradient and the Hessian matrix is proportional to n and n^2, respectively, for a function of n variables. For this reason, the quasi-Newton methods have been developed, where the Hessian matrix is estimated by means of the function values and the gradient values.

8.2.2.2 Search Based on Uniformly Distributed Sequences

Within the large set of methods to find optimal solutions, the *exhaustive search method* [81] is the simplest, but it requires a huge amount of computational effort. Orthogonal arrays and low discrepancy sequences are used to reduce as much as possible the number of combinations of design variables used to explore the design variable domain [109]. In multi-dimensional spaces (more than 3 and up to 30 or 40), a low discrepancy sequence can be used to define a set of design variables combinations to be exploited to sample the objective functions domain. Low discrepancy sequences differ from pseudo-random sequences in that the points are more evenly distributed in the feasible space (see [81,109] for a detailed description of this topic).

8.2.2.3 Evolutionary Algorithms

Evolutionary strategies are a class of non-gradient methods, which has grown in popularity since Holland first published his book on the subject [53]. Two types of evolutionary algorithms are considered here, namely, genetic algorithms (GAs) and simulated annealing (SA).

GAs are suitable for finding the minimum of a function (or of a set of functions) by performing a semi-stochastic search [12,17,46,53,99,105]. The design variable vector referring to a particular design solution is typically encoded into binary or real strings (chromosomes). GAs are based on an elitist reproduction strategy, where the strongest members of the population (design solutions) are selected for reproduction and are given the opportunity to strengthen the chromosomal (i.e., genes, namely, design variables) makeup of the next generation. Unlike many other search techniques, GAs consider multiple design solutions (a population) at each iteration.

Some comments on GAs are as follows:

- GAs work on function evaluations alone and do not require function derivatives.
- GAs proceed from several points in the design variable domain (population); consequently, the method has a better probability of locating the global minimum.
- GAs allow design variable spaces consisting of a mix of continuous and discrete variables.

- GAs use probabilistic transition rules, not deterministic rules.
- GAs can be easily implemented on parallel computers.
- Computational costs are high, and good performance often requires tuning of the algorithm for the specific problem at hand.

A ranking method can be easily included to grade the population in terms of pareto-optimality and construct a procedure able to identify the entire pareto-optimal set and not, as it occurs for standard algorithms, one single pareto-optimal solution for each run [12,18,46,105].

SA is a heuristic search method for obtaining good solutions to difficult optimization problem. Kirkpatrick and colleagues [65,96] showed how a model of simulating the annealing process in solids as proposed by Metropolis could be used for optimization problems.

Metropolis et al. [80] introduced a simple algorithm to simulate annealing process by considering a collection of atoms at a given temperature (T). To apply Metropolis algorithm for other than thermodynamic process, one must provide the following:

1. A description of possible system configurations
2. A generation of the random changes in the configurations
3. An objective function, whose minimization is the goal
4. A control parameter T and an annealing schedule

There has been some work done in multi-objective SA where the non-dominated solutions found during search are stored during the annealing process [107].

8.2.2.4 Global Approximation

Complex system design requires extensive use of simulation-based design and analysis tools, such as multibody dynamics simulations (MBD), finite element analysis (FEA), computational fluid dynamics (CFD), and other computationally intensive models. The need to quantify the engineering performance of complex products, such as automobiles, leads to computationally expensive models due to fidelity of modeling and to the obvious need for accurate results. Moreover, computer simulation codes can be discipline-specific, distributed, on different computer platforms. Sometimes, computationally expensive computer simulations and/or analyses are replaced by surrogate models, which are fast, simple approximations. To approximate functions, a vast series of techniques exist that go from a simple polynomial interpolation to very more accurate methods of representing function behavior, such as radial basis neural networks or Kriging models [97].

Optimization may require a prohibitive simulation effort, even with the most efficient techniques. In this case, the relationship between design variables and objective functions can be *globally approximated* by means of a simpler, approximate mathematical model (e.g., an artificial neural network or a piecewise quadratic function or other approximation). This approximate or surrogate model or pure numerical model is defined on the basis of a limited number of simulations (i.e., computational experiments) performed by means of the originally validated physical model of the system under consideration.

Typically, the simulation time for the pure numerical model is a small fraction (1/10 to 1/10,000) of the simulation time needed by the original model [82,85].

The accuracy in the approximation of the outputs depends on the approximation model employed and the computational effort expended to build the model. The first attempts using neural networks for global approximation were reported in [49]. A comparison of different approximation methods is given in [33] and some results are shown in Table 8.3.

8.2.2.5 Optimal Design of Multilevel Systems

Every system is analyzed at the level of complexity that corresponds to the interest of the designer. For this reason, we can identify hierarchical levels in the system definition; the system can be divided into subsystems that can be further subdivided.

TABLE 8.3
Approximation Methods

		Evaluation Accuracy		
	Approximation Domain	**Simple Model**	**Complex Model**	**Tuning Effort**
Linear interpolation	Local	+	−	+ +
Quadratic interpolation	Local	+	−	+ +
Neural networks (multilayer Perceptron)	Global	+ +	+ +	−
Statistical approximation (Kriging)	Global	+ +	+	−

Note: −, bad; +, good; + +, very good.

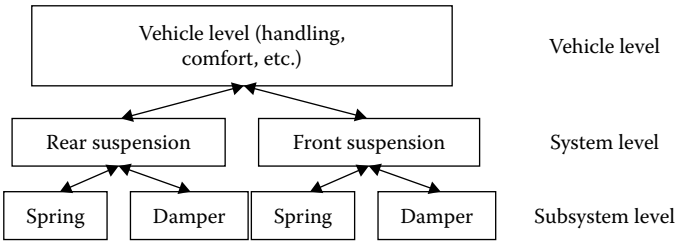

FIGURE 8.2 Example of hierarchical multilevel system decomposition.

ATC is a methodology for optimal design of hierarchical multilevel systems where outputs of lower-level elements are the inputs to higher-level elements (see Figure 8.2).

The objective is to identify the element interactions early in the design process, and to determine specifications that yield consistent system design with minimized deviation from design targets. The process formulates and solves a minimum deviation optimization problem for each element of the multilevel system. By solving the element optimization problems sequentially in an iterative manner, ATC aims at minimizing discrepancies between the optimal design variable values desired at elements higher in the hierarchy and response values that elements at lower levels can actually deliver [64,68,86,87,95]. In addition, if design variables are shared among some elements at the same level, their required common final optimal value is coordinated by their parent element at the level above.

8.2.2.6 Comparison of the Different Solution Methods

There is no unique answer to which optimization method is the best. Many studies have shown that different methods show the best performance, depending on the problem and on how much effort has been spent to tune the method itself (the procedure itself needs to be optimized).

Search based on uniformly distributed sequences can be computationally very expensive, but no parameters relative to the algorithm itself need to be tuned. GAs are robust and they can handle multimodal functions, but several parameters (population size, mutation, crossover probability, etc.) need to be tuned to get adequate convergence properties. SA is a robust method slightly less computational expensive than GA.

Standard nonlinear programming methods show very fast convergence rate and they are very easy to be tuned, but they are not as robust (i.e., get stuck in local optima) as the other methods. Moreover, they can just find one optimal solution for each run. Moreover, the solution of engineering

problems often requires a mixture of numerical simulations, analytical calculations, and selection of catalog components. Therefore, non-gradient optimization methods (i.e., search based on uniformly distributed sequences, GA, SA) are better suited for these types of problems, being impossible the calculation of the derivatives of the objectives function.

8.2.3 Reliability-Based Design Optimization

Because deterministic optimum designs obtained without taking uncertainty into account could lead to unreliable designs, a reliability-based approach to design optimization is preferable. Recently, many authors have introduced procedures that combine design optimization techniques with reliability-based design methods [3,8,41,45,69,74,103,104,113,114]. The approach allows the designer to minimize the objective function while accounting for the influence of stochastic variations of some parameters and/or variables. Typically, this involves trading (deterministic) optimality for robustness, whether in the value of the objective (robust design) or in the satisfaction of the constraints (reliable design).

In the presence of random variables and parameters, responses, such as objective and constraint value calculations, are themselves random variables, whose expected values and/or variances must be computed when solving probabilistic optimization problems. Evaluation of probability distributions of responses can be achieved using Monte Carlo simulation, but this is a very expensive process. Thus, various approximation schemes must be used in practical situations.

A mean-value first-order second-moment approach (first-order Taylor expansion about the current design) can be adopted to estimate the mean and standard deviation of the objective functions [45]. When a trained artificial neural network is used to compute model responses, an accurate estimate of the variance of the objective functions can be obtained with no additional computational cost [34,45].

Uncertainty can also come from considering market behavior when launching new products. For example, developing a new vehicle design in a dual-use context (commercial enterprise and government military uses) is affected by uncertainty in market penetration and cannibalization [14].

8.2.4 Analysis of the Pareto-Optimal Set

After the optimal solutions have been computed (pareto-optimal set), the designer can make a choice and select from this set the preferred solution featuring the desired compromise among objective functions.

This process can be preceded and even accelerated by special analyses allowing the designer to have an insight into the physical phenomena he is trying to analyze. In other words, there are some analyses by which the designer may understand the reason why the considered optimal solution requires such a design variable combination. In particular, these analyses may show which is

- Relationship between two objective functions (within the pareto-optimal set)
- Relationship between design variables (within the pareto-optimal set)
- Relationship between design variables and objective functions (within the pareto-optimal set)

These different relationships are shown in Figure 8.3.

The Spearman rank-order correlation coefficient [43,79,92] can be used to assess the earlier introduced relationships. This rank-order correlation coefficient has proved to be robust in presence of nonlinearity or outlayers.

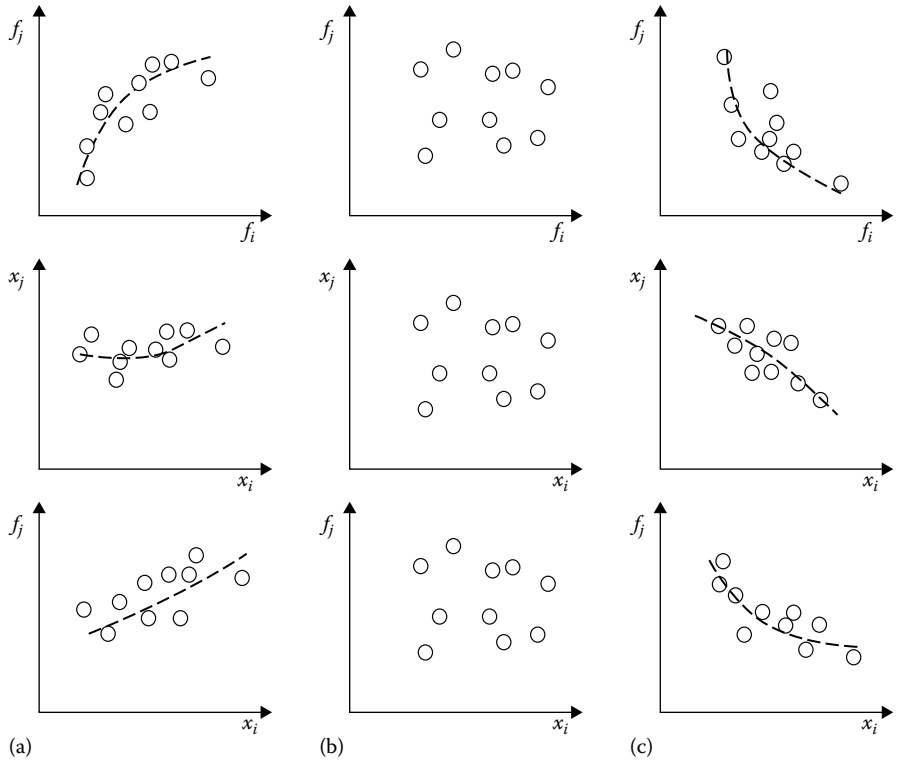

FIGURE 8.3 Relationship between pareto-optimal objective functions ($f_i - f_j$), between pareto-optimal design variables ($x_i - x_j$), and between objective functions and design variables ($f_i - x_i$). The values can be either directly correlated (column a), uncorrelated (column b), or indirectly correlated (column c).

8.2.5 Available Commercial Software for Engineering Design Optimization

A list of commercial software suitable for solving design optimization problems related to vehicles is given as follows.

The list is by no means exhaustive. The aim is instead to give to the reader an idea of the wide set of software solutions available on the market nowadays:

- ADAMS/Insight [59] is the optimization tool designed for use within the ADAMS multibody dynamics simulation environment. The software can use design of experiment techniques in order to define a global approximation of the objective functions (polynomial fit). The optimizer includes standard nonlinear programming algorithms and allows a multiobjective formulation of the design problem. Some analysis tools can be employed to identify the design variables that most affect the system design.
- FRONTIER [55] has a strong emphasis on multi-objective formulations. A design of experiments module can be used in the preliminary design phase (factorial, Sobol, etc.). Linear and nonlinear response surfaces for data modeling and approximation can be used (polynomial fitting, neural networks, etc.). A reliability-based design optimization tool is included.
- GENESIS [61] is a structural analysis and optimization software. It integrates various FEA and optimization capabilities (sizing, shape, topography, topometry, topology, etc.). It can also be used as a more general-purpose optimizer.
- iSIGHT [62] is a general-purpose optimization tool with a large number of alternative algorithms for optimization and building surrogate model functions. It includes ability to solve mixed-discrete problems and to generate pareto sets. It can also be used to perform probabilistic optimization.

- MATLAB® Optimization Toolbox [58] is a general-purpose collection of functions for optimization. The toolbox includes nonlinear programming, and multi-objective minimization algorithms (goal attainment, etc.). The tool can be integrated with different Toolboxes useful in building surrogate model functions. GA and Direct Search Toolbox extend the optimization capabilities with tools for using GA, SA, and direct search.
- NEXUS [57] is a general-purpose multidisciplinary and multi-objective optimization tool. The software can solve nonlinear, constrained, and unconstrained as well as mixed-discrete problems. A modular plug-in architecture extends its basic capabilities. Specific modules implement Design of Experiments and Response Surfaces methodologies. Standard nonlinear programming, direct search and evolutionary algorithms for single- and multi-objective optimizations are available.
- OPTIMUS [60] is a general-purpose optimization tool. The software can explore the design space using design of experiments; it includes several standard nonlinear programming algorithms and state-of-the-art evolutionary algorithms. Special algorithms are available for solving problems including a mixture of continuous and discrete variables. Multi-objective solution methods are implemented. A reliability-based design optimization tool is included.
- OPTISTRUCT [56] is a finite element–based software for both structural analysis and design optimization. The integrated state-of-the-art gradient-based optimization methods allow component size and shape optimization (sizing, shape, topography, topology, etc.). OptiStruct includes morphing technology to prepare finite element meshes for optimization. Size optimization defines ideal component parameters such as material type, cross-section dimensions, and thicknesses. Design of experiments capabilities and stochastic studies are included in the HyperStudy tool, which can be directly interfaced to OptiStruct.
- VisualDOC [61] is a general-purpose optimization tool. The software can perform linear, nonlinear, constrained, and unconstrained as well as integer, discrete, and mixed-discrete optimization. Gradient-based, non-gradient–based, and response surface approximate optimization algorithms are available. In addition, a design of experiments module and probabilistic analysis and design capabilities are included.

8.3 OPTIMAL DESIGN OF ROAD VEHICLES AND SUBSYSTEMS

The following state-of-the-art review is adapted from [32] and is reported here in an updated and extended form.

8.3.1 Vehicle System Dynamic Behavior

The first attempts to design optimally the suspension system of a road vehicle appeared in [16,52,54,63,76,89,102,111]. Some basic studies on the optimization of the ride comfort and active safety of road vehicles are presented in [37,39,40,90]. Both passively and actively suspended vehicles have been considered. Simple analytical formulae for the estimation of vehicle dynamic behavior are derived, and these formulae are used in conjunction with multi-objective programming (MOP) to find the optimal suspension design variables symbolically, ensuring the best compromise among comfort, road holding, and working space. In [36,37], the design variables, that is, suspension stiffness and damping, are considered as stochastic variables and the vehicle body mass and tire radial stiffness as stochastic parameters, in order to derive the optimal trade-off solutions in a optimal and robust framework.

Referring to the tuning of gains of an actively suspended vehicle, analytical formulae seem to have been derived only for simple system models (results reported in [2,40,54,110], establishing the

well-known "skyhook" control strategy). A basic study on the optimization of the handling behavior and active safety of road vehicles is presented in [83]. The work demonstrates how the front and rear tire cornering stiffness of a vehicle can be tuned in order to obtain a preferred compromise among the many conflicting performance indices that describe the handling behavior and active safety. Similar studies in optimizing vehicle handling behavior over a range of maneuvers but involving a much greater number of design variables are reported in [35,43,78,84,98,100,101,108]. In order to design a car effectively, one is often required to tune the entire set of design variables related to tires, aerodynamics, and chassis characteristics (stiffness, damping, and kinematics of the suspension system). Such tuning presents good opportunities for effective use of optimization methods [45].

8.3.2 Power-Train Design

Hybrid-electric propulsion systems have been optimized with respect to fuel economy, ride, and mobility targets in [67] by applying a target cascading approach.

A method for combined design optimization and power management of a hybrid propulsion system integrated within a complete vehicle system was proposed in [28]. A sequential quadratic programming (SQP) algorithm with a design space exploration–based multi-start technique was used to enhance the chances of achieving the global optimum.

The design of the synchronizer and selector mechanism of a vehicle gearbox is discussed in [41,42]. The main aim there is to improve shifting ability during a reference shift action. Fifty-eight variables of the system model were thus tuned. The approach proposed in [41] addresses both the optimization of nine system performance indices and the reduction of the sensitivity (variance) of the performance indices to stochastic perturbations. The variances are computed by means of a procedure based on the global approximation of the objective functions.

The use of ATC in vehicle transmission design was reported in [7]. ATC was applied to the simulation-based design of a CVT implemented in a mid-sized truck. The overall system was decomposed into three levels. The study highlighted two main issues. First, the development of the coordination strategy and appropriate models appeared to be an intricate task that benefits from extensive knowledge of the overall problem. Second, the values of the arbitrary weights defined at all levels had a significant impact on the results and of ATC as a practical and suitable approach.

8.3.3 Internal Combustion Engine Design

A probabilistic formulation of the ATC process has been used in [10,70] to solve an internal combustion engine design problem. An engine is considered at the top level system, which is then decomposed into subsystems representing the piston-ring/cylinder-liner subassembly of the cylinders. The system model predicts engine performance in terms of brake-specific fuel consumption. The ring/liner subassembly simulation takes as inputs the surface roughness of the ring and the liner (assumed to be normally distributed) and the Young's modulus and hardness and computes power loss due to friction. The engine simulation takes then as input the power loss and computes brake-specific fuel consumption of the engine.

An analysis of an optimized approach for designing engine mounts is given in [1]. GAs and SQP have been used for selecting the combination of parameters that can yield the deepest notch and shortest resonance peak in the dynamic stiffness of the fluid mounts.

The link between manufacturing process and product performance is studied in order to construct quantifiable criteria for the introduction of new engine technologies and processes in [73]. Cost associated with a new process must be balanced against increases in engine performance. A predictive engine simulation model is used to quantify performance gains due to the new surface finish obtained by means of abrasive flow machining for finishing the inner surfaces of intake manifolds for two engines. Subsequently, economic cost-benefit analysis is used to evaluate manufacturing decisions based on their impact on the firm's profitability.

8.3.4 Safety and Ride Comfort

In [5], GAs are used for determining the active control and passive mechanical parameters of a vehicle suspension system in order to minimize the vertical acceleration subject to constraints on road holding and suspension working space. In [31], a MOP approach using GAs is employed for the design of a multi-link suspension, based on performance indices related to vehicle handling and stability.

In [84], a procedure is presented for the integrated design (tuning) of tires and suspensions of a racing car. Proper objective functions are defined after a subjective–objective correlation analysis. Different driving situations (steady state, J-turn, lane change, power on–off while steering, braking on a bend, passing over a kerb while steering) are optimized with respect to 18 design variables related to the suspension system and the tire characteristics. A global approximation model was used together with a search method based on low discrepancy sequences. The same approach has been followed in [24,35,98,101] for the problem of the chassis design of a production car. In [43], the computation of the pareto-optimal set is performed, for a similar chassis design problem by using GAs. In [45], a method for the reliability-based multi-objective design optimization of tires and suspensions of a racing car is introduced and applied. The optimization has been performed on the basis of a global approximation procedure.

In [47], through the use of an optimization algorithm with finite-difference sensitivities, the suspension characteristics have been optimized. The ride optimization is achieved by finding the optimum of a ride index that results from a metric that accounts for the acceleration in several key points in the vehicle properly weighted. The extension by including the optimization of the handling characteristic is given in [48].

The design of heavy vehicles for good dynamic performance in a variety of scenarios or maneuvers (from standard test maneuvers to extreme emergency maneuvers) is discussed in [9]. The problem is formulated as a multi-criteria, multi-scenario design problem with the goal of finding an optimal vehicle design, which can improve the vehicle dynamic performance in all the considered scenarios simultaneously (lane change, pulse steer, and ramp steer, induced rollover). A modified Monte Carlo optimization technique is used to find the optimal designs.

A robust design approach for improving vehicle crashworthiness was applied using the Monte Carlo simulation method on a global response surface in [50].

In [103], a methodology for reliability-based multi-objective design optimization of automotive body components under impact scenarios is introduced. The approach is applied to minimize the structural mass while maximizing energy absorption of an automotive rail section under structural and occupant safety constraints.

In [66], the focus is on design optimization for safety and NVH. The set of vehicle system design variables is tuned in order to minimize the vehicle weight while satisfying constraints on the static torsion and bending displacements and limiting the injury criteria during frontal crash and side impact.

ATC has been used to optimize ride quality and handling performances by considering suspension, tire, and spring analysis models in [64,68,69]. Potential incompatibilities among targets and constraints throughout the entire system can be uncovered and the trade-offs involved in achieving system targets under different design scenarios can be quantified.

The problem of choosing a single solution within a set of pareto-optimal alternatives is addressed in [72]. Two methods, the k-optimality approach and the more general $k\varepsilon$-optimality method, were considered. These two methods theoretically justify and mathematically define the designer tendency to choose solutions that are "in the middle" of the pareto-optimal set. The methods were successfully applied to the optimization of the tire/suspension system of a car.

8.3.5 Vehicle System Design and Lightweight Structures

The optimal layout of structural components is discussed in many papers [38,51,71,75]. The problem of the definition of the layout of the entire vehicle is addressed in recent papers [51]. Real-coded GAs have been used to solve the multi-objective optimization problem employing an elitist search.

An efficient way to find good lightweight designs for vehicle structures is to use different tools for structural optimization [4,21,27,30,93,106]. Structural optimization includes several approaches, for example, material, size, shape, and topology optimization, where size and shape optimization are used for fixed topologies and for improvements of existing structures. Topology optimization, however, is a more general optimization method that can be used in the early conceptual design phase of vehicle development where simplified models often are enough to analyze the structural behavior. An application of this approach is shown in [29]. Using topology optimization methods, the most efficient structures can be found in a relatively early stage of the vehicle design process. Topology optimization has proven to be very efficient, especially when used to improve existing designs [11].

The automotive body structure design problem has been considered in [24–26,68] by applying a sharing penalty vector method in order to define the product platform, that is, choose which components to share and design the product family with minimal individual variation from the ideal individually optimized designs. A multi-objective reliability-based approach has been followed in [44] for designing a piezoelectric brake.

An iterative response surface method has been used in [15] for the multidisciplinary optimization of a full vehicle to minimize mass while complying with crashworthiness and noise, vibration, and harshness (NVH) constraints.

The ATC process has also been applied to the optimal design of complete vehicle systems. Novel technologies, such as a hybrid-electric propulsion system, in-hub motors, and variable height suspensions, were considered in [67]. Emphasis was given to fuel economy, ride, and mobility characteristics.

In order to reduce the product complexity and cost while offering many variants, a widely implemented strategy is the product platform strategy, that is, sharing components and production processes across a platform of products.

Research topics in the automotive field include platform design process development [25,26] and optimum platform component selection [91].

Several decision-making models related to the acquisition process of vehicles that address a range of conflicting concerns, such as customer needs, lifecycle costs, new technology and design, budget allocation, competitive bidding, and the ability of contractors to meet market targets, are discussed in [13].

The advance in supercomputing has accelerated the development of simulation-based optimization [66]. The multidisciplinary design optimization for a car body structure under constraints of NVH and roof crush has been described in [111].

8.3.6 Integration of Vehicle Electronic Controls

Basic studies on active suspensions optimization and integration are given in [40,78,115]. As discussed previously, simple analytical formulae for the estimation of ride comfort and active safety of vehicles are derived and used to get the optimal controller gains that offer the best compromise among comfort, road holding, and packaging. In [36,37], this problem is reformulated by considering the vehicle body mass and the tire radial stiffness as stochastic parameters in order to derive the optimal trade-off solutions in a stochastic framework.

Research in several application areas has unveiled a coupling between the plant (design) and control optimization problems. Due to this coupling, optimizing a plant and control sequentially does not guarantee system optimality. The results have been demonstrated using a simple combined passive/active car suspension case study in [23].

A method to improve ride and handling of an automobile fitted with four active suspensions (sky hook dampers, active antiroll bars), active four-wheel steering, and traction control (controlled differential) has been proposed in [78]. The designer is asked to iterate between an innovation stage and a trade-off stage, in order to assess the effectiveness of candidate design issues for the synthesis of new control schemes.

In [94], a vehicle dynamics–integrated control algorithm designed by using a nonlinear optimization method is proposed for four wheel–distributed steering and four wheel–distributed traction/braking systems.

8.4 OPTIMIZATION OF THE DYNAMIC BEHAVIOR OF VEHICLES

A simple example is presented in the following to show how very general results can be obtained by applying correctly the optimization procedures introduced earlier.

The problem is to select the stiffness and damping of a passively suspended vehicle. The vehicle behavior, while running on a randomly profiled road, is described by means of the well-known quarter car vehicle model (see Figure 8.4a) and the objective is to minimize discomfort (the standard deviation of the acceleration of the body of the vehicle, $\sigma_{\ddot{x}_2}$), road holding (the standard deviation of the force acting between the road and the wheel, σ_{F_z}), and working space (the standard deviation of the relative displacement between the wheel and the vehicle body, $\sigma_{x_2-x_1}$).

By using the symbols shown in Figure 8.4a, we define

$$q = \frac{m_1}{m_2}, \quad K_x = k_2 \frac{(1+q)^2}{k_1 q}, \quad R_x = r_2 \sqrt{\frac{(1+q)^3}{k_1 m_2 q}} \tag{8.3}$$

to derive the analytical expressions of the pareto-optimal set into the (nondimensional) design variables domain (K_x, R_x) for the three combinations of two objective functions (boundaries of the pareto-optimal set for the problem with three objective functions, namely $\sigma_{\ddot{x}_2}$, σ_{F_z}, $\sigma_{x_2-x_1}$, see [37,39]). These are

$$\text{Optimal } (\sigma_{\ddot{x}_2}, \sigma_{F_z}) \rightarrow R_x = \sqrt{(1+q)K_x - qK_x^2} \quad \text{with } 0 \le K_x \le 1$$

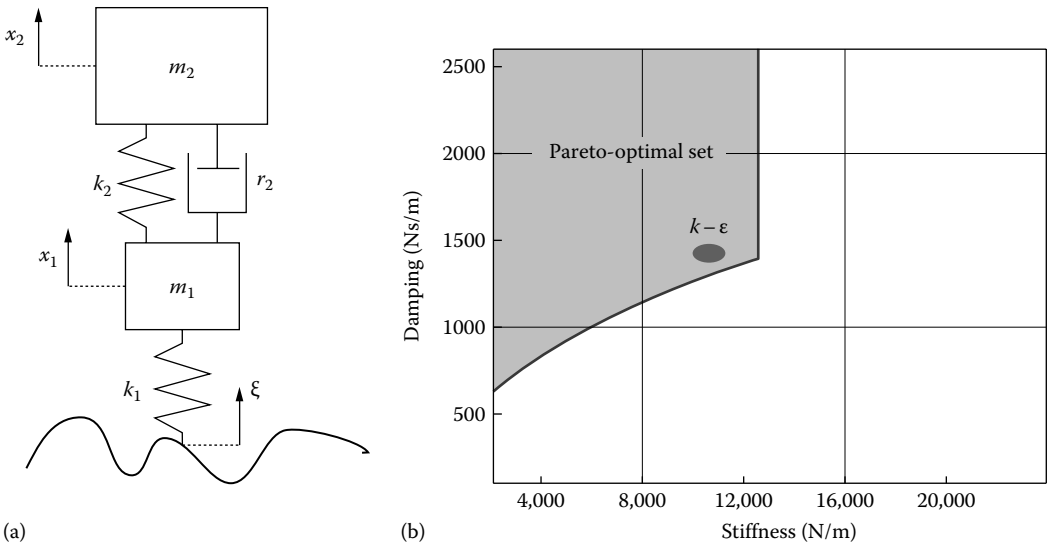

FIGURE 8.4 (a) Quarter car vehicle model, (b) Pareto-optimal set (filled area) and $k\varepsilon$-optimal solutions (see [72]) for the vehicle passive suspension optimization problem in the design variables space; suspension damping r_2 (Ns/m), suspension stiffness k_2 (N/m). Vehicle data are reported in [39]. k_1 (N/m) is the tire radial stiffness, m_1 (kg) is the unsprung mass, and m_2 (kg) is the sprung mass (for the quarter car model).

$$\text{Optimal } (\sigma_{\ddot{x}_2}, \sigma_{x_2-x_1}) \rightarrow R_x \geq 0, \quad K_x = 0 \tag{8.4}$$

$$\text{Optimal } (\sigma_{F_z}, \sigma_{x_2-x_1}) \rightarrow R_x \geq 1, \quad K_x = 1$$

The designer can get a direct insight into the suspension design problem by inspection of the expressions in Equation 8.4.

The pareto-optimal set into the design variable domain (suspension stiffness k_2 and suspension damping r_2) for the $\sigma_{\ddot{x}_2}$, σ_{F_z}, $\sigma_{x_2-x_1}$ problem is the filled area in Figure 8.4b (reference vehicle data are reported in [39]). The solutions belonging to the pareto-optimal set are equally desirable from the designer's point of view.

For the selection of the final suspension design solution, a $k\varepsilon$-optimality approach, extensively described in [72], has been followed. The result are the design solutions within the subset of the pareto-optimal set named $k\varepsilon$ (darker area) in Figure 8.4b. The result seems consistent with the solution selected by very skilled suspension specialists, after an expensive amount of trials.

In a stochastic formulation, the vehicle body mass m_2 and the tire radial stiffness k_1 can be considered as stochastic parameters due to the variety of possible loading conditions and to the variability of the tire pressure (m_2: CV = σ/μ = 0.10, k_1: CV = 0.10). The design variables to be optimized are the stiffness k_2 and the damping r_2 of the suspension considered as stochastic design variables due to variations with respect to their nominal value caused by production tolerances and/or wear (k_2: CV = 0.03, r_2: CV = 0.10). The computed pareto-optimal set is shown in Figure 8.5.

Figure 8.5 shows that the increase in robustness (higher reliability) implies a shift of the optimal solutions to higher values of the suspension stiffness k_2. It is shown that the pareto-optimal region computed by imposing a very high reliability (99.9999999%) is an extension of the deterministic one (see [37] for further details).

A similar approach can be used to optimize the handling behavior and active safety of road vehicles, as reported in [83]. The front and rear tyre cornering stiffness of a vehicle can be tuned in order to obtain a preferred compromise among the many conflicting performance indices that describe the handling behavior and active safety. The pareto-optimal set, shown in Figure 8.6, can be derived in analytical form.

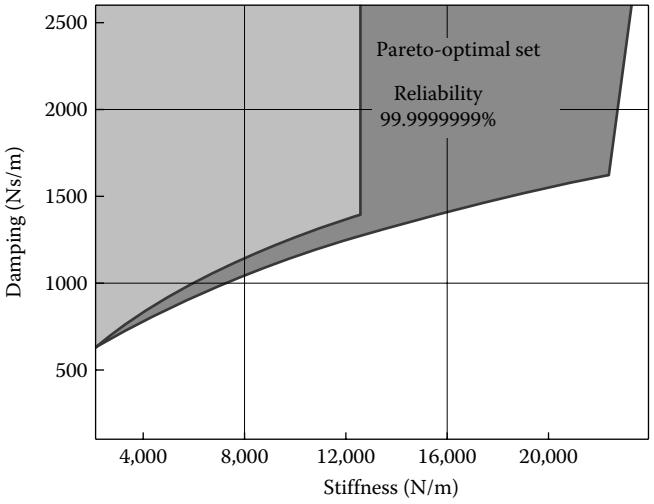

FIGURE 8.5 Pareto-optimal set (filled area) for the vehicle passive suspension optimization problem in the design variables space (suspension damping r_2 [Ns/m], suspension stiffness k_2 [N/m]), vehicle data reported in [39]. The deterministic solution (light color filled area) is reported together with the solution obtainable by applying a reliability-based optimization method (whole filled area).

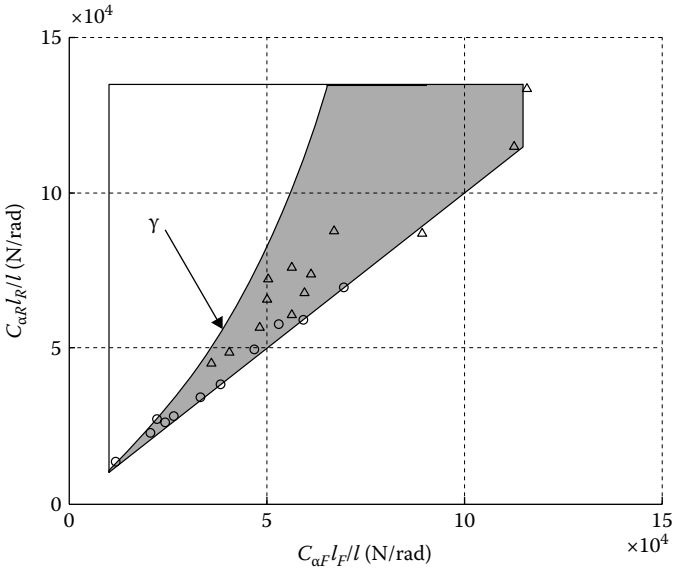

FIGURE 8.6 Pareto-optimal set (gray area) featuring the optimal handling performances of a road vehicle in the design variables domain $C_{\alpha F}/l_F$ and $C_{\alpha F}/l_F$. (From Mastinu, M. et al., *Optimal Design of Complex Mechanical Systems with Applications to Vehicle Engineering*, Springer Verlag, Berlin, Germany, 2006; Miano, C. et al., *ASME J. Mech. Design*, 126, 687, 2004.) Where $C_{\alpha F/R}$ is the front/rear cornering stiffness, $l_{F/R}$ is the respective distances from the center of gravity to the front/rear axles and l is the vehicle wheelbase. Experimental data denoted by ○ were derived from the literature; data denoted by Δ were available to the authors and measured by tire manufacturers. (Adapted from Miano, C. et al., *ASME J. Mech. Design*, 126, 687, 2004.)

8.5 CONCLUSION

A critical review of optimal design methods and their applications to solve vehicle system design problems has been presented. The correct optimization approach discards the "push the button and get the design" idea in favor of a realistic approach that recognizes the role of the designer as the leading force in the design process and the role of computers and software as indispensable tools. Successful optimization requires availability of appropriate analysis models and knowledge of the capabilities and limitations of the mathematical optimization techniques. Most of the modern software available for commercial use are capable of supporting such efforts effectively. However, an increased degree of familiarity is required before more complex studies are undertaken. The inclusion of uncertainty in the problem formulations is a relative recent development in the available optimization tools. Although solution robustness is desirable along with optimality, probabilistic optimal design formulations are substantially more computationally intensive than deterministic ones. Similarly, performing full pareto-optimality studies can be very expensive. The included (even still partial) list of references can be used to get a deeper insight into the subject and its potential practical implementations. These include problems in vehicle system dynamics, powertrain and internal combustion engine design, active safety and ride comfort, vehicle system design, lightweight structures, and controls.

9.1.4.5 Experimental Proof Tests 280
9.1.4.6 Notations 281
9.2 Load Data Acquisition 282
9.2.1 Acquisition of Load Data 282
9.2.2 Data Acquisition of Stresses 284
9.3 Derivation and Generation of Loads for Evaluation and Testing 285
9.3.1 Fundamentals and Influences on Fatigue Life 285
9.3.1.1 Mission Analysis and Usage Monitoring 287
9.3.1.2 Loading Sequence and Load Amplitude Variation 287
9.3.1.3 Influence of Overloads on Fatigue 290
9.3.2 Extrapolation of Measurements 290
9.3.3 Shortening of Load-Time Sequences 290
9.3.3.1 Omission 291
9.3.3.2 Truncation 293
9.3.3.3 Elastomeric Components 293

9.3.4 Synthesis of Load Data 293
9.3.4.1 Combination of Loading Segments 293
9.3.4.2 Frequency-Based Analyses 297
9.3.5 Standardized Load Sequence CARLOS TC 297
9.4 Accelerated Life Testing by Laboratory Road Simulation 297
9.4.1 Road Testing and Road Simulation 299
9.4.2 Definition of System to Be Tested 300
9.4.2.1 Spindle-Coupled Road Simulators 300
9.4.2.2 Wheel and Hub Road Simulators 301
9.4.3 Load File Development 302
9.4.4 Evaluation of Test Results 302
References 303

This chapter aims to give a short overview on structural durability as understood and practised at present. It is subdivided into the following four sections:

Section 9.1 gives a short overview of structural durability. It explains the influencing parameters material, geometry, manufacturing, and loading, defines stress and strain Woehler curves and Gassner curves and the transferability of fatigue data. For design purposes, different concepts are discussed. This section shows that structural durability cannot be handled as a material characteristic only, but must always be seen also under the aspect of a component and load-related material behavior.

Section 9.2 deals with the acquisition of loads. Measurements conducted under service conditions to determine damage parameters relevant to structures form the basis of experimental and numerical simulations, strength evaluations, and standardization. Special load sensors first enabled data acquisition technology to measure internal loads and efficient acquisition devices and sensors are now available. Nevertheless, the challenge of recording measurements under service conditions is always associated with a certain degree of effort. A systematic application of measurement acquisition of loads and stresses and strains substantially increases the reliability of components and assemblies being developed. Even during the predevelopment stages, the use of previously measured loads can be utilized and in the development process itself, the load assumptions can be finely adjusted and verified. Thus, load data acquisition is to be seen as an indispensable instrument in the development of reliable components and systems.

Realistic assumptions about loads are essential for a sound analysis of structural durability. Section 9.3 gives a brief overview on how to derive and generate the loading for numerical evaluation as well as physical testing purposes.

In Section 9.4, it will be shown that experimental proof is an essential measure for reliability, robustness, and quality. Since many vehicle components are relevant for operational safety, these parts must not fail and cause an accident. This can be ensured by laboratory road simulation. Hence, service load simulation and evaluation becomes an instrument to actively guide the product development process, rather than to release newly developed parts only. If both loading and assembly interactions are incorporated in a realistic manner, cost and time are saved due to the elimination of specialized on-track measurements.

Typically, multiaxial test rig hardware is used together with digital controllers for forces and motion. This leads to accelerated life testing on a subsystem level, for example, chassis and suspension or unsprung rotating components such as wheels and hubs. The load files are derived from road measurements or using scalable standardized information on the loading.

9.1 STRUCTURAL DURABILITY

Structural durability (service strength) is a generic term for a spectrum of stresses (loadings) that a component must endure during its required life without failure. Basic parameters are the material, design (component geometry), manufacturing process (e.g., casting, forging, welding, or surface treatment),

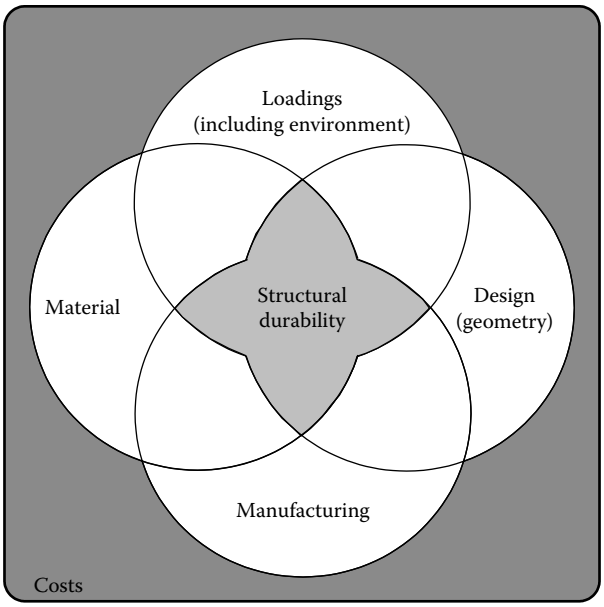

FIGURE 9.1 Parameters influencing the structural durability of components.

and loading (mechanical as well as superimposed environmental influences) [1–6]; the costs are ultimately responsible for the fact that products come on to the market optimized rather than optimal (Figure 9.1).

Despite many years of research, the release of reliable components on the basis of a purely numerical proof of structural durability is not possible. Not only the shortened development time but also the complexity of components and, in some cases, integration of, for example, smart structures, demand even more numerical analysis in order to be able to competently accompany future development processes and to meet requirements for product reliability. The methodological development, used to broaden the basis for design and optimization, extends to parameters such as manufacturing methods, surface state, size effect, and strength hypotheses. The transferability of fatigue data to components is closely associated with both local microstructural properties and failure mechanisms and requires the support of metallographic and scanning electron microscopic investigations. The present understanding of structural durability distinguishes itself from the original definition introduced by Ernst Gassner in 1939, which equated structural durability with fatigue behavior under variable amplitude (VA) loading. The definition today comprises

- Special loadings (overloads, which, for example, approach the component's structural, yield strength, for example, chassis components whilst slowly driving over an obstacle), bulging, or buckling of structures and misuse through dynamic loading (high speed and energy impact loading, for example, driving at speed over a pothole), where brittle fracture without deformation due to incorrect design and/or material choice must be excluded; that is, ductile fracture could be admissible
- Creep loading, for example, turbine blades subject to high temperature and centrifugal force
- Wear between frictional parts, for example, gear wheels
- Cyclic (not dynamic) loading (fatigue strength) with constant amplitudes (CAs) or VAs with superimposed assembly or loading-dependent mean values can lead to material fatigue, crack initiation, and finally to failure of components. The strength behavior under CA is

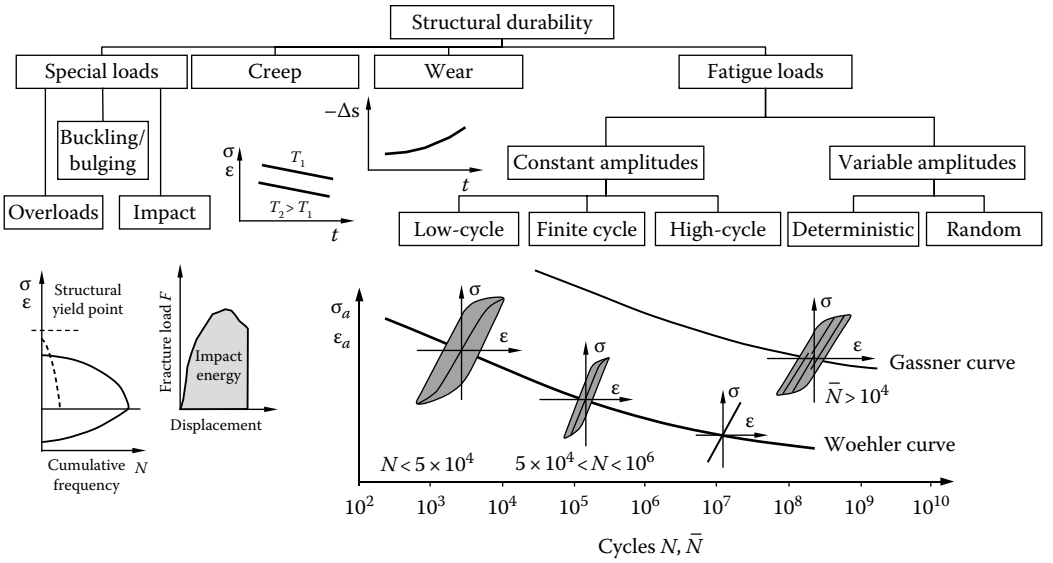

FIGURE 9.2 Partition of structural durability.

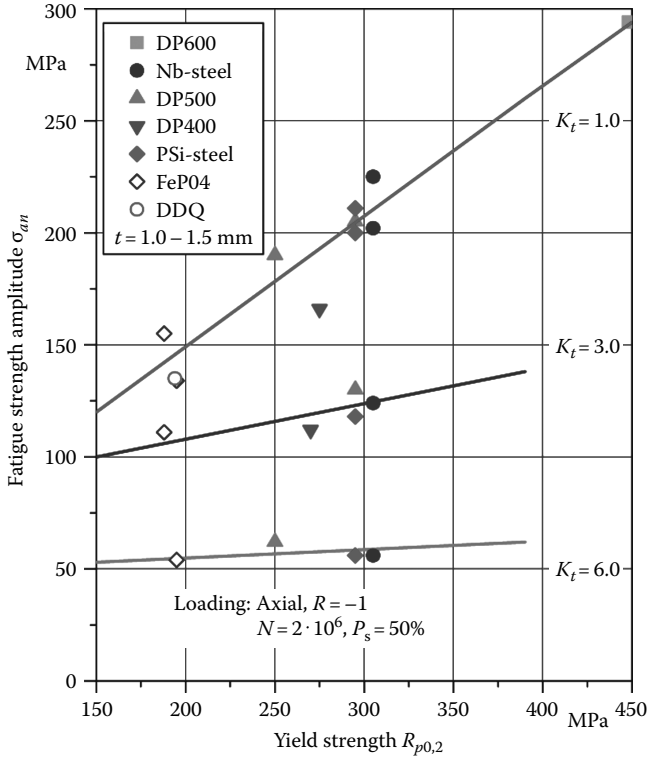
described by the Woehler curve (S–N curve: endurable stress/strain amplitudes under CA loading; in this section, denoted as "Woehler" curve in order to distinguish it from the endurable stress/strain amplitude loading, i.e., the Gassner curve) and under VA by the Gassner curve (Figure 9.2)

The Woehler curve is divided into three regions: low-cycle fatigue (elastoplastic deformations with a larger plastic part, defined up to 5×10^4 cycles), finite fatigue life region (elastoplastic deformations, endurance between 5×10^4 and 1×10^6 cycles), and the so-called "endurance limit" (macroscopical elastic deformations with endurances greater than 1×10^6 cycles). In this region, one must anticipate a continuous decrease in fatigue strength depending on material, manufacturing method, and environment. That is, an "endurance limit" does not exist [7,8]. The Gassner curve can be extended between 10^4 and more cycles up to 10^{10} while the VA loading can occur deterministically or stochastically. Typical components lying in the low-cycle fatigue region are reactor pressure vessels; those in the finite fatigue life region are vehicle door hinges and those in the so-called endurance limit region are gear wheels, crank-shafts, or con-rods. Typical components that are designed for variable service loads are chassis parts, for example, wheels, steering rod, front and rear axles, stub axles, braking systems, etc. The types of loading described here (special events, creep, wear, and cyclic loading) seldom occur individually in service; they can by all means occur successively or together such that their fatigue life defining interaction must be considered. However, loadings or stresses with only CAs, be it in the region of low-cycle fatigue, finite fatigue life, or so-called endurance limit, occur very seldom. In service, a composition of amplitudes of different magnitudes mainly exists, which is described by the term spectrum (cumulative frequency distribution of amplitudes). A knowledge of this spectrum is a prerequisite for determining the Gassner curves.

9.1.1 Influencing Parameters

9.1.1.1 Material, Geometry, and Manufacturing

In general, an increase in the values of ultimate tensile or yield strength for metallic materials is accompanied by an increase in the fatigue strength. However, this applies only to unnotched or lightly notched component regions, since the notches, dependent on design, significantly, influence



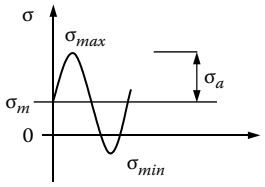


FIGURE 9.3 Fatigue strength of car body steels subjected to the notch factor K_t.

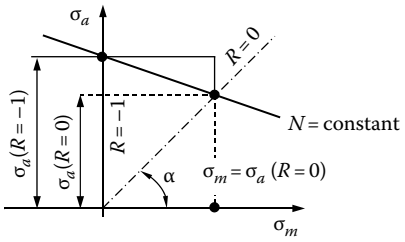
the fatigue strength. Notches with increased stress concentration (e.g., shoulders, fillets, bore holes, etc. with small radii) lower the external tolerable load. For notches, with high stress concentrations ($K_t > 2.5$), the fatigue strength cannot be raised by choosing a high strength material (Figure 9.3).



Therefore, the material's higher strength can only be exploited when stress concentrations are explicitly reduced by design, in most cases by incorporating larger radii. In cases where it is not possible to reduce stress concentrations, mechanical or thermomechanical surface treatment operations can be added to the manufacturing process. However, materials with higher tensile strength or yield strength also experience greater enhancement in fatigue strength than materials with lower strengths [9]. This enhancement is due to the material's ability to establish higher and stable compressive residual stresses. During mass production, effective options for enhancing fatigue strength are implemented, for example, surface rolling or induction hardening. According to the material, geometry, and loading (e.g., fully reversed, pulsating, CAs or VAs), enhancement of the endurable stress amplitudes up to a factor of 3 may be reached by these options under CA loading. Under VA loading, depending on the load level, the observed increase can be reduced due to the diminishing of compressive residual stresses by local plastic deformations [5]. This enhancement is dominated by the process-dependent compressive residual stresses introduced into the surface layer. The fatigue strength can be frequently enhanced more effectively using these measures than by design features. Basically, all surface layer states affecting fatigue strength are to be assessed from the perspective of "manufacturing induced" residual stresses, for example, milled, turned, and ground. A further important parameter is the mean stress sensitivity M, which serves to assess the influence of assembly and loading-dependent mean stresses on the endurable fatigue strength (Figures 9.4 and 9.5).

Mean stress sensitivity M and stress ratio R:

$$M = \frac{\sigma_a(R=-1)}{\sigma_a(R=0)} - 1 \qquad R = \frac{\sigma_{min}}{\sigma_{max}} = \frac{\sigma_m - \sigma_a}{\sigma_m + \sigma_a}$$

Mean stress and amplitude in the Haigh-diagram:

$$\sigma_a = \sigma_m \cdot \frac{1-R}{1+R} = \sigma_{max} \cdot \frac{1-R}{2}$$

FIGURE 9.4 Parameter of the Haigh diagram.

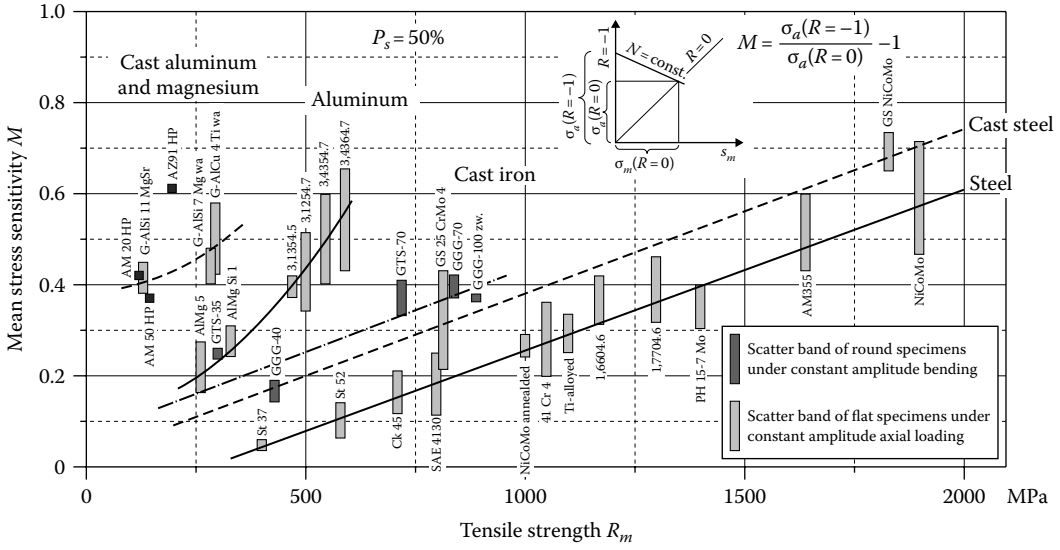


FIGURE 9.5 Mean stress sensitivity of some metallic materials.

M describes the ratio of the endurable stress amplitude σ_a for a material subject to fully reversed loads ($R = -1$) and the pulsating loads ($R = 0$). For all metallic materials, tensile mean stresses σ_m diminish the endurable stress amplitude σ_a, compressive mean stresses elevate σ_a. If stress ratios occurring in service deviate from fully reversed ($R = -1$) or pulsating loadings ($R = 0$), the fatigue strength amplitudes belonging to the respective mean stress can be approximately derived from the Haigh diagram by interpolation or extrapolation (Figure 9.4). However, for data lying outside the range $-1 \leq R \leq 0$, experimental verification is recommended.

9.1.1.2 Loading

In addition to the applied mechanical loadings (CAs or VAs, uniaxial or multiaxial loading), environmental influences such as temperature or corrosive media on the fatigue strength must be considered. Oxidation and creep effects can also occur during long holding periods, for example, stationary operations at high temperatures. Depending on their chloride ion concentration, solutions

containing chlorides very severely degrade the fatigue life (or the corrosion fatigue strength), since the Woehler curve's knee point is shifted to higher numbers of cycles or disappears completely. The loss in fatigue strength produced by a corrosive environmental medium is generally lower for VAs (service load sequences) than for CAs [10]. The extent to which coatings, for example, such as thermal spraying, galvanizing, etc., can be effective against corrosion fatigue must be investigated for individual cases. Examples of other media, which must also be considered during the design assessment, are fuel and brake fluid. A further type of corrosion that takes place under cyclic loading is fretting fatigue. This occurs by the relative movement between mating materials. Fretting fatigue can be very effectively reduced by shot peening and surface rolling (surface work hardening with induced compressive residual stresses) [11]. Surface treatments for steels such as nitriding, induction or case hardening (surface hardening with induced compressive residual stresses) would be expected to increase fatigue strength.

9.1.2 Cyclic Data

9.1.2.1 Presentation of Cyclic Data

The Woehler curve is a double logarithmic plot of loading or stress or strain amplitude (often stress) against the fatigue life (number of cycles, endurance), where a failure criterion (total rupture, a defined crack size, a reduction in stiffness, etc.) for the fatigue life must be defined. The significant influencing parameters are the material, the theoretical notch factor K_t (provided it can be defined for the section to be assessed), the loading or stress ratio $R = X_{min}/X_{max}$ (information about the mean value on which the amplitude is superimposed), type of loading (axial, bending, torsion), and the environment (temperature, medium). Loads are external parameters such as force, moment, pressure, or parameters resulting locally in the component strain, stress, or deformation (Figure 9.6).

The parameters for describing a Woehler curve are the slope k in the finite fatigue life region, the numbers of cycles at the knee point N_k, stress (or strain) amplitude at the knee point, for example, σ_{ak}, and the slope k' following the knee point; a probability of survival or failure P_s or P_f respectively, is assigned to these parameters. Both the height and position of the knee point together with the slopes are dependent on the influencing parameters. The scatter of the results T (in loading or life) is dependent on the material and manufacturing process, and is necessary for a safety

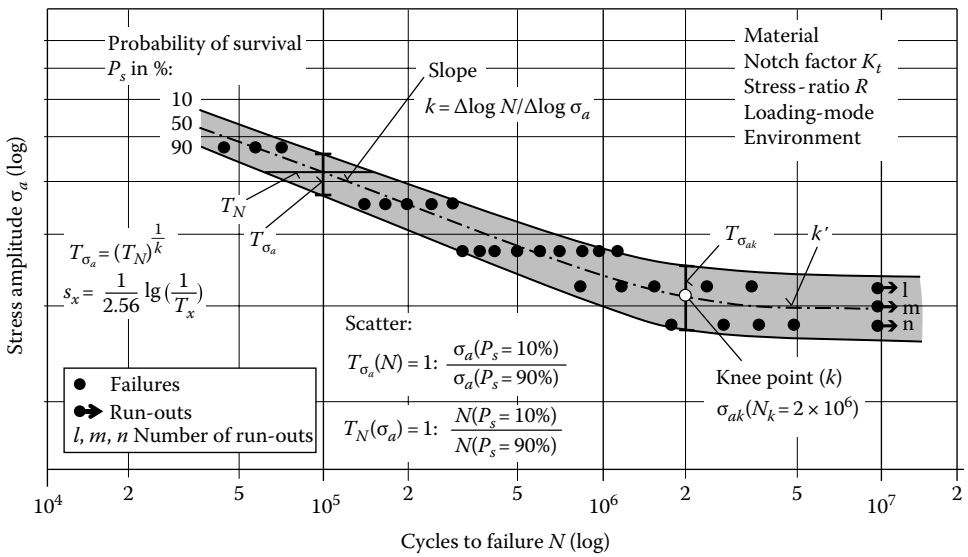

FIGURE 9.6 Parameters to determine and describe the Woehler curve.

consideration, whose computation frequently uses the Gaussian log-normal distribution. Under this assumption, the standard deviation can be computed from the scatter T, which is defined as the ratio between the probability of survivals $P_s = 10\%$ and 90%, $T_X = 1{:}X(P_s = 10\%)/X(P_s = 90\%)$ (Figure 9.6). The scatters T_N and $T_{\sigma a}$ in the region of finite fatigue life are coupled through the slope k. The scatter bands become wider toward the knee point with increasing fatigue life. The designation of scatter of fatigue life N for the region $N > N_k$ makes no sense because of the Woehler curve's shallow course following the knee point and may result in $T_N = \infty$. Therefore, for this region only, the scatter T of the loading or stress amplitude is determined. This does not become greater than the scatter in the transition region from the steep to the shallow sloped regions of the Woehler curve. That is, the scatter determined in the region of finite fatigue life just before the knee point can be considered to remain constant after the knee point. This assumption is expedient, since the stair case method [12] and its modifications, which are used to determine the endurable load, strain, or stress amplitudes for a fixed number of cycles at or after the knee point, provide only a reliable mean value but no reliable scatter. The aforementioned parameters are correspondingly valid for the determination and description of the Gassner curve (identified by "—" and denotes "the peak value of loading"), although the scatter in the Gassner curve can be lower than that in the Woehler curve. According to the shape of the spectrum, the slopes of Gassner curves can be often shallower than those of Woehler curves ($\overline{k} \geq k$). Generally, both can be referred to as fatigue life curves. Only by plotting on a double logarithmic scale does the representation give a straight line with a slope k, k', or $\overline{k}$. As a rule, the amplitudes are plotted on the loading or stress axis; a possible superimposed mean value emerges from the R-value. On determining Gassner curves, a subsequence, for example, as peak value sequence with a defined sequence length, must exist [13,14]. A load spectrum is the sum of the endured subsequences. The tests are carried out at different load levels whereby the number of subsequence repetitions and the magnitude of the amplitudes are level-dependent. A higher and a lower level merely define a linear increase and decrease, respectively, of all amplitudes and their associated mean values (Figure 9.7).

In order to represent service loading conditions, a subsequence must be repeated at least 5–10 times up to failure in order to provide a service-like mixing. The results of a Gassner test are plotted (at least in German-speaking countries) against the amplitude's peak values of each applied subsequence and resulting number of cycles to failure. Considering the R-value, this enables a comparison with the material's yield strength or component's structural yield strength. Furthermore, it is discernable how much the peak value exceeds the knee point of the Woehler curve [15,16] (the so-called endurance limit). This gives information about the lightweight design possibilities [13,14,17]. The precise position of the Gassner curve, as a function of the used sequence, can be theoretically computed from the damage accumulation [5]. However, it is only reliably determined by tests.

9.1.2.2 Strain Woehler Curves

To assess the material behavior for loading conditions exceeding the yield stress, it is necessary to know both the tensile and cyclic stress–strain curves together with the crack initiation Woehler curve under strain-controlled conditions [18] for assessment of the elastoplastic material behavior. The basis of dimensioning components, according to the local strain concept, is the simulation of cyclic behavior at notch roots of components using the results of strain-controlled tests on unnotched specimens. Owing to stress gradients in highly strained/stressed regions of components, the local deformations behavior is strain-controlled, provided that the structural yield point is not exceeded. Strain Woehler curves are the basis for component design according to the local strain approach. (In the macroscopically elastic region, strains and stresses are convertible to each other by the E-modulus, so that in this region local strain and stress concepts are identical.) The coefficients and exponents according to Coffin–Manson–Basquin, with which the strain Woehler curve is described, and those according to Ramberg–Osgood for the monotonic and cyclic stress–strain curve are used as input data for commercial dimensioning software [13,19]. By contrasting the monotonic with the cyclic stress–strain curve, it can be seen whether by repeated elastoplastic

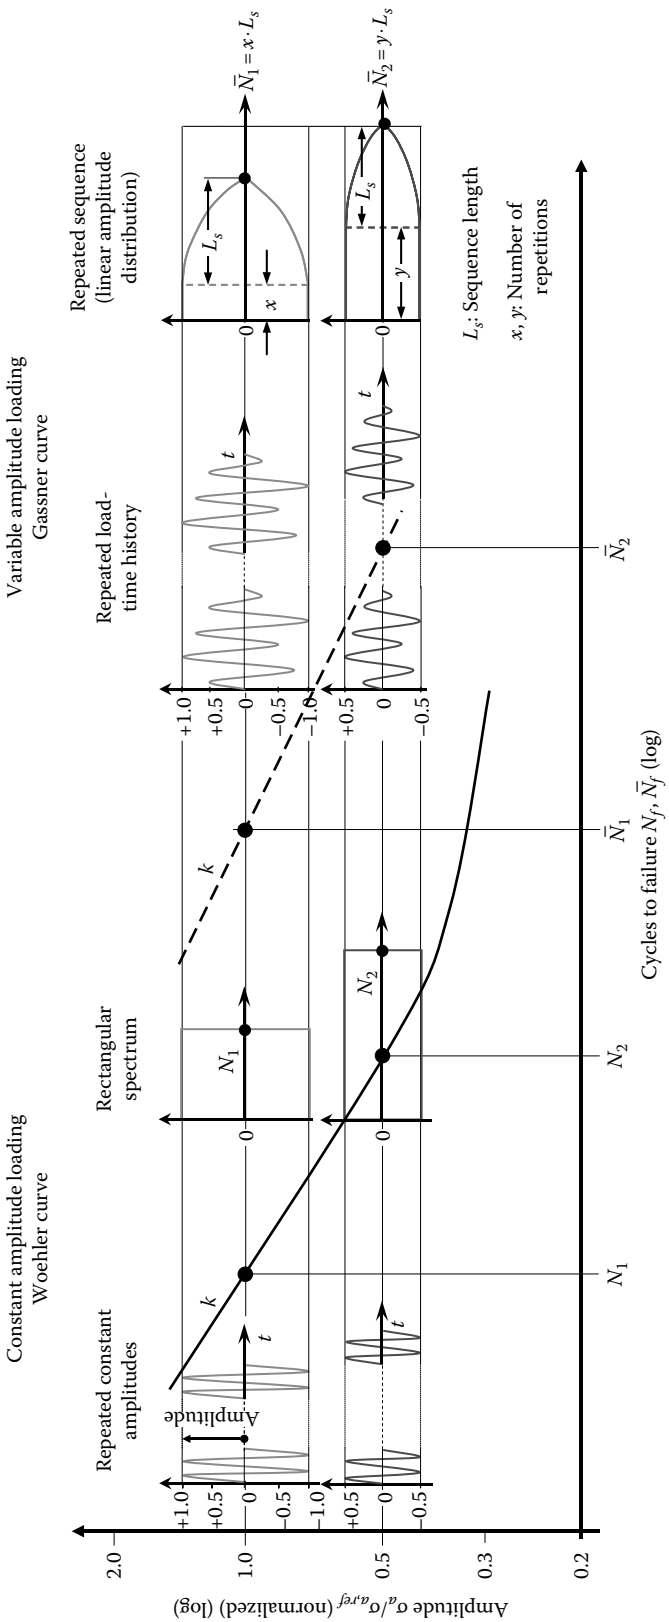

FIGURE 9.7 Presentation of constant and variable amplitude test results.

deformation a material cyclically hardens, softens, or is unaffected. Moreover, these curves are used for computing the notch root strains and stresses, for example, by implementing the Neuber rule or its modifications [20,21].

9.1.2.3 Significance of Tests with VAs

The significance of tests with VAs lies in the fact that, in contrast to tests with CA and identical peak values, they yield distinctly longer fatigue lives and exceed the Woehler curve in dependency of the spectrum shape. This is attributable to the fact that the smaller spectrum amplitudes in the Gassner tests damage less than the unchanged magnitudes of amplitudes continuously occurring in the Woehler tests. How much greater the fatigue life in the Gassner test is compared to that in the Woehler test depends on the shape of the sequences used. In the case of a straight-line distribution, the portion of smaller amplitudes is greater than those in the normal distribution (Figure 9.8); correspondingly, the associated Gassner curve shows a longer fatigue life. The advantage of knowing the spectrum's shape and its influence on the fatigue life for a given loading can be exploited for a lightweight design of component.

If, for example, a fatigue life of 10^8 cycles (after omitting the non-damaging load cycles) is required for a vehicle's steering rod and the peak load of $\bar{F}_a = 100$ kN measured in service is known, a diameter of $d = 22$ mm can be computed from the Woehler curve with an endurable stress amplitude of $\sigma_a = 260$ MPa. However, since a steering rod in service is subjected to a loading with VAs (for this particular case, measurements support a rectilinear distribution), knowledge of the corresponding Gassner curve for a fatigue life of 10^8 cycles with a stress amplitude of $\bar{\sigma}_a = 500$ MPa as a spectrum peak value, a diameter of 16 mm is computed. By allowing the Woehler curve for 10^8 cycles to be exceeded by a factor of 1.9, a reduction of cross section from 22 to 16 mm is achieved [22]. The consideration of VAs in engineering practice is the merit of E. Gassner (1939) and the most substantial improvement in lightweight component design, since A. Woehler (about 1870).

9.1.2.4 Size Effect and Transferability

Size effect is an essential factor in transferring fatigue data from specimens to components. The size effect can be divided into technological, stress gradient–related, statistical, and surface state–dependent contributions; however, a complete uncoupling of all size effect mechanisms is not

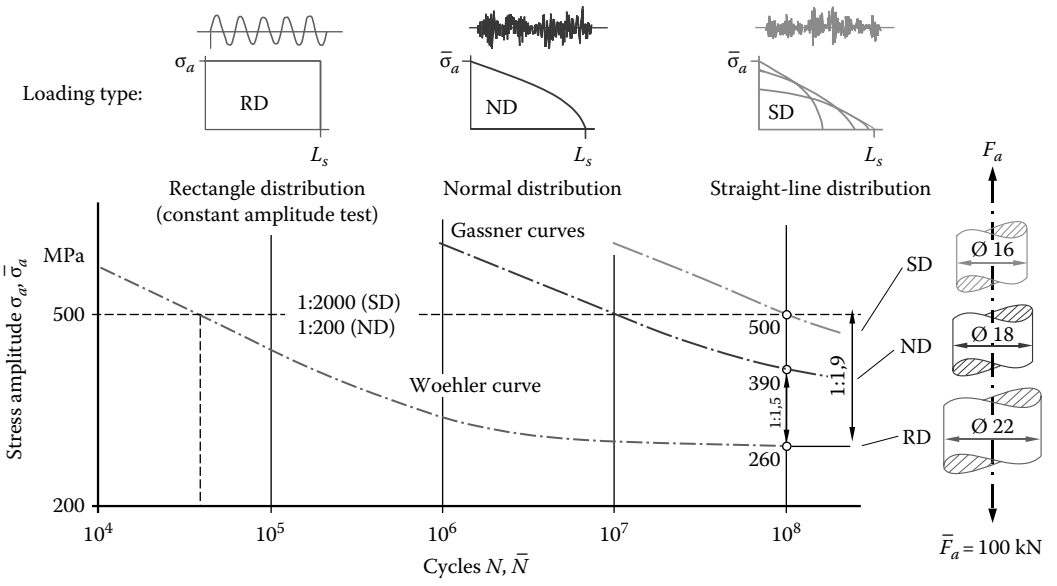

FIGURE 9.8 Influence of the spectrum on the fatigue life and component's dimension.

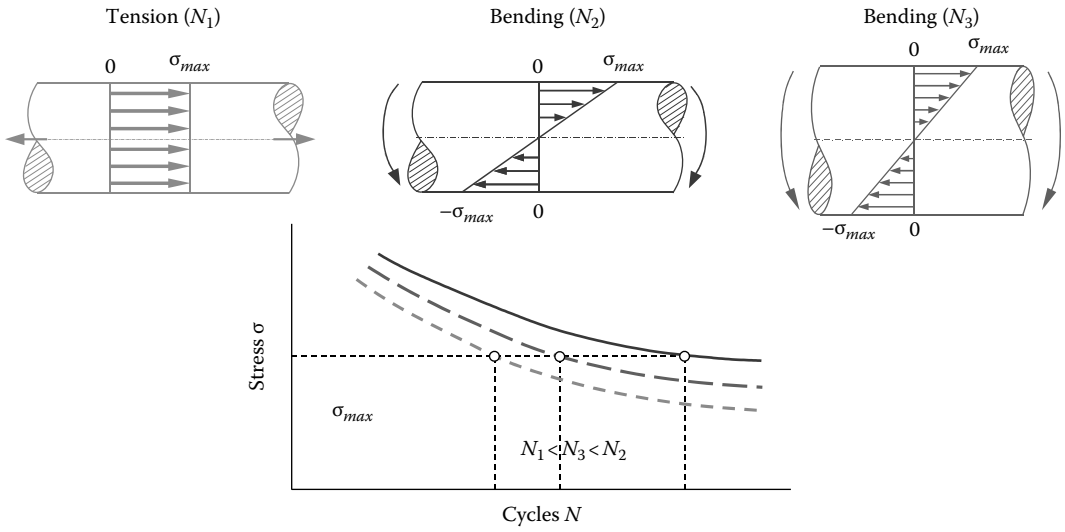

FIGURE 9.9 Influence of the maximum stressed material volume on the fatigue strength.

always possible [23–25]. A possible engineering consideration is given by the concept of highly stressed material volume, which considers the interaction between the stress gradient–related and the statistical size effect [20,21,26].

The highly stressed material volume is determined by the stress gradient depending on the component's geometry and the type of loading. The higher this volume, the higher is the failure probability. The so-called technological and surface state–related size effects are considered by separate examination of the surface, surface layers, and microstructural condition. Since the crack initiation not only is limited to the surface but also occurs in the region near to the surface, it has proved useful to define those volumes in which the maximum local stresses at the surface as well as into the depth fall by 10% (so that at least 90% of the maximum local stresses prevail) as the highly stressed material volume $V_{90\%}$ and to consider them for the evaluation purposes. The larger the highly stressed volume is, the greater is the probability that a material defect initiates a crack. For this reason, the local endurable stresses from larger highly stressed material volumes become smaller (Figure 9.9). For the transferability, it is initially assumed that the material, surface, and surface layer conditions, including the possible existence of residual stress conditions of, for example, specimens and components, remain the same. That is, the technological and surface state–related size effects are considered.

9.1.3 Component Design/Assessment

9.1.3.1 Initial Design/Assessment Data

In assessing and designing components, their functionality and their service behavior must be reliable.

For this assessment, many boundary conditions such as initial data must be known, for example,

- Loads (forces, moments, pressures, etc.) or local strains/stresses (including media and temperature), their magnitude and cumulative frequency (load spectrum), and their probability of occurrence
- Endurable stresses in the form of a fatigue life curve
- Design fatigue life and failure probability, etc.

Of special significance are the user-specific stress spectra. These are most appropriately determined by service measurements. The strength evaluation takes many forms and ranges from experimental proof tests on the component to pure computational verification (e.g., [27], Figure 9.10).

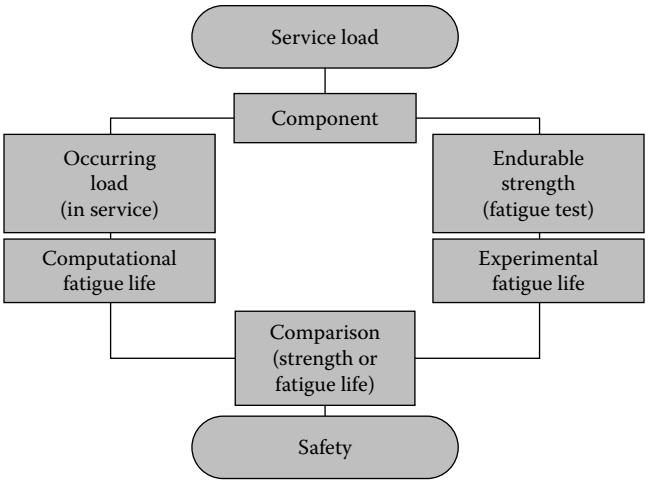

FIGURE 9.10 Component design (verification test).

9.1.3.2 Design Concepts

The criteria for an appropriate component design are the reliability of the components of the construction or of the entire system (service reliability) and the safety (no failures before reaching the designed fatigue life for a required theoretical failure probability). The following engineering design criteria are applied (Figure 9.11):

- Static design, usually against the yield strength.
- Design against the (so-called) endurance limit, assuming infinite life design, when the spectrum lies below the Woehler curve following the knee point, but the spectrum's peak value occurs much more than 10^6 times; this is the case, for example, with connecting rods, crank shafts, and gears. Although the loading occurs in these examples with VAs, they are treated as CA loadings because of the high occurrence of the spectrum's peak values.

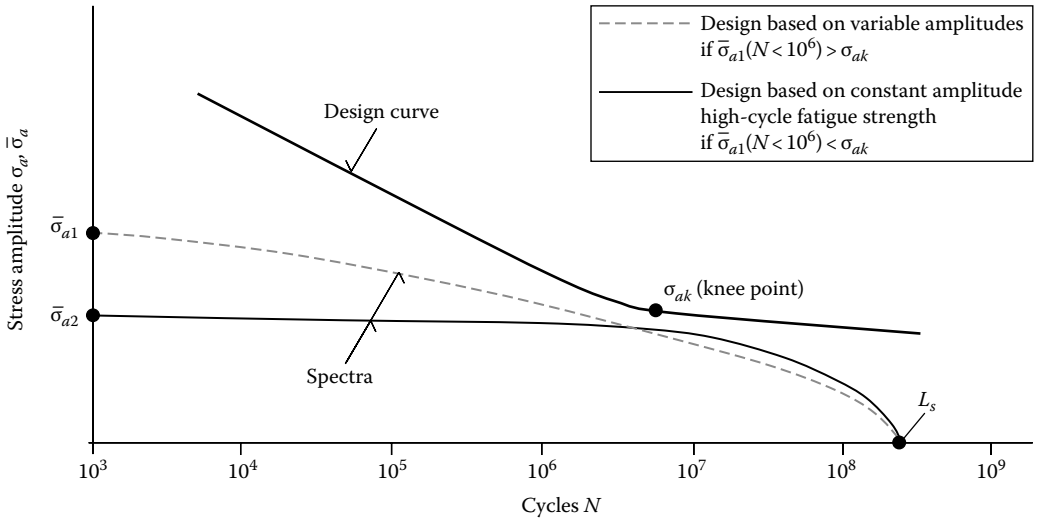

FIGURE 9.11 Criteria for component design based on constant and variable amplitude loading.

- Structurally durable design, when the spectrum's peak values exceed the Woehler curve following the knee point and also when a limited number of VAs are allowed. Permitting higher stresses than those at the Woehler curve's knee point leads to smaller component cross sections (lightweight design).

The following concepts are sometimes applied simultaneously in different technical branches:

Nominal stress concept: The nominal stress concept requires both the definition of a nominal stress and also the classification of a notch factor or, with welded joints, a fatigue class. According to the definition of both of these parameters, a design Woehler curve referring to the nominal stress system must be taken into account for which the same notch factor or fatigue class exists for the component that is to be evaluated. This concept, with which a nominal strain can also be used, reaches its limits of applicability for complex geometries for which neither a nominal stress nor a notch factor or fatigue class can be defined [28]. Moreover, since the present possibilities offered by numerical simulation (FEM) provide the local strains/stresses, this concept is increasingly superseded.

Structural stress concept: This was developed for welded joints [28]. The concept, which can also be based on strain, extrapolates the stress distribution outside of the weld's seam to the weld's toe according to stipulated criteria thus defining a hot-spot stress. This stress is then assigned a structural stress Woehler curve and then evaluated. The advantage of these concepts lies in the fact that for complex geometries, the problem of the definition of a nominal stress or that of a fatigue class is avoided. In contrast to the nominal stress concept, only few fatigue classes for welded joints are given. The disadvantage lies in the fact that critical regions, which are not externally accessible, for example, weld roots, cannot be assessed with this concept.

Local concept: The local concept can be used with both stresses (local stress approach) and strains (local strain approach). Here, the load-dependent notch stress or strain must be determined and for whose evaluation the local endurable stress or strain must be available. That is, the Woehler curves for the local system, taking into consideration the size effects, surface, and material state, must be available. The advantage of this concept, also used for welded joints, lies in the fact that difficult geometries can be assessed by calculating the load-dependent local stresses or strains.

Fracture mechanics approach: This concept [29] assumes that, in a component's critical region, crack-like defects or geometries exist, from which a crack can be initiated or propagated. Crack initiation can be treated by the definition of stress intensity and the crack propagation by additional linear-elastic or elastoplastic constitutive equations. If the crack initiation phase up to a defined length or depth is not taken into consideration, this part of fatigue life is not considered by this design method.

9.1.3.3 Strength Hypotheses

In general, components in service are subjected to multiaxial loads with existent and changing principal stress directions. For a fatigue life evaluation, the local stress states have to be reduced to an equivalent stress for comparing them with fatigue properties derived under uniaxial loading. For the evaluation of an equivalent stress, different hypotheses are established. They were primarily developed for static load cases, but some of them have also proved to be suitable for cyclic loading:

- Ductile materials (e.g., fine-grained steel, quenched and tempered steel, etc.): Shear stress hypothesis according to Tresca or the distortion energy criterion according to von Mises
- Brittle materials (e.g., cast iron, aluminium casting): Criterion of maximum normal stress according to Galilei

Proportional loading situations can be assessed fairly well with these criteria, but special attention has to be paid to changing principal stress directions, since materials react differently to this special load situation and the numerical assessment is highly complex. This is the case for ductile and

semi-ductile materials. Ductile materials reveal a decrease of fatigue life under multiaxial loading with changing principal stress directions in contrast to constant directions. Brittle materials show an increase of fatigue life while semi-ductile materials present an indifferent behavior [30,31]. To account for these different features, for ductile as well as for semi-ductile materials (e.g., cast steel, wrought aluminium), plane-oriented hypotheses have been developed in recent years. While for ductile materials the criterion for the calculation of an equivalent stress [30,31] is the integration of shear stresses over all planes, for semi-ductile materials the criterion is the critical plane with the most unfavorable combination of shear and normal stresses. In the case of brittle materials, the equivalent stress is the maximum normal stress occurring in the critical plane and corresponding to the principal stress. Also, approaches on the basis of strains, energy density, and short cracks [32,33] have been proposed but require detailed information of the material properties and are most demanding in application [34,35].

9.1.3.4 Estimation of Fatigue Life

The question of fatigue life estimation arises for VA loading [6]. To computationally estimate the fatigue life according to the hypotheses of linear damage accumulation [5] according to Palmgren (1924) and Miner (1945) (Figure 9.12), knowledge of the spectrum (Rainflow matrix or level crossings in combination with range pairs [16]) and also of the Woehler curve is required.

Since, in general, the spectrum's amplitudes show different *R*-values as displayed in a Rainflow matrix, a transformation on to the *R*-value of the Woehler curve has to be carried out. For the original Palmgren–Miner computation, the Woehler curve following the knee point is horizontal. That is, it is not considered that amplitudes below the knee point cause damage, which is wrong. Therefore, the Woehler curve, depending on the type of modification of the Palmgren–Miner rule, is continued after the knee point with a changed slope, for example, with $k' = k$ (Palmgren–Miner elementary) or with $k' = 2k–m$ (a modification according to Haibach; $m = 1$ for wrought materials, $m = 2$ for cast, welded, or sintered materials). This is carried out in order to allow for damage caused by amplitudes below the knee point. The most used modifications are aforementioned. Following the summation of the damage increments n_i/N_i, the fatigue life $\bar{N}_{calc}$ can be calculated (estimated) using the theoretical damage sum $D_{th} = 1.0$. However knowledge of the real damage sum D_{real} is required for a correct estimate which, in most known cases, is <1.0. The estimate can only be determined from tests (Woehler and Gassner curves) as a ratio of the experimentally determined fatigue life and that calculated with $D_{th} = 1.0$ ($D_{real} = \bar{N}_{exp}/\bar{N}_{calc}$ ($D_{th} = 1.0$)), and is linked to the computing procedure. In the event that other spectrum shapes exist in service as those used in the test, the position of the corresponding

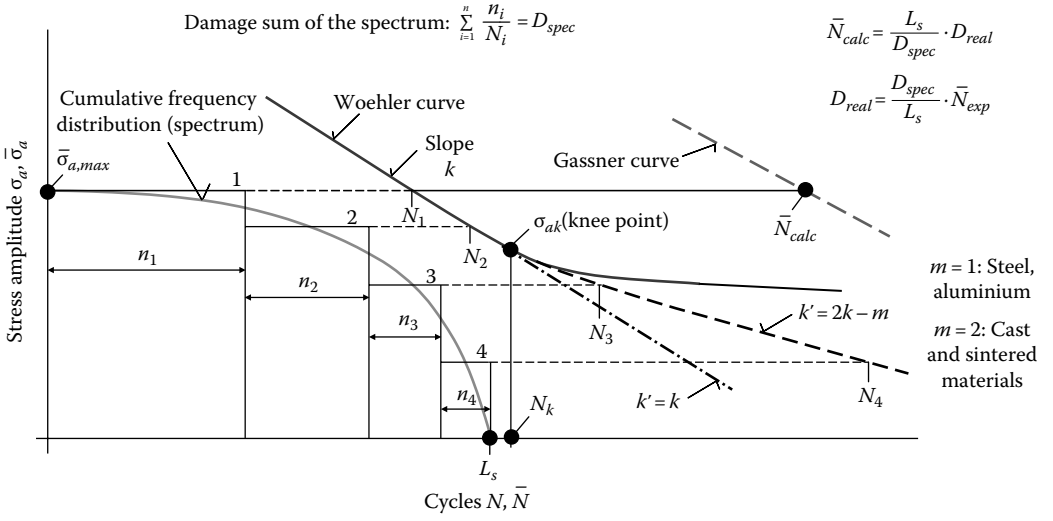

FIGURE 9.12 Modification of the Woehler curve and calculation of fatigue life (schematically).

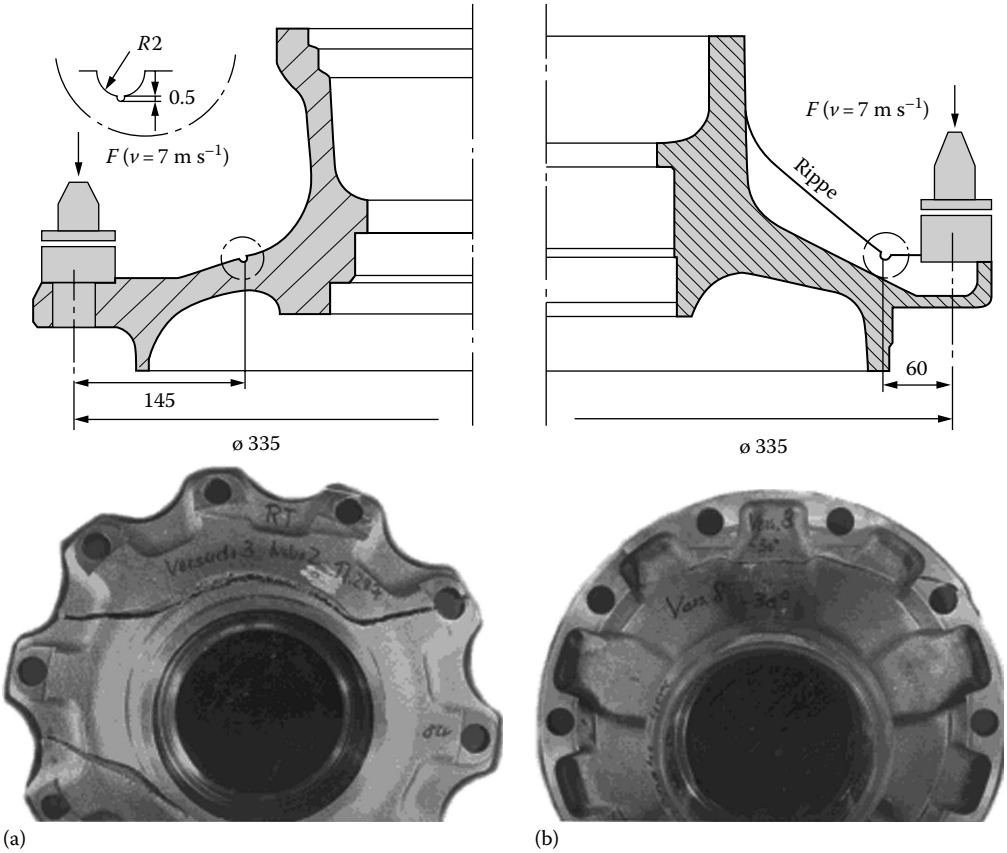
Gassner curve can, in this case, be estimated by a relative damage calculation; however, it may not be always correctly calculated. The real damage sums can be scattered over three logarithmic decades. Approximately 90% of the experimentally derived damage sums lie below the theoretical value $D_{th} = 1.0$; that is, calculations with $D_{th} = 1.0$ give, in most cases, an overestimate of the fatigue life [36]. Therefore, the allowable damage sums $D_{all} = 0.5$ for welded joints and $D_{all} = 0.3$ for non-welded components (FKM guidelines [27]) are assumed for an initial assessment for estimating the fatigue life. For load-time histories with high variations of mean values, damage sums of 0.2 and 0.1, respectively, should be used instead of 0.5 and 0.3 [13,14]. Owing to these uncertainties, experimental verification of structural durability, where possible, is always recommended, particularly for safety critical components. In cases that an experimental verification is not possible, inspections are necessary.

9.1.4 Endurable Loading

9.1.4.1 Fracture Behavior Subject to Impact Loading

For a structurally durable design, especially safety critical components having developed unanticipated cracks must withstand loading due to misuse, for example, an impact, and must never reveal a brittle failure. Such loadings can occur while driving over obstacles, by potholes, or from a collision with a curb stone.

Figure 9.13 contrasts two commercial vehicle's wheel hubs made from forged and cast materials of the same weight. In both hubs, an artificial crack of 0.5 mm deep was inserted at the highly



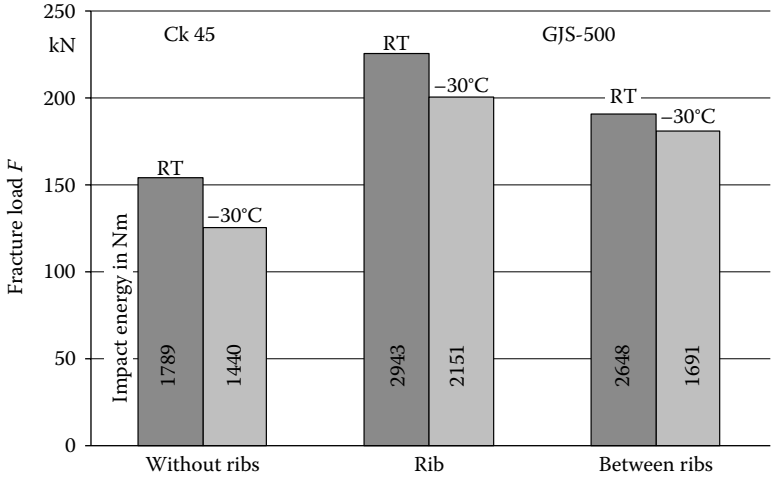


FIGURE 9.13 Influence of design on impact behavior of truck hubs with artificial cracks. (a) Forged hub of Ck 45, (b) cast hub of GJS-500.

(*continued*)

Material	$R_{p0.2}$ [MPa]	R_m [MPa]	A_e [%]	Z [%]	$A_v(RT)$ [J]
Ck 45 coarse-grain annealed	359	707	15	33	19
GJS-500	373	577	7	7	5

(c)

FIGURE 9.13 (continued) Influence of design on impact behavior of truck hubs with artificial cracks. (c) Fracture load.

stressed area. Using the conventional material data, the forged steel appears to be quite superior to the cast material, although, on the basis of the cast form (ribbing in the critical region), a significantly higher impact load is required to cause rupture in contrast to the forged hub. In this example, the magnitude of the rupture force is strongly influenced by the geometry. Thus, no correlation exists between conventional static and impact material data obtained with simple specimens.

9.1.4.2 Structural Yield Strength

The 0.2% yield strength of a material is the stress at which a remaining plastic deformation of $\varepsilon_{pl} = 0.2\%$ occurs and is determined from the stress–strain curve using an unnotched specimen ($K_t = 1.0$) in a tensile test or during a strain-controlled fatigue test. As soon as the linear elastic region of the stress–strain curve is exceeded, the material will tend to flow in an uncontrolled under manner axial loading of an unnotched specimen. The material flows according to its hardening properties in the absence of existing support effects (no stress gradients). This can only be prevented by strain controlling (strain Woehler curve), that is, the strain control simulates the flow restricting effect of strain–stress gradients in notches. On the other hand, in contrast to the 0.2% yield strength of an unnotched specimen, a higher local total strain is required to obtain a remaining plastic deformation of $\varepsilon_{pl} = 0.2\%$ by reaching the 0.2% component's structural yield strength [10] at a component or a notched specimen. This is caused by the stress gradients at the component's or specimen's notch. The ratio between the local total strain in the notch of the component and that at the unnotched specimen yielding a 0.2% remaining plastic deformation is defined as the support factor. The stress gradient in the notch, as long as the 0.2% component yield strength is not exceeded, locally impedes an uncontrolled yielding. That is, the gradients locally exert, despite the external

load control, a strain control. For this reason, there exists a greater linear region between external loading and local straining in components and notched specimens than in unnotched specimens. From the point of view of structural durability, the important component structural yield strength, which can be reached by a service stress as a consequence of a special event, must not impair the fatigue strength. According to material and component geometry, the allowable component yield strength may be lower than the 0.2% limit, for example, $\varepsilon_{pl} = 0.02\%–0.05\%$.

9.1.4.3 Choice of Relevant Design Data

Fatigue data are predominantly determined and made available using specimens. The informative value of these data depend to what extent the user, to whom the data have been made available, is in a position to evaluate the different factors of influence. Furthermore, the failure criterion is important. Fatigue data determined on unnotched specimens mostly provide a conservative approach, since the uniaxial loaded specimens possess no stress gradients. Higher strength values are determined under bending depending on the stress gradients and size of the specimens (Figure 9.9). It is, therefore, very difficult to make data for dimensioning purposes available, as displayed in Figure 9.3, since these always require a lot of knowledge (consideration of local properties like microstructure, strength, surface states, highly stressed material volume, surface treatment, etc.), which enables the reliable transferability of data from specimens to components. As long as no experience with respect to the transferability of fatigue data exist, a verification test on the actual component is always recommended. If this is not possible, a fatigue life curve should be derived using a specimen with comparable local properties taken from the component.

9.1.4.4 Safety Considerations—Endurable and Allowable (Permissible) Stresses

Starting from a fatigue life curve with a probability of survival of $P_s = 50\%$ (endurable stresses or strains), a design fatigue life curve (allowable stresses or strains) is derived for a component design. With regard to this, a theoretical probability of failure $P_f = 1 - P_s$ is initially defined according to the component's risk potential. For vitally important components, which must never fail, for example, brakes, $P_f \leq 10^{-6}$ (Gaussian log-normal distribution assumed). For components which are frequently inspected and which are operated in secure areas, for example, a pressure vessel in a bunker, $P_f = 10^{-3}$. Furthermore, the following must be known:

s_X: The standard deviation around the mean value $X(P_s = 50\%)$ of the endurable stress, strain, load, deformation, pressure with $s_X = (1/2.56)\log(1/T_X)$

s_M: The standard deviation of the mean value depending on the batch and production (quality control).

s_L: The standard deviation of the external loading; in cases where the maximum loading is assumed to be known, then $s_L = 0$.

By assuming a logarithmic normal distribution, the total standard deviation

$$s = \sqrt{s_X^2 + s_M^2 + s_L^2}$$

can be calculated from the individual standard deviations [37]. The allowable (permissible) stress, strain, etc. for a required theoretical failure probability is given by

$$X_{all} = \frac{X\left(P_s = 50\%\right)}{j_X}$$

$$j_X = 10^{-s \cdot u_0(P_f)}$$

$u_0(P_f)$ depends on P_f and is the normalized safety factor [3,4]. Table 9.1 shows the value of u_0 for several probabilities of failure P_f.

TABLE 9.1
Calculatory Probability of Failure P_f and Normalized Safety Factor u_0 for Gaussian Logarithmic Distribution

P_f	10^{-1}	10^{-2}	10^{-3}	10^{-4}	10^{-5}	10^{-6}
$-u_0$	1.28	2.33	3.09	3.72	4.27	4.75

A further good approach to obtain j_X is also given by [38]:

$$j_X = 10^{\left(2.36\sqrt{|\log P_f|}-1\right)s}$$

As the scatter is dependent on the stress level and the corresponding number of cycles, different magnitudes of safety factors will result along the fatigue life curve ($P_s = 50\%$) from which the design fatigue life curve is derived. The emphasis on theoretical failure probability is well founded, since the real distribution outside the regions $P_s \approx 5\%–95\%$ is unknown. Nevertheless, the implementation of the theoretical failure probability is legitimate when its specification is supported by verifiable experience with respect to the safe service of a component. To derive the safety factors, other distributions, for example, Weibull, can also be used. For this purpose, the corresponding service experience must also exist.

9.1.4.5 Experimental Proof Tests

Basically, components must be designed such that the required fatigue life is reached without failure. This requirement can be fulfilled according to the component's relevance using different quality and economic standards. These standards depend on the classification into primary and secondary components according to considerations of safety and service reliability; in this connection, primary components are classified as safety and functional components. For safety components, for example, steering knuckles, wheels, brakes, failure must be excluded, since this represents a danger to the life of the user and the environment. High safety factors underlie the design of such components. The avoidance of failure is indeed equally the aim for functional components, since the functionality of system will be then prevented (e.g., connecting rod and crank shaft). However, a failure should not cause a danger to the user and environment. On the other hand, damage to secondary components, for example, exhaust manifolds, have, in many cases, no direct effect on safety or functional reliability. As a result, higher quality requirements are set for primary components due also to the economic consequences of failure, for example, given by recall actions. For example, the dimensioning of vitally important safety components must cover all service loads according to the present state of technology and knowledge. For this, not only is the accurate acquisition of the service loads required, but also knowledge of critical regions for failure of the components and the relation between occurring and allowable equivalent stresses depending on manufacturing process, material, and component geometry is required. Accordingly, the tolerable quality of the component can be stipulated under consideration of the economical-efficiency. Quality requirements, which are coupled to the safety of a component, can only be verified by achieving the corresponding experimental proof tests under simulated service conditions in which critical regions and the type of failure must be recognized. A further advantage of fatigue tests lies in the fact that they constantly verify the stability of the production quality and are subjected to the use of statistical methods, for example, as is the case of the production of mass products like connecting rods and crank shafts. The proof of fatigue strength must be supported by the corresponding quality specifications in the construction, the material procurement, and the manufacturing. The measurement of service loads for the verification and, if needed, timely corrections of computations should, as far as possible, be provided. To shorten the test's duration, an omission (leaving out non-damaging low cyclic

loads) may be carried out under consideration of the appertaining amplitude's mean values and the damage equivalent compensation of omitted loads [39]. With multiaxial tests, the correlation between the individual time signals must be taken into account [40,41].

9.1.4.6 Notations

A_e	Elongation at fracture
A_v	Notch impact energy
D	Damage sum
d	Diameter
F	Load
L_s	Sequence length
j	Safety factor
k, k'	Slopes of fatigue life curves
K_t	Notch factor
m	Wild card for calculating k'
M	Mean stress sensitivity
n	Cycle numbers of spectrum segments
N	Cycles
P_f	Probability of failure
P_s	Probability of survival
R	Ratio (min/max of load, stress, or strain)
$R2$	Radius of 2 mm
R_m	Tensile strength
$R_{p0.2}$	Yield strength
s	Standard deviation
T	Temperature
T_σ, T_N	Scatter in stress direction or cycles direction
U_0	Normalized safety factor
V	Loading velocity
$V_{90\%}$	Highly stressed material volume
X	Wild card for stress, strain, load, deformation, pressure
Z	Area reduction at fracture
Δ	Range
Δs	Deflection
α	Angle
ε	Strain
σ	Stress

Indices

1, 2, 3, 4, or i	Numbers for differentiation
a	Amplitude
all	Allowable

spec	Spectrum
th	Theoretical
x	Wild card for N or σ
X	Wild card for stress, strain, load, deformation, pressure

9.2 LOAD DATA ACQUISITION

Measurements form the basis of the operating design of almost all mechanical engineering safety components. In particular, knowledge of the magnitudes and frequencies of the applied loads and of the stresses and strains during the operational life required for the customer's application are essential as input parameters for evaluating structural durability. In order to determine these data for vehicles and machines, applied loads and local stresses and strains are measured during operating tests over relatively short time periods of 1–4 weeks. These data can then be extrapolated to the required fatigue life in order to

- Carry out an appraisal of the fatigue life using the applicable regulations
- Derive a testing program
- Make the input parameters available for a numerical simulation

According to each problem definition, strain gauges are located at different places. Loads are measured at the least disturbed regions. Critical strains are determined in regions where the highest stresses are expected. In Section 9.2.1, details of the load acquisition are dealt with and in Section 9.2.2, the application of strain gauges at critical regions is addressed.

9.2.1 Acquisition of Load Data

Loads form the input parameters, which ultimately cause the damaging stresses and strains in components. By considering road vehicles, wheel loads have over the last 30 years been determined as the global input parameters. Initially, chassis components were instrumented and calibrated. Today, measuring wheels are available for road vehicles, with which the three components of both force and moment at the wheel–road contact point can be determined. For rail vehicles, there is, at present, no satisfactory solution. A measuring wheel developed for this purpose for local track transport [42] is depicted in Figure 9.14. One can see that the wheel design incorporates pockets for locating ~100 strain gauges. Here, the difficulty lies in the positioning of the strain gauges such that the three components of both force and moment can be measured with the least possible cross talk. Simultaneously, the structure is to be sufficiently compliant such that the strains lie within the measurable range, but the fatigue strength of the structure is noncritical for the intended application.

To determine internal loads in systems, load sensors are integrated into the line of force transmission. In particular, of great interest are the internal loads in over-determined systems, in which elastomeric bearings are integrated—for example, double wishbone axles in automobile chassis. Here, system components are then, as a rule, instrumented with strain gauges and calibrated for force or moment (Figure 9.15). However, this has the disadvantage that they can only be applied for that specific system. The complexity of the problem definition increases with the number of degrees of freedom to be measured. Nevertheless, since the quality of the numerical multibody simulation steadily increases, the data acquisition technology for measuring loads are, at present, becoming increasingly more important for structurally durable designs.

The great advantage of measuring load data in comparison to local stresses and strains is that the former are independent of component geometry. By measuring load data, a system is described with which the results can be transferred to modified or similar systems. Thus, for the

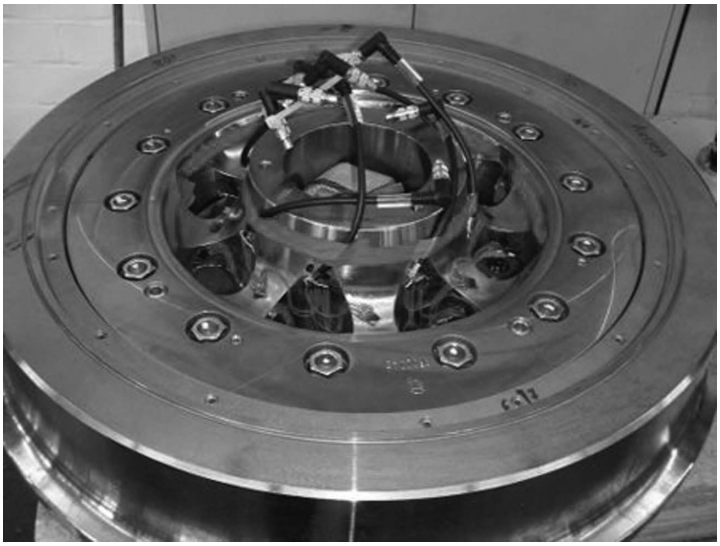

FIGURE 9.14 Tram wheel load sensor with machined pockets and strain gauges.

FIGURE 9.15 Instrumented and calibrated spherical hinge bearing as a load sensor for two load directions.

vehicle- and machine-manufacturing industries, load measurements form the basis of the continuous development of loading assumptions. This advantage can be used to increase the reliability of loading assumptions for designs, in particular the design of safety components. Moreover, by using long-term measuring concepts—the so-called "usage monitoring"—the changing usage profiles and customer requirements can be initially determined or finally verified.

9.2.2 Data Acquisition of Stresses

If strain gauges are implemented to evaluate fatigue strength, then the choice of sensors, their location, and orientation are of great importance. To ensure that the usual stress–strain relations and component fatigue strength are not impaired by holes, notches, keyways, and cut-outs, strain gauges can in general only be manually attached to accessible locations on the accessible surfaces of the component. If the governing stresses and strains are to be directly measured at a critical location, then the location of the measurement must first be chosen to be as near as possible to the assumed initiation point of the fatigue fracture. Secondly, the direction of the measurement must be chosen to coincide with the maximum principal strains and, if required, with the transverse direction. Since welded seams exhibit different characteristic types of fractures and failure locations, the correspondingly different possible strain gauge configurations are to be distinguished.

In joints that fracture from an undercut notch at a transitional cross section (see Figure 9.16), the location of the fracture initiation is, as a rule, accessible such that a strain gauge can be suitably attached near to the fracture initiation point.

In this case, the strain gauges are applied to the parent material at a definite distance from the seam. The reason for this is that the strains, which are integrated over the gauge length of the strain gauge and since, in the region of the run-out or in the notch of the seam, the cross section is not defined; a small shift of the strain gauge could produce a large change in the measured strain. The choice of the gauge length of strain gauge and its distance from the run-out of the welded seam depends on the plate thickness concerned. In Figure 9.17 and Table 9.2, recommendations are given for the choice and location of the strain gauges. Similar procedural regulations are given in the technical literature, for example, applications according to the "hot spot" structural stress concept of the IIW guidelines [43].

In joints where seams are subjected to longitudinal stresses and where the fracture runs transverse to the seam, one may assume in many cases that the overall fractured cross section was subjected to a uniform longitudinal strain. For this type of joint, the strain gauges that are attached to the parent material next to the run-out of the seam in the direction of the seam give, as a rule, the strain at the fracture initiation point (Figure 9.16c and d). In particular cases, it is advisable to attach a second strain gauge to the opposite side of the sheet or seam. By assuming a linear strain distribution, it is then possible to interpolate the strain at the fracture initiation point from the strains at both measuring locations.

In contrast to this, joints, whose fracture initiation points are located at notch roots, are in general inaccessible to a direct stress–strain measurement. In these cases, knowledge of the notch root geometry is required in order to construct a numerical model of the welded seam. This numerical model can be verified using data from strain gauges attached near to the welded seam subjected to

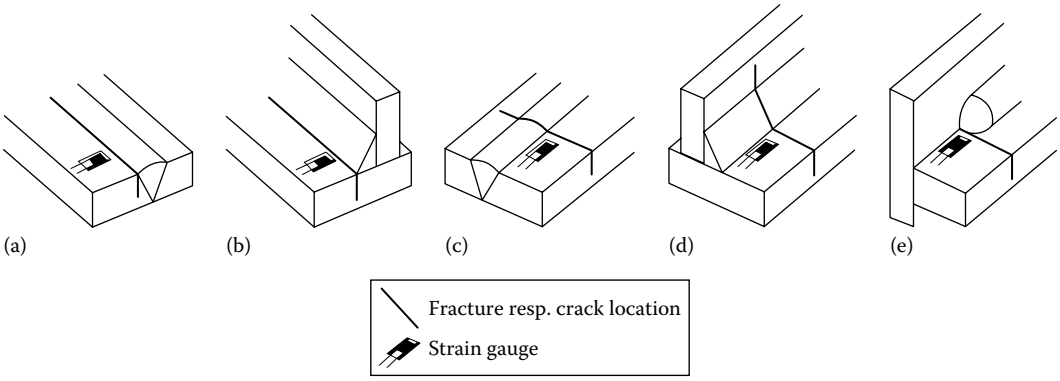

FIGURE 9.16 Possible configurations of strain gauges at welded seams where the fatigue fracture is initiated on the seam's upper side, that is accessible to measurement.

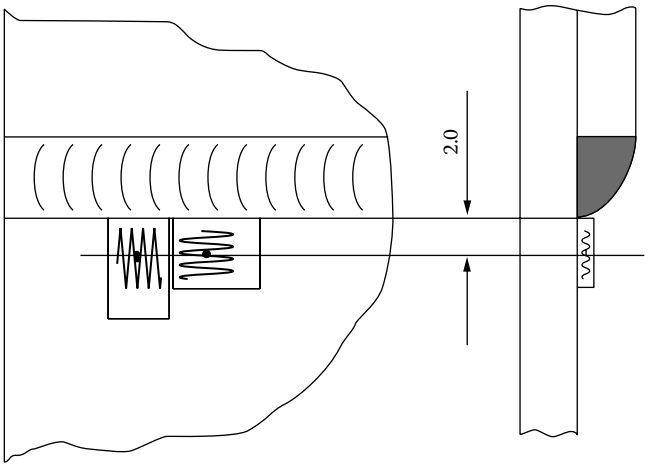

FIGURE 9.17 Recommended applications of strain gauges at run-out of welded seam.

TABLE 9.2
Recommendations for Attaching Strain Gauges at Run-Out of Welded Seam

specified loads, which occur under operating conditions. The evaluation of the notch root is then carried out using the numerical simulations and local concepts.

9.3 DERIVATION AND GENERATION OF LOADS FOR EVALUATION AND TESTING

Realistic assumptions about loads are essential for a sound analysis of structural durability. A simple application of a CA loading instead of the loading during service, which is characterized by VAs can lead to misjudgements when analyzing complex components with several possible failure sites.

Figure 9.18 shows an example in which failures occur at different regions depending on the chosen amplitude of the CA loading. A fatigue analysis is only possible by considering the service load spectrum.

The scatter band of service loads is typically larger than that of the component's strength (see Figure 9.19). On the other hand, relatively small changes in the loading already lead to comparatively large changes in the fatigue life. For example, an increase in the load's amplitude of 15% leads to a shortening of the fatigue life by almost a half (assuming a CA loading and an S–N curve's gradient of $k = 5$). The outlay on more appropriate load assumptions reduces uncertainties in design and thereby leads to lighter or more cost-effective designs.

9.3.1 Fundamentals and Influences on Fatigue Life

In deriving the load-time series or load sequences, various aspects should be taken into account. Some of these aspects are discussed in the following. For an overview on load data analysis from the perspective of structural durability, see [44–51].

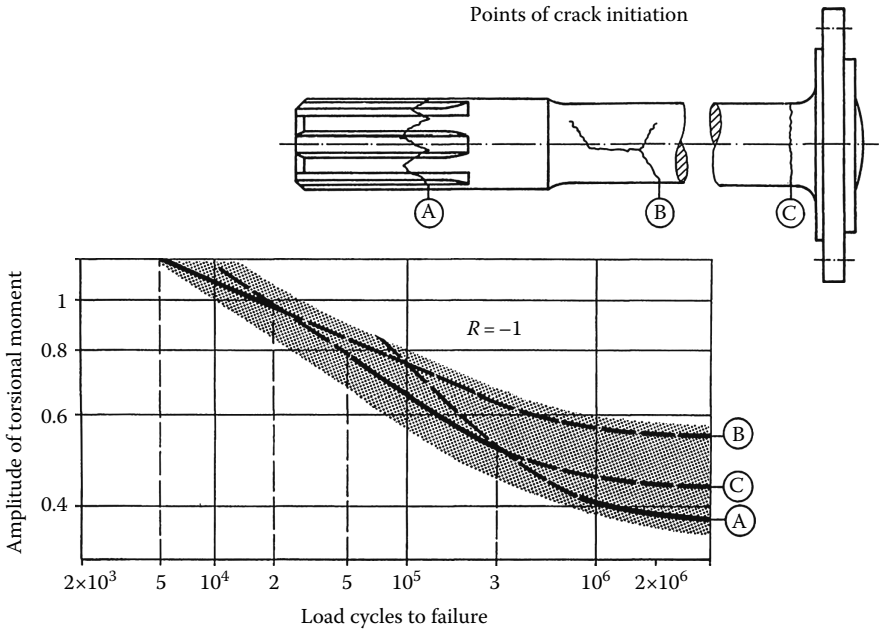

FIGURE 9.18 S–N curves of a drive shaft under CA torque loading: locations of crack initiation depend on load amplitude.

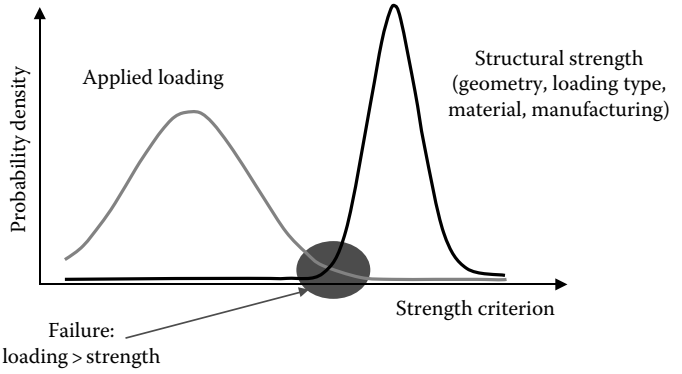

FIGURE 9.19 Applied loading and structural strength: 1D perspective.

The derivation and generation of loads for numerical and experimental analyses of fatigue life are, as a rule, based on evaluating service loads (e.g., using measurements of loads during service), and on a service profile, which is given by the anticipated use of the structure under consideration (see Figure 9.20).

Counting procedures [52] form the basis for the specification of service loads, that is, the determination of parameters (amplitude, mean value) and the number of occurrence of cycles. In the case of multiaxial loading or dynamically responding systems, other characteristics of the load-time function are important (correlation, frequency content, etc.). In each case, the operating loads are to be determined and specified separately for all loading conditions occurring during the anticipated use of the construction.

The service profile includes the frequency, distribution, and sequence of the individual loading conditions for the construction's service life. On establishing the service profile, decisions must be made that go beyond the purely technical considerations, since they can affect questions of product liability, costs, competitiveness, company image, etc.

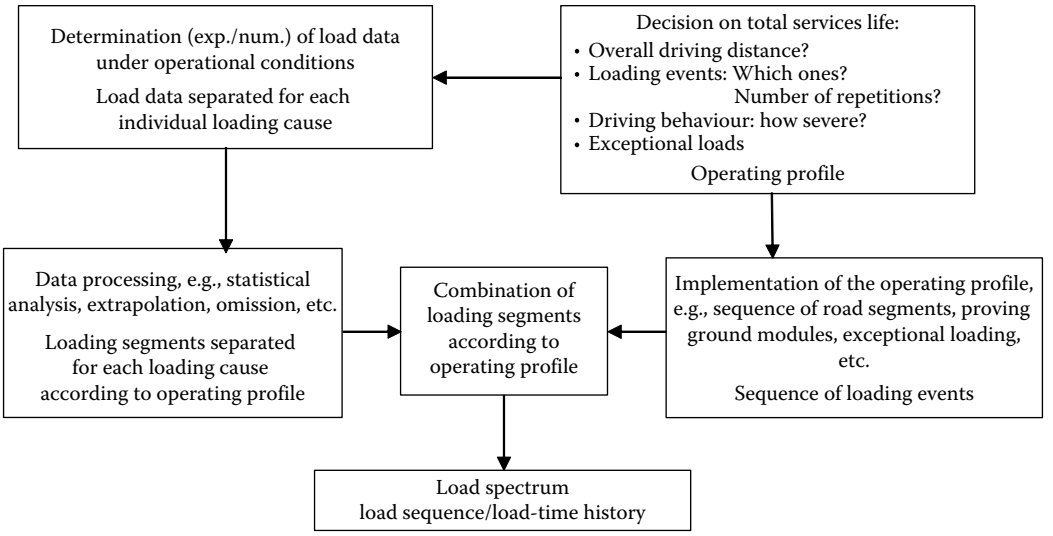

FIGURE 9.20 General approach for load assumptions: determination of load spectra or load sequences.

Both the compendium of loads, determined for all the individual loading conditions corresponding to the service profile, and the allocation of a probability of occurrence ultimately lead to a design spectrum which can directly lay the foundation of a numerical analysis.

Usually, the number of cycles in the design spectrum is so large that further modifications are necessary with regard to a reasonable test period for deriving test spectra or testing load sequences (drive files), as the case may be. Methods for generating shortened load sequences or load-time functions, as the case may be, will be elucidated.

9.3.1.1 Mission Analysis and Usage Monitoring

Typically, the total loading of a structure is generated by more than a single load or one operating condition. Examples are the different phases, maneuvers, payloads, and environmental conditions of a vehicle's usage (cornering, braking/accelerating, rough road conditions). The compilation of the overall spectrum requires one to separately record the individual operating conditions and to extrapolate them to the total service life. Figure 9.21 exemplifies the sub-spectra of the vertical and transversal forces, which were determined for a railway vehicle's wheel set (extrapolated to the total mileage with more than 10^9 cycles) [53].

The spectrum's region, which covers the most frequently occurring amplitudes, was obtained by superimposition of the sub-spectra multiplied by the number of repetitions during the total service life. Extreme values are to be considered separately.

For cars or motor cycles, the service profile of the customer's usage is not known completely. In this case, the basis for compiling loading spectra can be provided by questionnaires, long-term measurements on customer's vehicles as well as by carrying out supplementary measurements under known conditions [54].

9.3.1.2 Loading Sequence and Load Amplitude Variation

It is known that the sequence and the (missing) variation of load amplitudes influence the fatigue life. Figure 9.22 depicts an example of this for measured service loads. Experimental investigations on circumferentially notched specimens subject to synthetically generated load sequences (Figure 9.23) show differences in fatigue fracture life by a factor of $f_N \approx 0.5$–2, depending on the order of the load cycles. As a consequence, attention should be given to a realistic combination of the individual load amplitudes on generating load-time sequences.

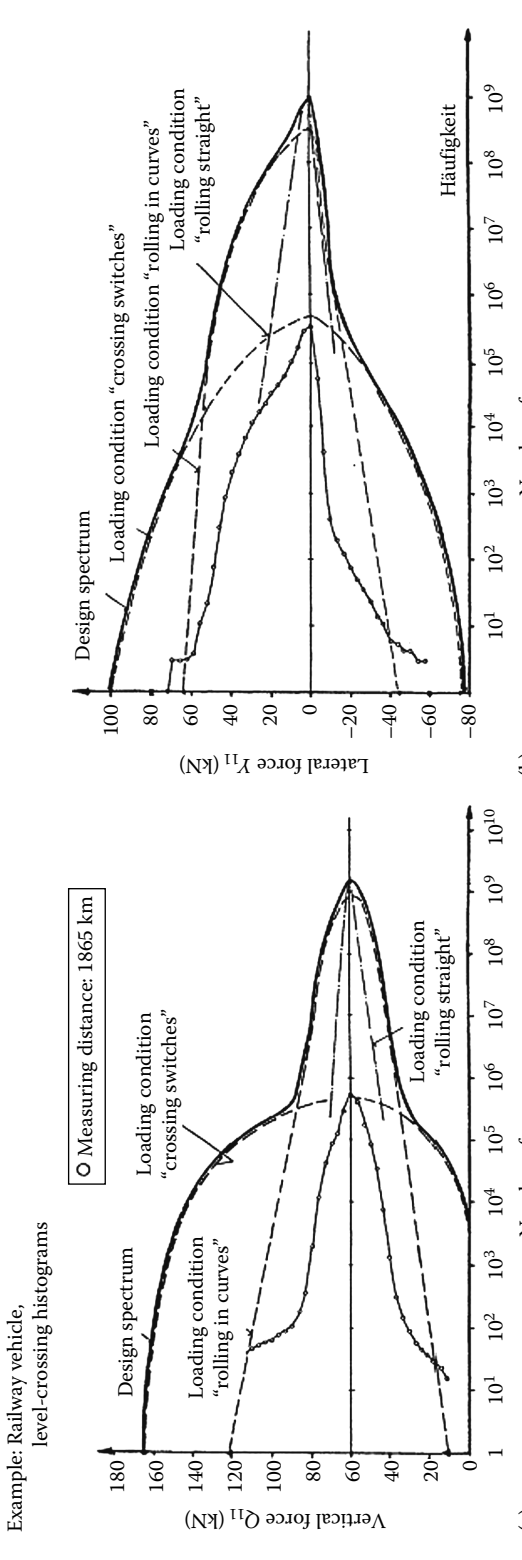

FIGURE 9.21 Composing a design spectrum based on individual loading conditions: (a) vertical force Q_{11} and (b) lateral force Y_{11}.

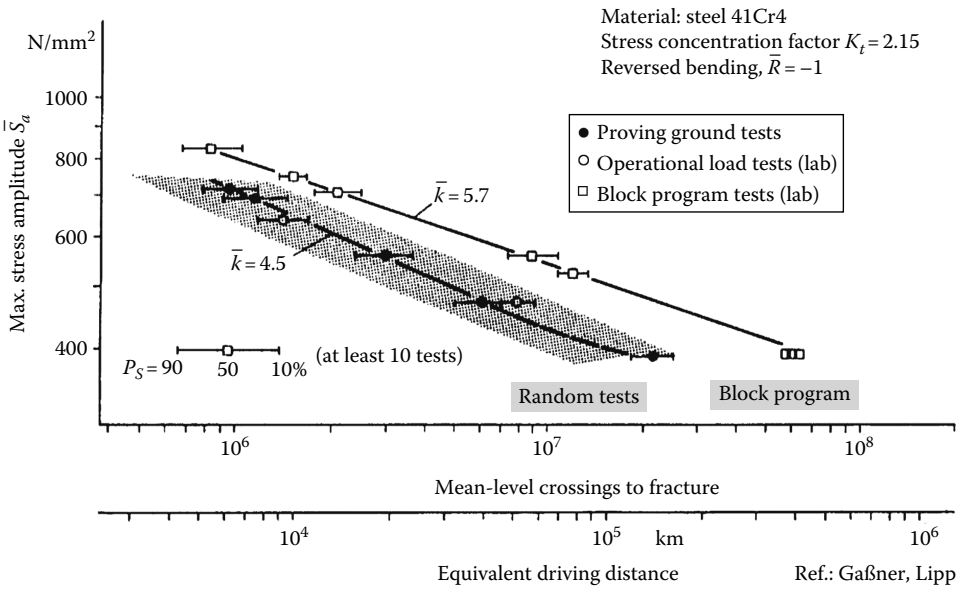

FIGURE 9.22 Fatigue life curves from proving ground and laboratory tests (constant calculated damage sum for same maximum stress amplitude).

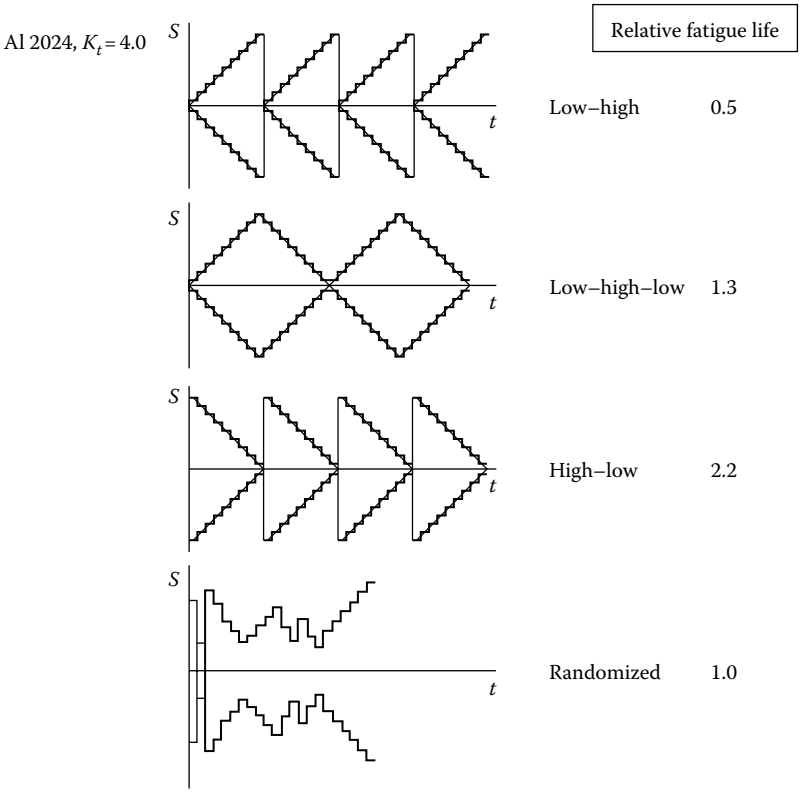

FIGURE 9.23 Influence of sequence and combination of cycles on the fatigue life of notched specimens.

9.3.1.3 Influence of Overloads on Fatigue

On specifying extreme loads, overloads that only rarely occur or special events for a testing sequence, different phenomena in material behavior are pertinent. The effects of extreme loads or overloads on the fatigue life depend on, among other things, the type of loading, magnitude and frequency of occurrence, component's geometry as well as the material. Overloads can both extend or shorten the fatigue life (or act in a neutral manner).

Shell-type structures in the aircraft industry mainly demonstrate fatigue crack growth under plane stress conditions. Here, the fatigue life–extending effect of (tensile) overloads is known to be related to crack growth retardation due to crack closure. This influence is less pronounced for compact and massive components (where plane strain conditions as well as a smaller plastic zone are more likely at the crack tip).

Larger pre-strains that exceed the elastic limit in material specimens lead to a decrease in fatigue strength for a high numbers of cycles applied. However, overloads frequently have less or no effect on the structural strength of metallic materials provided that the overloads produce no macroscopically observable cracks or stable residual stresses that are not rearranged owing to the operating loads. For extremely flat S–N curves (e.g., material specimens, lightly notched components subject to torque loads), overloads can significantly decrease the fatigue life or the fatigue strength, as the case may be.

9.3.2 Extrapolation of Measurements

Estimating expected extreme load values is an important aspect of specifying the (sub-)load spectra. If the expected extreme value is not already contained in the measurements (estimatable, e.g., from physically limiting conditions), extrapolations using extreme value statistics provide useful assistance [50]. Here, it is assumed that the frequency distribution of the process, from which the extreme value originates, obeys an exponential distribution law and that no physical limit exists for the maximum load values. Within the scope of the analysis, the question should be answered: how the scatter of the measured extreme values is to be treated. That is, whether the scatter of the measured extreme values (a random sample) and that of the design spectrum (total population) resemble each other.

In [55], a procedure is described in which only those extreme values (maxima or minima, as the case may be) which lie, respectively, above and beneath a stipulated threshold provide the basis for the extrapolation. This is particularly important when the data base contains only a small number of measurements. That is, more than one extreme value must be employed using a single measurement. The extrapolation can also be carried out based on the Rainflow matrix [56,57]. Here, the distribution of the additional numbers of cycles, which arise from the extrapolation, is described by a scalable function, the so-called kernel. The application of this procedure requires some experience, in particular for the scaling of the kernel.

9.3.3 Shortening of Load-Time Sequences

It is frequently required to shorten a design or test spectrum in order to be able to carry out tests within an acceptable time period and budget. Figure 9.24 gives an overview of the methods which permit the shortening of uniaxial load signals.

Typically, shortening processes that operate with time windows are applied to time sequences, since these processes also allow handling of multiaxial loading. Here, the damage-relevant time segments are to be identified in the individual channels, which may be supplemented with their linear combinations. The damage-relevant time segments are identified for each channel. Such time segments, which do not show any significant damage content for all individual channels, are removed from all channels. The Rainflow counting [58] is generally employed for components

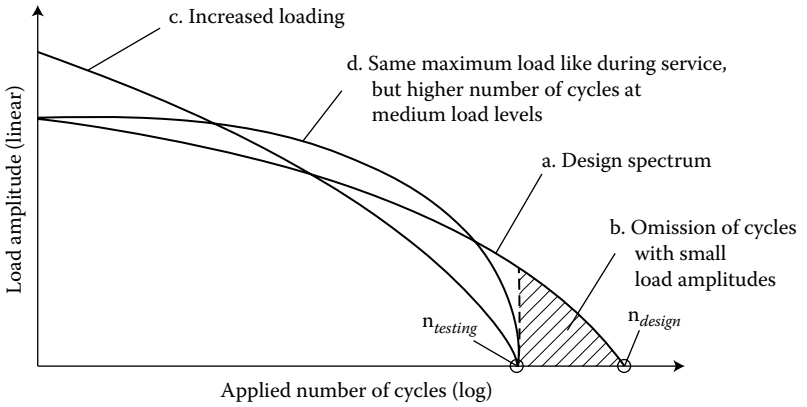

FIGURE 9.24 Overview on procedures to reduce the testing time.

whose fatigue life is independent of the loading frequency and can be characterized by the amplitude, the mean value and the number of cycles applied. With uniaxial loading, a shortening process can also be carried out based on a Rainflow matrix.

9.3.3.1 Omission

In the first instance, small cycles can, for this purpose, be removed or filtered (omitted) from the load sequence. Here, the criterion must be that neither the fatigue life (expressed as equivalent service life, driving distance, etc.) nor the failure site(s) are changed. The following have been found to be reference values for "permissible" filter limits for metallic components (e.g., chassis components with typical spectrum range of approximately $H_0 = 10^7$ cycles):

a. Approximately 15% of the maximum amplitude
b. Approximately 50% of the considered detail fatigue strength at the knee point of its S–N curve

For criterion (b), knowledge/assessment of the "fatigue strength at the knee point of the S-N curve" is required (the knee point of the S–N curve characterizes the strength, which does not, or only slightly, falls with higher number of cycles). On testing complex structures with numerous potential failure sites (e.g., a vehicle's front axle), this method is thus—without a previous numerical analysis—applicable only to a very limited extent.

It is advantageous to carry out the filtering using the Rainflow method in order to preserve the sequence of the remaining load cycles. Furthermore, the influence of the mean loads is taken into consideration (filtering out cycles of larger amplitudes with zero mean loads in comparison to cycles with nonzero mean loads). This requires knowledge of the mean load effects (e.g., the mean load sensitivity M). When the relationship between the load and the local stresses and strains is not known or not well-defined, both the tensile and compressive mean loads must be considered as detrimental. Bending load cases are an example of this.

For components which are multiaxially (nonproportionally) loaded, a shortening is typically carried out based on the load-time sequence. Simultaneously, additional channels, which are generated from linear combinations of the original channels, can also be taken into consideration. Using the procedure to simultaneously condense and optimize multiaxial time signals as an example [59], the modification of a five-channel signal for operating a test rig is outlined in Figures 9.25 and 9.26. Besides omission, adapting the load variations (velocities, accelerations) to the potential of the test rig can still be carried out. With respect to the latter, the component damage must be independent of the loading frequency.

FIGURE 9.25 Simultaneous procedure: example with five load-time histories.

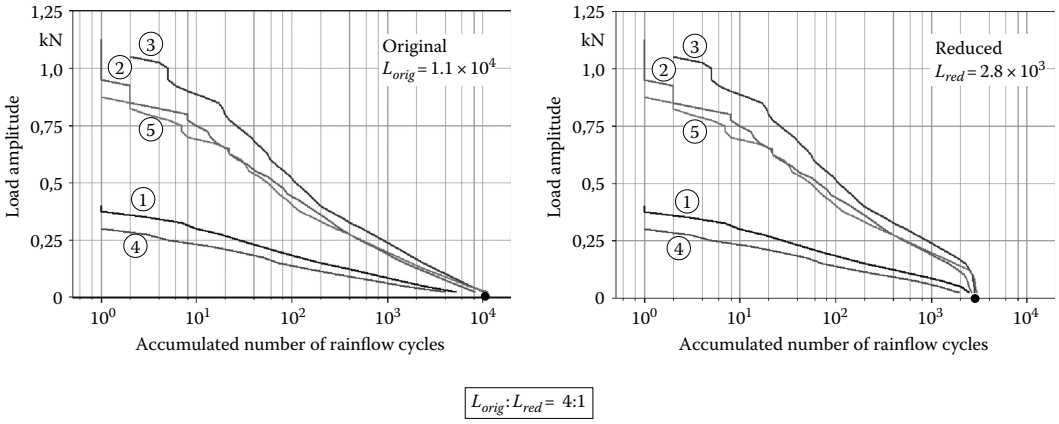

FIGURE 9.26 Simultaneous procedure: range-pair histograms of original and reduced signals.

9.3.3.2 Truncation

Limiting overloads or high loads (truncation) leads to a shortening of the fatigue life for shell structures (plane stress conditions), such as those prevailing in the aircraft industry. There is a danger of overestimating the fatigue life of aircraft parts, which are not subjected to these overloads in service. With larger sheet thicknesses, the crack retardation effect is not or, as the case may be, is less strongly pronounced. In massive structures, overloads, if anything, tend to shorten the fatigue life or act neutral manner.

Unrealistically high overloads or, as the case may be, unduly raising the total level of loads to shorten the testing time conceal the danger that this causes unrealistic rearrangements of the residual stress field or a loosening of bolts, which can change the test results compared to the actual service operations.

9.3.3.3 Elastomeric Components

Filtering load-time sequences for complex elastomeric components, such as hydro bushings, requires additional considerations. In contrast to the assessment of massive metallic components, the nonlinear force-deformation behavior as well as the frequency-dependent effects, such as for example the attenuation, should be considered in the load analysis. Based on investigations in [60], procedures [60–62] were introduced, in which the external loading was resolved into separate loading components (elastic force, damping force, and force at limit stops) by taking into account quasi-static load-displacement curves in order to improve the detection of different causes of damage. Here, the filtering may only be carried out in time periods where the deformations are not limited by contact.

9.3.4 Synthesis of Load Data

It is assumed that load-time segments (gained from measurements or numerical simulation) exist for both the relevant individual loading conditions (and channels) and the service profile. With this input, the design spectrum can be compiled. Examples of loading sub-spectra are depicted in Figure 9.27 for an axle component shown in Figure 9.28. The individual load-time segments contain the information concerning both the correlation of the channels and the frequency content during service loading.

9.3.4.1 Combination of Loading Segments

Typically, the load-time functions, which form the basis of the design spectrum, are quite long and therefore unwieldy for both the physical testing (drive-file iteration) as well as the numerical simulation, e.g., the simulation for multiple bodies. Thus, often a load-time sequence is compiled that consists of as few correlated load segments as possible, which are typical for the individual physical load cases. With this, the correlation (and frequency content) corresponding to the service conditions is guaranteed for the fatigue-critical loadings. An example of this is the

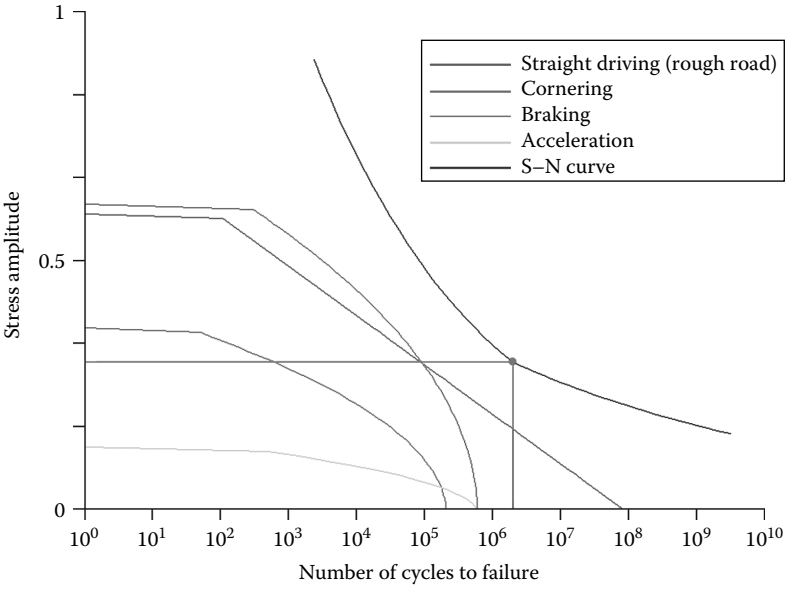

FIGURE 9.27 Local stress spectra for individual loading conditions.

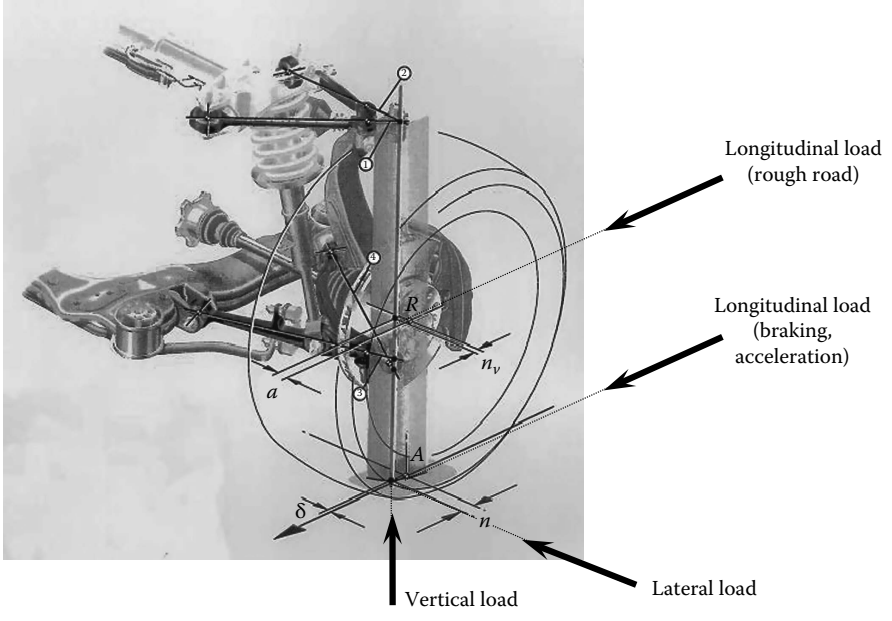

FIGURE 9.28 Multiaxial loading—example: loads acting at a wheel.

multiaxial loading program, which is based on synthetic segments for axle components outlined in Figure 9.29.

In the following, the general case of multiaxial loading is to be illustrated, for which a design spectrum exists in the form of a set of Rainflow matrices or range-pair and level-crossing histograms (for individual channels), and for which time histories for all channels must be derived. In the Simultaneous Procedure for producing multiaxial load-time sequences [59], the required load segments LS_i together with their number of repetitions (or frequency) $f(LS_i)$ and, if necessary, their

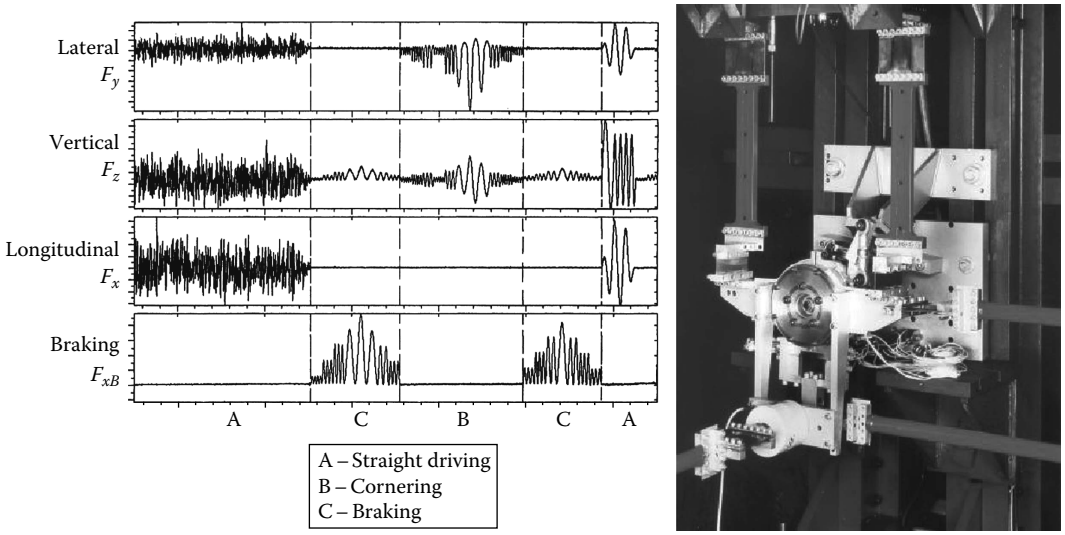

FIGURE 9.29 Multiaxial load program for axle components based on synthetic segments.

scaling factors $a(\mathrm{Ch}_j; \mathrm{LS}_i)$ are determined using an optimization procedure (Figures 9.30 and 9.31). A similar method is described in [63], which is based on an optimization of the Rainflow matrices without the option of scaling amplitudes. A prerequisite for the success of these approaches is that the basic load segments (events) contain all the relevant combinations (phase and amplitude relations) of the acting loads.

With uniaxial loadings, the synthesis of the load data can only be carried out using Rainflow matrices under specific boundary conditions. Here, the load sequence is derived from the resulting Rainflow matrix by means of a reconstruction procedure.

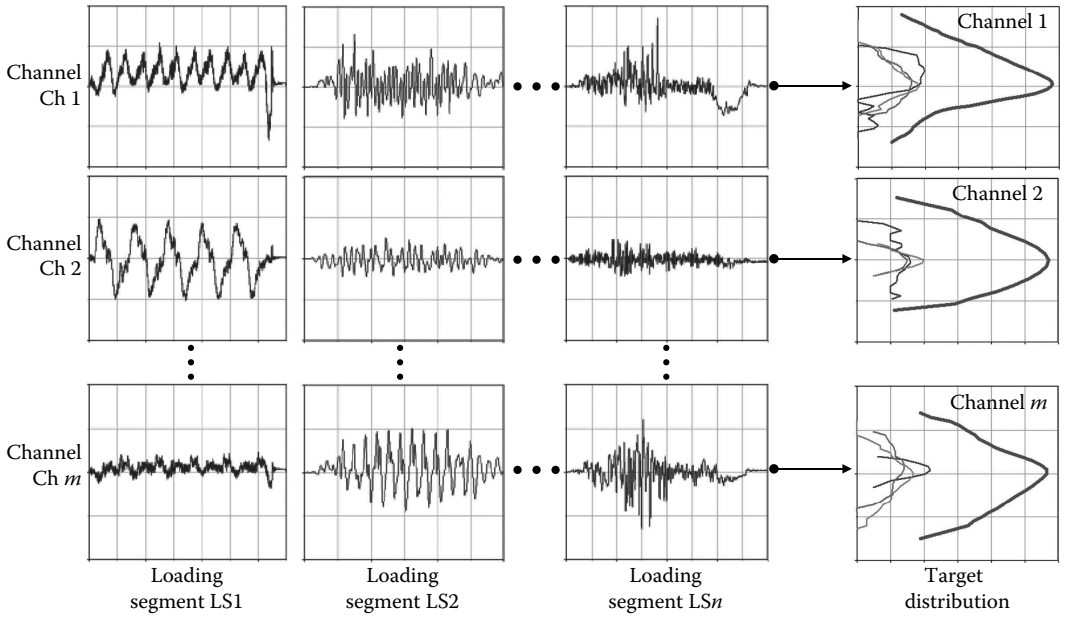

FIGURE 9.30 Generation of multiaxial load-time histories by correlated loading segments (determine frequencies $f(\mathrm{LS},i)$; scaling factors $a(\mathrm{Ch},j; \mathrm{LS},i)$).

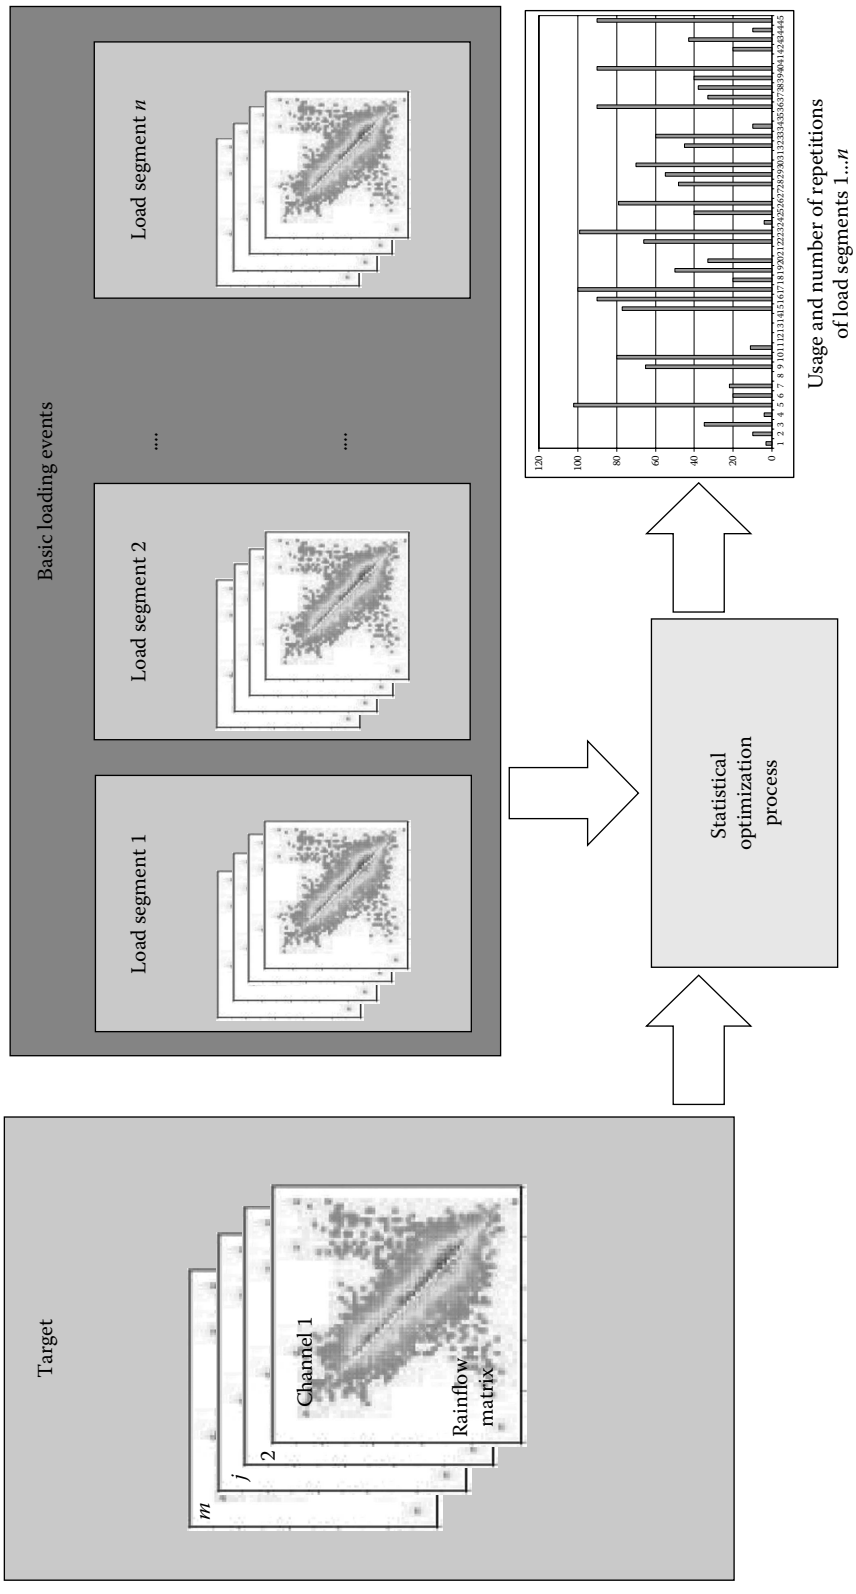

FIGURE 9.31 Approximation of target based on loading segments and their Rainflow matrices.

9.3.4.2 Frequency-Based Analyses

In principle, it is possible to generate the load-time sequences from the frequency region (by using the power spectral density together with other input parameters or, as the case may be, using assumptions) [64–67]. However, the corresponding procedures are only partially adequate in reproducing the extreme values of a signal.

The frequency content of a signal is vitally important for flexible and/or vibratory structures. Here, caution must be taken that the load amplitudes on the test rig are applied with the appropriate frequency spectrum. Typical application examples are axles or entire vehicles, but also shock absorbers, hydro bushings, or tuned mass dampers.

9.3.5 Standardized Load Sequence CARLOS TC

The previously described methods were used to compile the standardized load sequence CAR LOading Standard Trailer Coupling (CARLOS TC). This load sequence is used to design and test passenger car trailer couplings (TCs). Typically, apart from the visible hook (ball joint), the TC includes a construction consisting of a cross member and longitudinal struts, which incorporates the hook and transmits the trailer service loads into the chassis. These loads act on the coupling ball in the three spatial directions.

A considerable amount of measured data from TC service loadings together with the verification requirements based on the experience of several motor vehicle manufacturers was made available for deriving a three-channel load sequence. The D-value was used as a parameter for normalization, which is calculated from the mass of the pulling vehicle m_V and that of the trailer m_T (see Figure 9.32). By using the "Simultaneous Procedure" [59], the following objectives were realized: near service range-pair histograms and correlations between the force components as well as adapting the testing frequency, velocity, and acceleration of the test's control signals to the performance of the hydraulic actuators. The CARLOS TC load assumptions exist in the form of a three-channel load-time sequence that is subdivided into three modules for practical purposes. Figure 9.33 depicts the longitudinal force frequency distributions of the test modules M1, M2, and M3 with which the required overall spectrum is realized according to an iterative code.

Besides comparing the measured loads when appraising a prepared load sequence, it is also of interest to compare the local stresses and strains. Figures 9.34 and 9.35 [68] show this as an example of a relative comparison of local damage intensities caused by both loading with CARLOS TC and with loads, which were measured using a manufacturer's vehicle on a test track.

Finally, it should be pointed out that standardized load sequences can represent a benchmark for appraising load assumptions beyond direct applications for testing or designing.

9.4 ACCELERATED LIFE TESTING BY LABORATORY ROAD SIMULATION

Traditionally, the life testing of the vehicle and its major components has been performed on the road. Since long-term testing cannot be used within the vehicle development process, the life-cycle events have to be condensed significantly. Therefore, all car manufacturers developed so-called proving grounds and accelerated test strategies giving the capability to shorten the time for durability testing.

While road testing relies on the availability of complete vehicles, these tests are quiet costly. Consequently, the enhancements in building and controlling multiaxial test rig hardware that started in the 1960s were used to develop strategies for accelerated life testing by laboratory road simulation. Today, the laboratory-based durability approval is performed for many subsystems and will be even more important in the future because there are so many platform derivatives as well as niche products, which have to be developed within extremely short time scales [69].

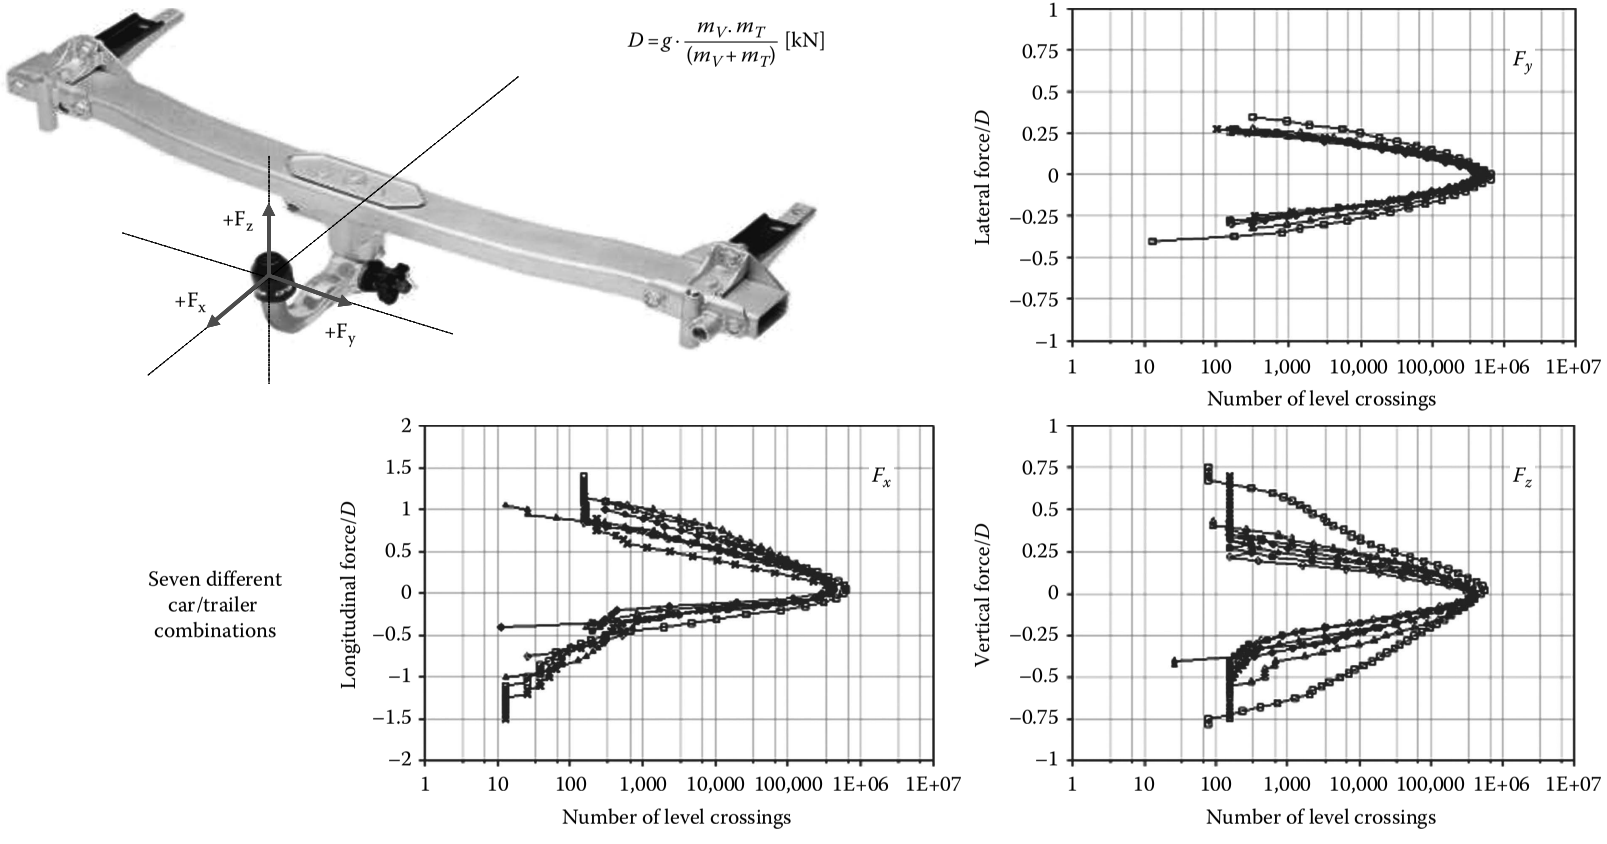

FIGURE 9.32 CARLOS TC: measured load spectra (normalized by *D*-value).

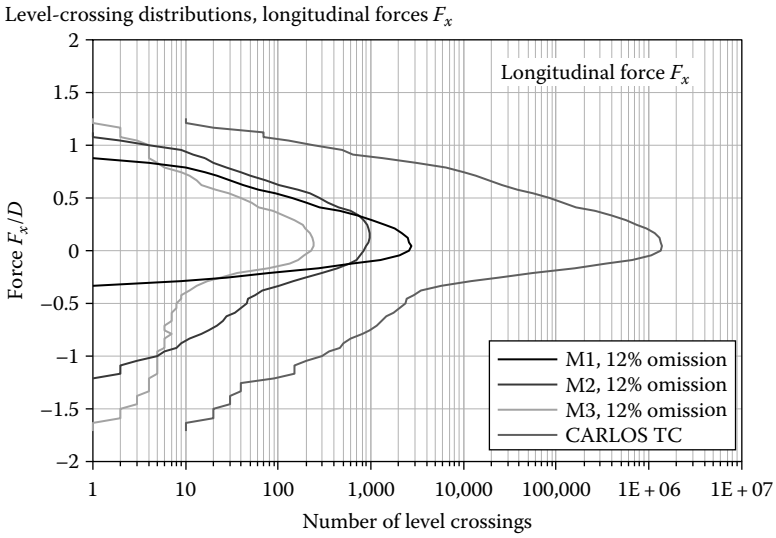

FIGURE 9.33 CARLOS TC: distributions of test modules M1, M2, M and whole test procedure 10*(5*(10*M1+M2)+M3).

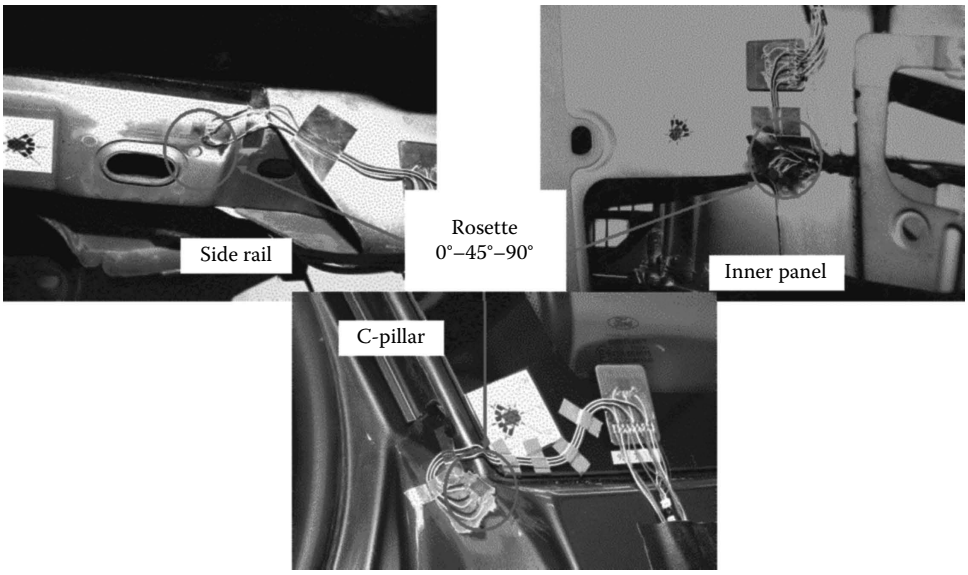

FIGURE 9.34 Measurement locations for correlation analysis on a Ford Focus (five doors).

9.4.1 Road Testing and Road Simulation

Usually, the final durability evaluation and approval is performed by road testing, which is carried out on a vast array of test beds, proving grounds, and public roads. These tests are a collection of worst driving and obstacle routes imaginable in customer operating scenarios—pot holes, rough cobblestones, speed bumps, non-surfaced roads, railway crossings and others. They are highly dynamic courses, on which chassis and driveline, vehicle body, and the running gear are tested [70].

Laboratory road simulation means the replication of conditions experienced by a vehicle in service—especially the simulation of motion and forces for the vehicle and its subsystems [71].

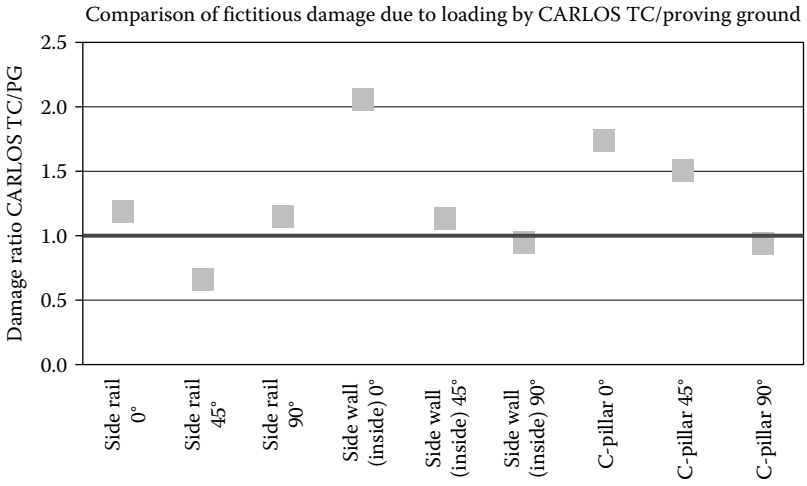

FIGURE 9.35 Correlation analysis between proving ground tests and CARLOS TC on a Ford Focus (five doors).

The advantage of service simulation is that these tests can be carried out in a controlled manner to enhance repeatability while offering savings in time and cost over road testing. Accelerated life testing is feasible, providing significant advantages for the vehicle development process [72].

Successful laboratory road simulation means that there is a complete understanding of the constraints and loading conditions and the practical limitations of the test rig hardware are known exactly.

9.4.2 Definition of System to Be Tested

The loading conditions are usually determined by measurements from real vehicle or workhorse tests on the road. Typically, wheel forces and motion, as the basic inputs for vehicle dynamics, are examined by using sensorized wheels or wheel force transducers. Hence, the basic excitation of the vehicle running on the ground is accessible, which helps to identify this portion of transient input data [73]. Actually the parts, which interface with the ground directly, are tires, wheels, and hubs—acting as unsprung rotating masses. The next subsystem is given by springs, dampers, and structural suspension components, such as struts and beams, having different kinematics compared to the rotating parts. Then the loading is transferred into the vehicle body and other major systems.

At this point there are a few main groups, which are different from each other in a couple of terms. Hence, the appropriate strategy for laboratory simulation clearly depends on the system to be examined. Since the suspension, the brakes, and the steering are safety critical subsystems, all of these need to be evaluated extremely carefully. Rotating components such as wheels or hubs are totally different to other suspension parts with regard to load kinematics; this has to be considered when choosing the test rig hardware for the laboratory simulation. Since the objective of the service simulation is to reproduce the damage of the operational conditions, subsystem constraints and loading have to be as close to reality as possible.

Therefore, laboratory road simulators are multiaxial loading systems to which the vehicle or one of its subsystems is attached.

9.4.2.1 Spindle-Coupled Road Simulators

For the interface between the ground and the vehicle, the road simulators often use spindle-coupled actuators for the loading operation [74]. A single corner may be used as an environment for testing and developing a quarter-car suspension system. By using two or four such corners, a complete

FIGURE 9.36 Road testing and laboratory road simulation.

suspension or even a full vehicle test rig can be configured [75]. Here, the vehicle can be tested as a fixed body having some ground coupling, or as a floating body simply supported by its inertia.

The four–post test rig provides the basic platform for carrying out various dynamic tests targeted at the vehicle chassis and body. More advanced test rig hardware enables up to 6 DOF per corner, which is the basis for a complete and sophisticated laboratory road simulation having vertical, lateral, and longitudinal translations, brake and drive torque, as well as steer and camber moment (Figure 9.36).

Accuracy issues may be caused by cross talk of the different channels, or some interference of the test rig loading devices and the vehicle suspension with regard to resonant frequencies.

9.4.2.2 Wheel and Hub Road Simulators

Since the load kinematics of wheels and hubs are totally different from suspension beams and struts, the use of spindle-coupled road simulators is not appropriate for durability testing of unsprung rotating components. Actually, these parts have cyclic loading sequences simply because the local stresses are given by the height of the external loads as well as the position relative to the load input area. Consequently, the design of a laboratory road simulator for wheels and hubs has to deal with the complete assembly including the tire as the element for transferring the loads into the subsystem.

The most complete laboratory road simulator for wheel durability testing is the biaxial wheel fatigue test machine (ZWARP) [76], which uses an inner drum as the moving ground (Figure 9.37). The wheel assembly is loaded by vertical and lateral actuators, which are capable of introducing service-like operational conditions such as straight driving on rough roads or heavy dynamic

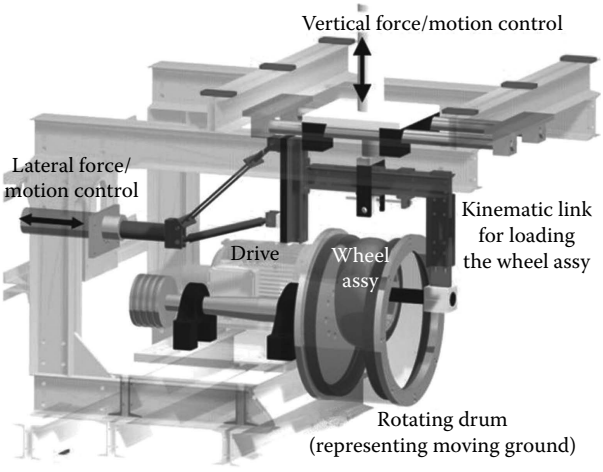

FIGURE 9.37 Biaxial wheel fatigue test machine (ZWARP).

cornering. Occasionally, torque loading can be introduced to examine the fatigue behavior of spoke-type wheels or performance issues such as unintentional wheel bolt loosening.

The so-called ZWARP technology is the leading international standard for wheel and hub laboratory road simulation [77]. Different to the biaxial simulation, there are more simplified durability procedures such as rotating bending or radial fatigue tests, which do not simulate service-like loading.

9.4.3 Load File Development

Vehicle dynamics implies loading, which is time-dependent. Hence, a special characteristic of using road simulators is the load file, which gives the force or motion time history for the individual channels. The load files can have standardized loading information, which is scalable for the specific vehicle, or they can be derived from individual road measurements.

The standardized load files include dedicated vehicle maneuvers such as straight driving, cornering, or braking, as well as information about load amplitudes and number of cycles [78]. They are generated semi-analytically by calculating the individual load histograms for all relevant vehicle maneuvers. Finally all load sequences are compiled and typically a block-type load file is created, which can be optimized very well for accelerated life testing.

While standardized loading information has its advantages, especially when road load data are not available—that is in an early stage of the vehicle development process or for a comparative benchmark of different vehicles—the dedicated load file accounts for all specific properties regarding vehicle and roads used. There is some significant amount of work to create such a load file having true time histories for the individual DOF (degree of freedom). By using techniques such as omission, extrapolation, or scaling, the basic load amplitude and phase correlations between the different load channels are kept, and the load file finally represents an accelerated test spectrum [79].

Since overstress acceleration of the test spectrum could cause severe impact on the damage mechanism by generating stresses beyond the structural yield limit, the more appropriate strategy is to apply usage rate acceleration.

Typically, the time scaling between the design life and the duration of the test is about 30 for suspension durability. This means the complete vehicle life cycle is performed within a period between 100 and 600 h. While the biaxial wheel fatigue testing using standardized load information and running at 100 kph takes only about 100 h, the range of frequency scaling for multiaxial suspension tests is limited by the test rig hardware as well as by the temperature shift of elastomeric bushings.

To control the different load and motion channels, digital controllers are used. The process of setting up highly accurate replications of multiaxial time histories is supported by road simulation software. These products create the test rig drive file typically by using an iteration strategy. Based on an identification process of the system's response, the initial load information is created and this is subsequently refined until the time histories are generated with high precision.

Since fatigue phenomena are the result of local strain time histories, it may cause inaccuracies when only forces and motion are controlled. Hence, there is often additional information from strain gauges at heavily stressed components, which has to be considered for the drive-file iteration. Highly sophisticated iteration strategies use virtual test laboratory support to reduce the effort for test rig hardware iteration. Therefore, a multi-body dynamics (MBD) representation of the test rig is used to identify improved initial loading information, which subsequently reduces the effort for hardware iteration.

9.4.4 Evaluation of Test Results

The repeatability of accelerated life testing by laboratory road simulation enables the test engineer to decide on the durability approval for the components tested. Since there is a huge amount of scatter with regard to durability performance—much more than dimensional tolerances only—an

TABLE 9.3
Multi-Tiered Failure Evaluation

Type	Object	Mode	Remark
I	Failure	Severe operational incident	Not allowed for safety relevant parts
II	Intervention	Unplanned occurrence, that requires interaction on maintenance level	
III	Event	Not related to failures	Engineering interest due to its frequency of occurrence

appropriate number of samples has to be tested. The exact number of samples depends on the strategy for reliability growth that is chosen. Within automotive development, there are usually a couple of samples available, which are used for censored test strategies. Therefore, all samples must achieve a specific test life target having none or minor fatigue cracks only [80].

Since complex products can have a large number of distinct failure modes, a certain degree of flexibility is called for in the failure definition. Hence, it is beneficial to have a multi-tiered failure evaluation process, which takes into account time to failure and its severity (Table 9.3).

Consequently, the final approval depends on the results of the multi-tiered failure evaluation process, which helps to prepare a rating for fatigue failure risk assessment.

10.1 INTRODUCTION

Over the last two decades in particular, devices combining mechanical, electrical, and software functionalities, so-called mechatronic systems, became more and more important within all branches of the modern mass market. The reliability assessment of mechatronic systems is regarded to be one of the key issues in their acceptance. The present chapter aims to give an overview on the state of the art and some recent developments in this field.

In the first section of this chapter, a brief introduction to the theoretical background of reliability engineering is given (Section 10.1). Here, general aspects of reliability are addressed, such as failure probabilities represented by statistical distributions for quantitative analysis. Also, a well-established procedure for qualitative reliability analysis is introduced.

In the second section, some aspects of the reliability assessment of mechatronic systems in early development phases are presented (Section 10.2). Information about the design details of a system may not be available in an early stage. It is demonstrated how a reliability estimate can be obtained from existing data.

With increasing complexity of the systems, experimental costs become exceedingly large. For this reason, great efforts are taken to replace traditional test methods by computational simulation tools which have to be able to reproduce the complex system performance and also account for various failure and fatigue scenarios. The third section of this chapter presents an example of a qualitative numerical reliability investigation of a complex prototype automotive noise reduction system (Section 10.3).

Here, dominant failure modes are identified via numerical modeling and sensitivity analysis.

10.2 GENERAL ASPECTS OF RELIABILITY

The development of modern products is currently confronted with increasing functional requirements, higher complexity, interconnectedness of hardware, software, and sensor technology as well as low development and product costs. What significance does reliability have and what is even meant by this concept? The concept of reliability is connected to the functional capability of a product [1]. According to the VDI Guideline 4001 [2], reliability is defined as follows:

Reliability is the probability that a product does not fail during a specified time interval under given functional and environmental conditions.

To reach a high level of customer satisfaction, the reliability of the system must be regarded as the prime issue during the entire product development process. With regard to this, suitable organizational and substantive measures must be implemented [1]. It is important that all groups along the chain of development are included: errors occur at all phases. The available methodological tools should be appropriately chosen during the entire product lifecycle and consistently implemented in a coordinated way (Figure 10.1).

Reliability analyses can be subdivided into qualitative and quantitative approaches [1,3]. As the aim of qualitative analysis is a systematic investigation of failure, the aim of quantitative analysis is to calculate the reliability. Figure 10.2 shows different qualitative and quantitative reliability methods [1].

In the following, a few essential basic principles of reliability engineering are presented. On the one hand, fundamental terms for the calculation of the reliability as well as different distributions are discussed. On the other hand, the most established qualitative method—the failure mode and effects analysis (FMEA)—is presented.

10.2.1 Quantitative Reliability

To describe failure behavior, the following statistical functions can be used: Probability density function $f(t)$, distribution or failure probability function $F(t)$, survival probability or reliability function $R(t)$, and the failure rate $\lambda(t)$.

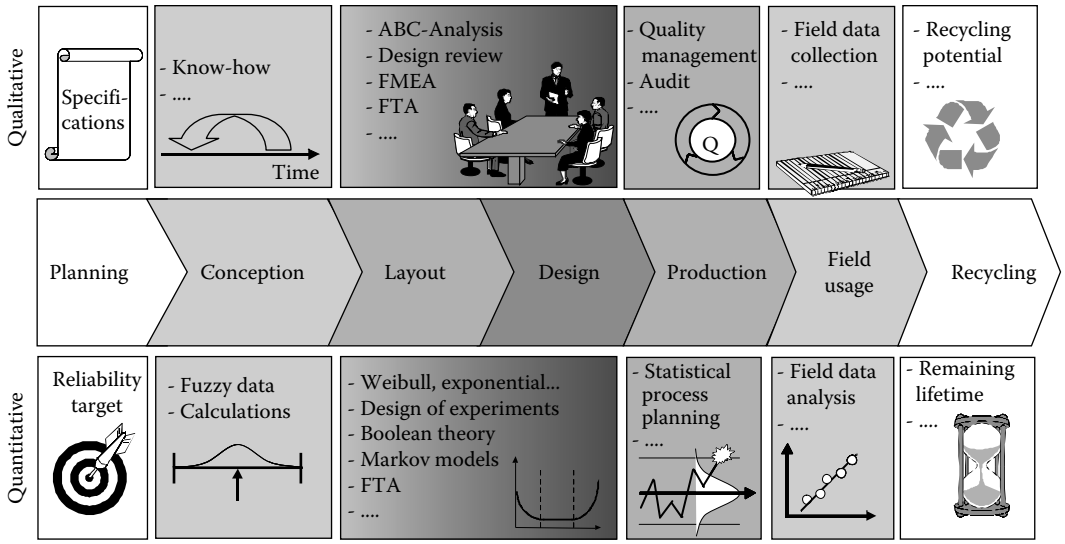

FIGURE 10.1 Qualitative and quantitative reliability methods in different phases of the product life cycle. (From Bertsche, B., *Reliability in Automotive and Mechanical Engineering*, Springer, Berlin, Germany, 2008.)

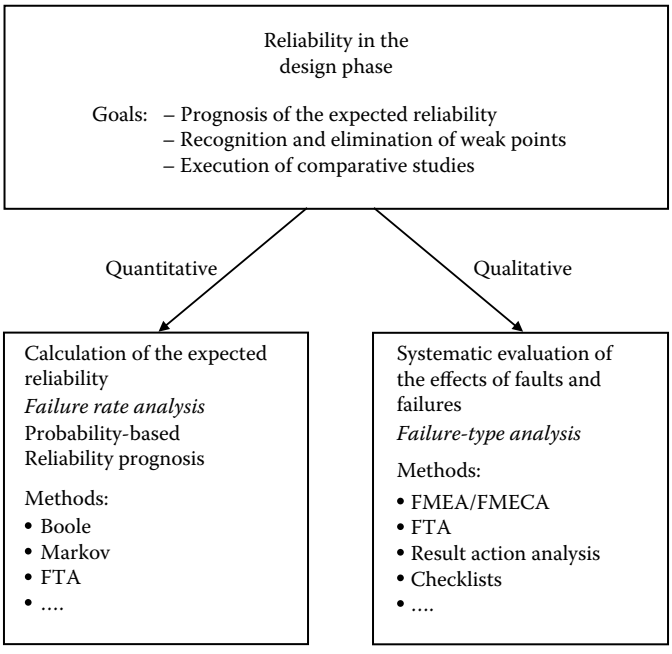

FIGURE 10.2 Goals as well as differentiation of quantitative and qualitative reliability methods in the design phase. (From Bertsche, B., *Reliability in Automotive and Mechanical Engineering*, Springer, Berlin, Germany, 2008.)

10.2.1.1 Histogram and Density Function *f*(*t*)

A histogram of the failure frequency provides the simplest option for graphically representing failure behavior. Figure 10.3 shows a histogram which is based on a Wöhler test for the frequency of a defined load.

The times of failure or rather the load cycles at which the component fails occur in a certain period purely randomly. In order to assign these times of failure, the number n, the abscissa, on which the times of failure are plotted, is divided into different classes n_k. In these classes, the number of failures is determined. Since the number of classes is not easily defined—too few classes result in a loss of information and gaps can occur with too many classes—a rough approximation or estimated value for the number of classes n_k is given by

$$n_k \approx \sqrt{n} \tag{10.1}$$

Instead of a histogram, the failure behavior can also be described by the empirical density function $f^*(t)$. Here, the midpoints of the tops of each column in the histogram are connected to each other. The underlying ideal density function $f(t)$ is to be found when the number n of the tested components is increased. In the limit as $n \to \infty$, the histogram's outline approaches a smooth continuous curve. The limit as $n \to \infty$ implies that all components of a very large population were tested and thus the failure behavior was precisely determined (Figure 10.4).

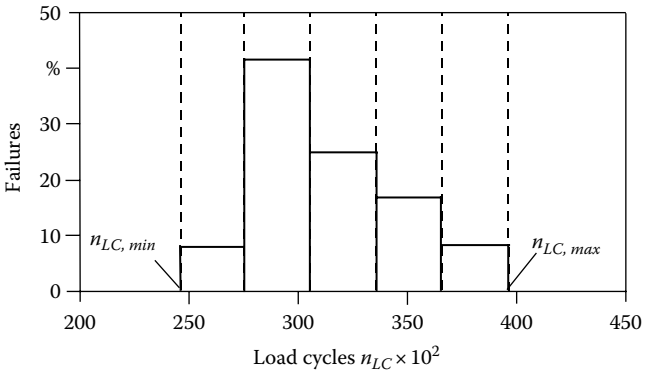

FIGURE 10.3 Histogram for the failure frequency depending on the number of load cycles. (From Bertsche, B., *Reliability in Automotive and Mechanical Engineering*, Springer, Berlin, Germany, 2008.)

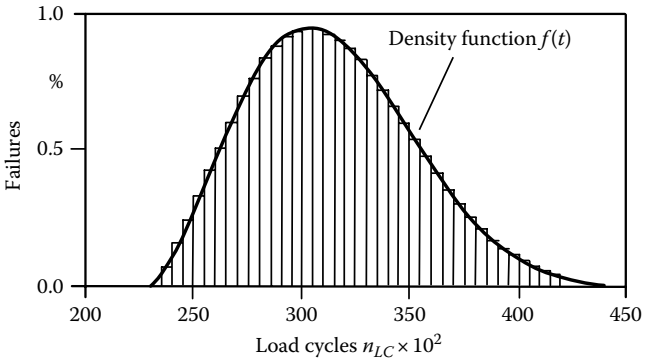

FIGURE 10.4 Histogram of failure frequencies and density function $f(t)$. (From Bertsche, B., *Reliability in Automotive and Mechanical Engineering*, Springer, Berlin, Germany, 2008.)

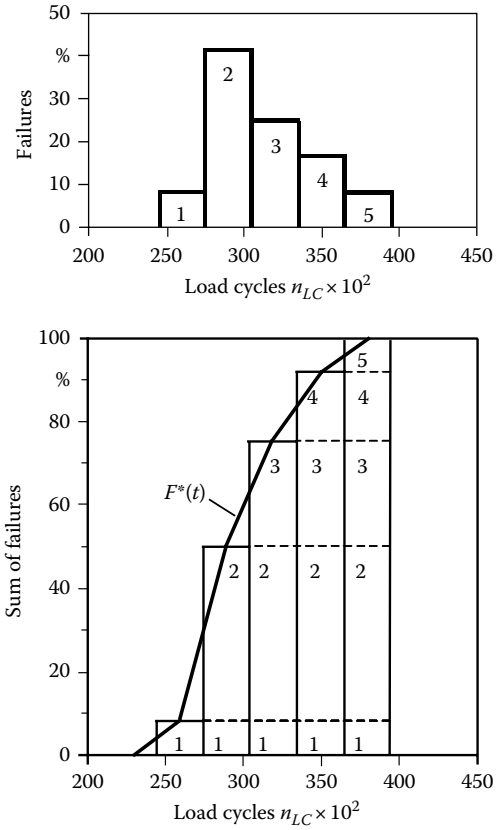

FIGURE 10.5 Histogram and distribution function. (From Bertsche, B., *Reliability in Automotive and Mechanical Engineering*, Springer, Berlin, Germany, 2008.)

10.2.1.2 Distribution Function or Failure Probability *F*(*t*)

In order to obtain the distribution function, that is, how many components have failed at a particular time, the observed failures from the histogram are added up (Figure 10.5).

10.2.1.3 Survival Probability or Reliability *R*(*t*)

The survival probability $R(t)$ and the distribution function are interdependent as follows:

$$R(t) = 1 - F(t) \tag{10.2}$$

Since at $t = 0$ failure has not yet occurred, the survival probability $R(t)$ always begins at $R(0) = 1$. In reliability theory, the function is referred to as the reliability $R(t)$.

10.2.1.4 Failure Rate λ(*t*)

Describing the failure behavior with the failure rate $\lambda(t)$, the failures at a time t or in a class i are not related to the sum of failures, as with the relative frequency, but to the sum of the surviving units. This implies that the failure rate $\lambda(t)$ is the quotient of the density function $f(t)$ and the survival probability $R(t)$:

$$\lambda(t) = \frac{f(t)}{R(t)} \tag{10.3}$$

The failure rate is frequently used to describe early, random, and wear-out failures. An attempt is made to register the overall failure behavior of a component or a machine. This is done using the "bathtub curve" (Figure 10.6) [1,3].

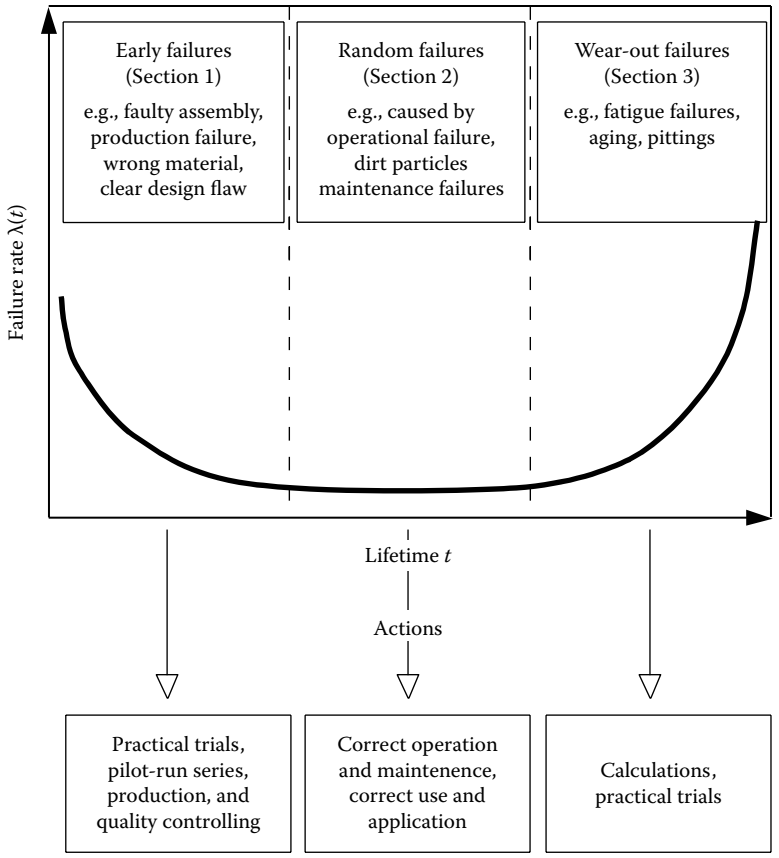

FIGURE 10.6 Three sections of the failure rate (bathtub curve). (From Bertsche, B., *Reliability in Automotive and Mechanical Engineering*, Springer, Berlin, Germany, 2008.)

Here, three sections are distinguished. In the first section, early failures are to be found, which result from faulty assembly, production failures, or wrong material. The second section represents random failures caused by operational failure, dirt particles, or maintenance failures. The third section describes wear and fatigue failures, which occur through fatigue fracture, aging, or pitting.

10.2.1.5 Durability Distributions

Durability distributions mathematically describe the progress of failure behavior. The most well-known "durability distribution" is the Gaussian or normal distribution [1,3,4] which is nevertheless only very rarely used in reliability theory. The exponential distribution is frequently employed in electrical engineering and the Weibull distribution is commonly used in mechanical engineering [1,3,4]. The log-normal distribution is occasionally employed in materials science and mechanical engineering [1].

10.2.1.6 Weibull Distribution

Very different failure behaviors can be described with the Weibull distribution (Figure 10.7a and b). This is most clearly demonstrated by representing the density function with the help of the Weibull function. Subject to one of the two distribution parameters—the shape parameter b—the density function changes considerably. For small values of b ($b < 1$), failures occur which are typical of early failures. A constant failure rate λ is found with $b = 1$. For $b > 1$, the density function always begins at $f(t) = 0$. After increasing, the fatigue life reaches a maximum and finally falls gradually to low values. For increasing values of b, the density function's maximum is translated further to the right until the value $b = 3.5$ is reached, where the density function becomes symmetrical.

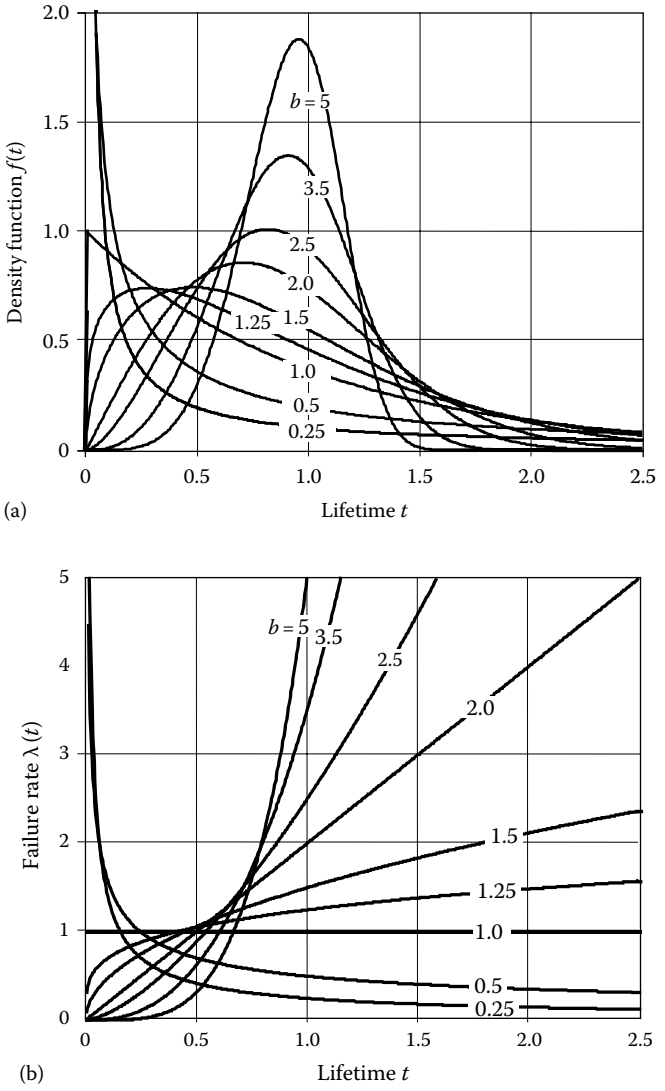

FIGURE 10.7 (a) Density function of the Weibull distribution. (b) Failure rate of the Weibull distribution.

Apart from the graphical considerations, it is possible to describe the Weibull distribution mathematically (Table 10.1).

[1,3–7] gives the other durability distributions as well as a more detailed insight of the reliability analysis.

10.2.1.7 Boolean Theory

Boolean theory represents the simplest system theory. Starting from the component failure behavior, the failure behavior of the system can be computed using the Boolean system theory. As described in Section 10.2.1.5, the failure behavior of individual components can be represented [1]. To implement the Boolean theory, the following prerequisites must be satisfied:

- The system is "non-repairable," that is, the first system failure ends the system's life.
- The system's elements can only assume two states: "operative" or "failed."
- The system's elements are "independent," that is the failure of one component is not influenced by the failure of another component.

TABLE 10.1
Formulae for the Weibull Distribution with the Shape Parameter *b* and the Scale Parameter *T*

$R(t) = e^{-(t/T)^b}$	Reliability function
$\lambda(t) = \frac{f(t)}{R(t)} = \frac{b}{T} \cdot \left(\frac{t}{T}\right)^{b-1}$	Failure rate
$F(t) = 1 - e^{-(t/T)^b}$	Failure function
$f(t) = \frac{dF(t)}{dt} = \frac{b}{T} \cdot \left(\frac{t}{T}\right)^{b-1} e^{-(t/T)^b}$	Failure density function

Using the system's elements, a reliability circuit diagram can be drawn up, from which the reliability configuration of a system is discernible [1]. At the same time, the reliability circuit diagram shows how the failure of components affects the overall system. The system is then operative if and only if a connection between the input and output in the reliability circuit diagram exists and on which all the depicted components are intact. The failure of an arbitrary component in a serial configuration leads to the failure of the overall system. In a parallel configuration, the system does not fail until all components have failed.

10.2.1.8 Fault Tree Analysis

Fault tree analysis (FTA) is a deductive method that serves to illustrate the system's function and to quantify the system's reliability. The method can be used both as a diagnostic and as a development tool. In this way, potential failures in a system can be identified and alternative designs can be evaluated. One of the advantages underlying the FTA is that the method yields both qualitative and quantitative results. FTA is based on Boolean theory.

10.2.2 Qualitative Method—Failure Modes and Effects Analysis

Failure modes and effects analysis (FMEA) is the most commonly and most frequently implemented method in reliability engineering. FMEA was developed in the United States by NASA [1] in the mid-1960s for the Apollo project. It was subsequently used as a general method in the aerospace industry. In the meantime, FMEA represents a standard method in the automobile industry both in Europe and also in Japan and the North America Free Trade Agreement (NAFTA). German standards can be found in [8], international standards in [9,10]. As extension, the failure mode effects and criticality analysis (FMECA) can be used. Compared with the FMEA, the FMECA includes a criticality analysis [11].

FMEA is a systematic method whose fundamental idea is to identify all possible failure modes for arbitrary systems, subsystems, and components. Simultaneously, the possible failure effects and causes are identified. Finally, risks are evaluated and optimization measures are specified. The aim of the method is to identify a product's risks or weak spots as soon as possible in order to carry out timely improvements.

The implementation of FMEA is carried out in interdisciplinary groups or so-called FMEA teams. This is expedient since only then it is guaranteed that all parties involved in the manufacturing chain can satisfactorily participate.

The five stages of the FMEA system according to [8] are depicted in Figure 10.8 and explained as follows:

Step 1: System elements and system structure. Definition of the system's configuration (system, assemblies, components)

Step 2: Functions and function structure. Definition of the system's, the assemblies', and the component's functions, e.g., by means of coordination, previous FMEA, requirements, specifications.

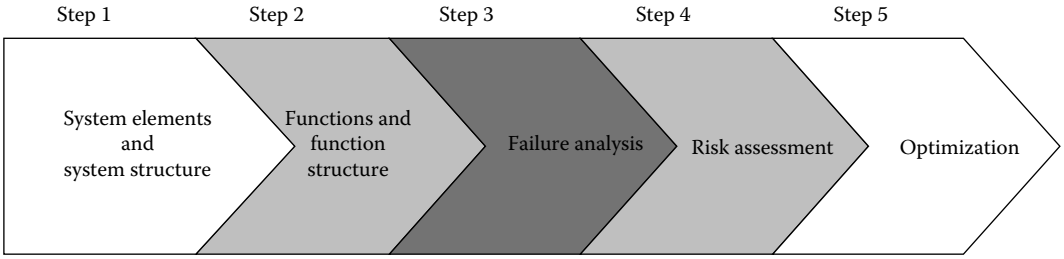

FIGURE 10.8 Five steps of the system—FMEA.

Step 3: Failure analysis. Determination of product defects—Failure, failure cause, failure effect, e.g., by means of coordination, previous complaints, previous FMEA.

Step 4: Risk assessment. Definition of avoidance and detection measures and evaluation of the defect severity (S) of the defect's effect, evaluation of the probability of occurrence (O) and of the probability of detection (D).

Step 5: Optimization. Derive the need for action, introduction of new, improved measures including target date and responsibility, controlling measures.

10.3 RELIABILITY ASSESSMENT IN EARLY DEVELOPMENT PHASES

Today's products are characterized by their ever-increasing complexity. As an example, consider how a gearbox has evolved over the years. It is noticeable that an increasing amount of software and electronic components has been integrated into the manual, the automatic, and the double clutch gearboxes. Since, on purchasing an automobile, the primary consideration of the customer is its reliability and not its appearance or price [1], this priority of ranking should be reflected by the manufacturer.

However, if one considers the actual reliability activities for mechatronic systems, the following shortfalls can be identified:

- Isolation of domains
- Consideration of reliability only in the latter phases of development; this entails great expense in modification and loss of time
- On the whole, only the reliability of components and assemblies is established
- The necessary data for the reliability calculations have, until now, been rarely available or deficient in quality and quantity

Consequently, there is a need for action that must focus on a mutual and holistic reliability system for mechatronic systems in early development phases.

10.3.1 Development Process and the V-Model

Generally, a procedure for a reliability analysis of mechatronic systems must be incorporated into the mechatronic development process. Only then, it is guaranteed that the reliability activities can accompany the development process.

The sequence of a mechatronic development process can be described with the help of the V-model from [12]. Since, in the framework of this process, the early development phases are decisive, the V-model's phase of system design is important (Figure 10.9).

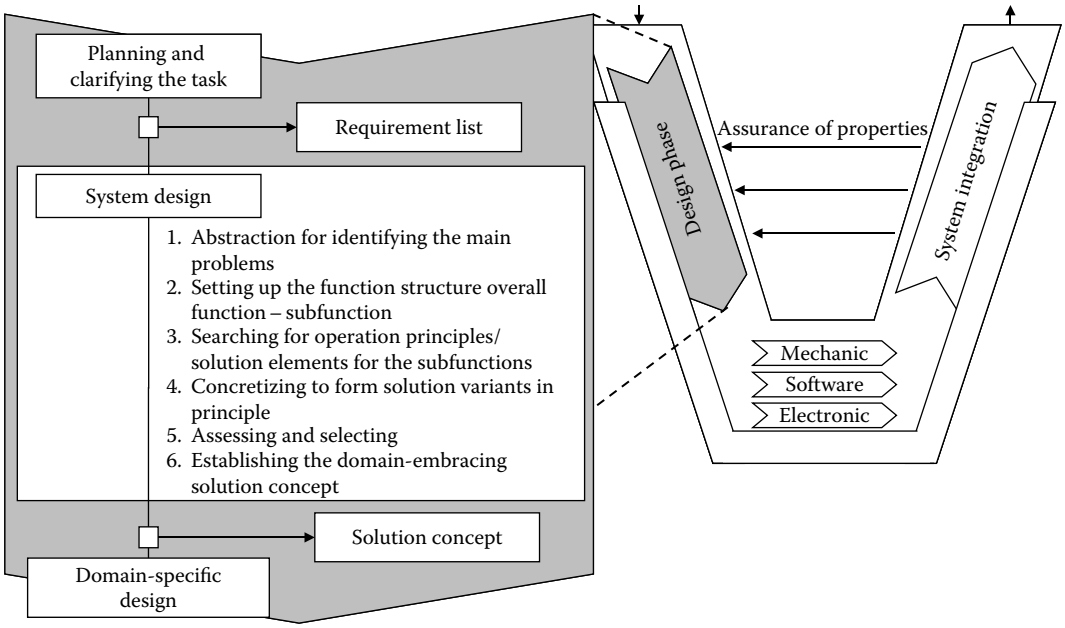

FIGURE 10.9 Extract of the V-model according to [12]. Activities in the system design.

10.3.2 Reliability Methodology for Mechatronic Systems in Early Development Phases

Starting from Figure 10.9, one has to ascertain how far the reliability can be incorporated into the system design. This approach is depicted in Figure 10.10.

To clarify the method, a component of an automatic transmission, the converter lockup clutch, is taken as an example (Figure 10.11). The approach is clarified by means of this example in the following sections.

10.3.2.1 Identification of Product Function/Malfunction

In the method's first stage, the product's top functions and its top malfunctions are specified similar to the FMEA. However, nonfunctional considerations like ease of repair or guarantee are not included. The top malfunctions are subsequently assigned to interception classes according to [16]. A reliability target value is allotted to each interception class. This value mainly results from consideration of marketing strategies.

For the example of the converter lockup clutch, the top functions are as follows:

- Close the clutch
- Open the clutch
- Transfer of torsional vibrations to the gearbox is prevented

The corresponding top malfunctions are

- Clutch does not close
- Clutch does not open
- Deletion of torsional vibrations is not guaranteed

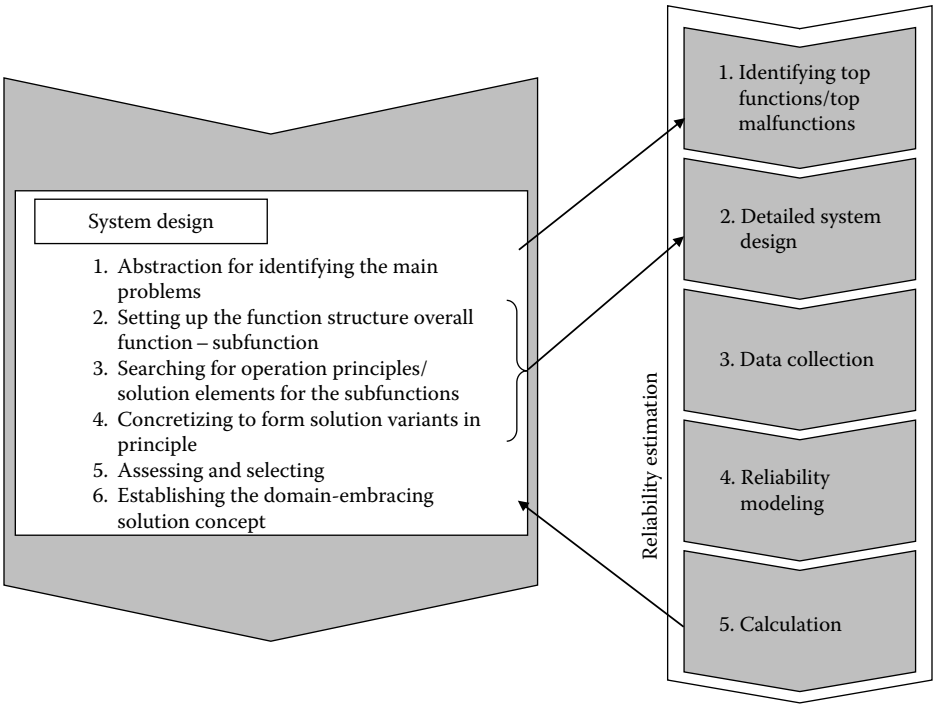

FIGURE 10.10 Approach for the reliability estimation in early phases of development which is incorporated to the first phase of the V-model—the system design. (From Jäger, P. et al., Zuverlässigkeitsbewertung mechatronischer Systeme in frühen Entwicklungsphasen. 4. Paderborner Workshop Entwurf mechatronischer Systeme, Universität Paderborn, Paderborn, Germany, 2006; Gäng, J. et al., *Determining Mechatronic System Reliability Using Quantitative and Qualitative Methods, ESREL 2007*, Stavanger, Norway, June 25–27, 2007.)

FIGURE 10.12 (a) Functional description of the system by means of use cases and (b) a first physical model generated on the basis of the use cases.

10.3.2.2 Detailed System Design

In the early development phases, information about the system already exists; this originates from previous or similar products. Using this knowledge, it is possible to annotate functional interrelationships using so-called use cases. Helped by the description, potential components for the converter lockup clutch can be singled out. These components can be adopted into a physical model that contains actuators and sensors necessary for the overall system (Figure 10.12). At the initial stage, it is sufficient that the electronics and the software are combined in information processing. However, they are to be differentiated at a later stage with the aid of the Unified Modeling Language (UML).

10.3.2.3 Data Collection

Reliability data for mechanical components is available from fatigue life models or simulations. The problems here are the uncertainties, such as manufacturing quality or effective engine performance. It is also possible to acquire data on electronic components using reliability models and standard elements with very narrow loading profiles. Problems are, for example, plug and socket connections. It is more difficult with software since there is, at present, no useful reliability model for software [17]. However, manufacturers often have intuitive and experience-based know-how. This expert knowledge should be exploited for the reliability model and data acquisition. In considering the software, the expert is asked about the input parameters which, using a Bayesian belief network, yields a defect density [13,17]. Despite the inaccuracy of the input data, it is possible for the experts to evaluate individual systems relative to each other. Here, the aim is no longer to determine a reliability parameter such as a B_{10} fatigue life (at this time, 10% of the system components are failed), but to ascertain the scope of development to attain the required reliability target. This scope of development is specified by the parameter α.

10.3.2.4 Reliability Modeling

Since the component configuration as well as the components themselves has a large influence on the overall reliability, it should be considered at this stage, which options are the best for the present system. When all the components have been pre-ascertained, these options can, using Boolean algebra, be structured in their respective primary defective functions (Figure 10.13) and, at a later stage, assigned to different complaint classes.

10.3.2.5 Calculation

By using a mathematical model of the system or, as an alternative, the Monte Carl method, with which it is possible to deal with inaccuracies, and the reliability target values defined in Section 10.1, it can be shown which of the investigated systems is comparatively the best (Figure 10.14).

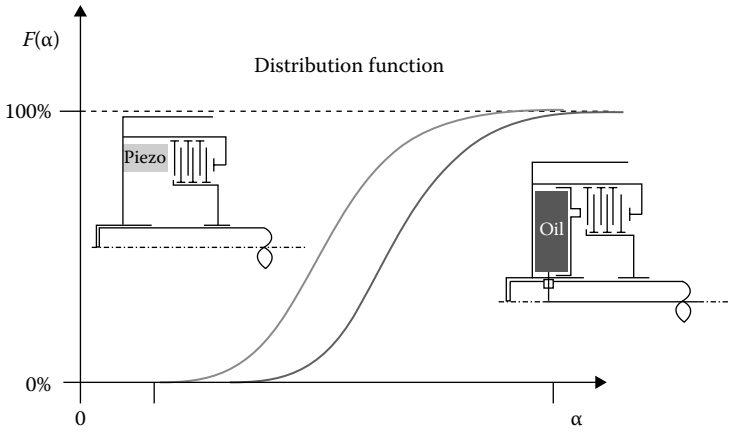

FIGURE 10.14 Comparison of different alternative solutions via quantification of the concept advantage.

10.4 NUMERICAL SENSITIVITY ANALYSIS AND RELIABILITY INVESTIGATION OF AN ACTIVE NOISE REDUCTION SYSTEM

Adaptronic systems react intelligently to variations of load conditions or their operating environment. Their functionalities include the active suppression of undesired noise and vibration, which are very promising for a number of automotive applications. Reliability of these complex adaptronic systems is hard to estimate for several reasons. Structural integration of sensor, actuators, and even control electronics, which are typical for adaptronic systems, requires a comprehensive analysis of all the physical domains involved to assess the complex system performance. Well-established methods for the design of mechatronic systems as outlined in the guideline VDI 2206 [12] focus on systems comprising of discrete electronic and mechanical components rather than integrated adaptronic systems which utilize multifunctional materials. A priori undetermined interactions between various influencing parameters, unknown fatigue properties of the multifunctional materials employed in sensors and actuators, and very complex system performance requirements make it difficult to predict the circumstances under which these adaptronic systems may fail. A sensitivity analysis (SA) of the comprehensive adaptronic system model has proven to be a valuable tool for the identification and assessment of scenarios that are relevant for system reliability [18,21]. By using an appropriately well-defined model, output and failure modes—that are designed as uncertain distributed input parameters, SA can be used to both identify and classify the importance of the different input values and to assess the reliability of the system with respect to each implemented failure mode.

As an example, the method is outlined for an active oil pan which is equipped with piezoelectric sensors and actuators to suppress structural vibrations. These are subject to more or less severe degradation and other failure modes which depend on operating conditions, applied control algorithm, and load-time history [19]. The performance of the active system, characterized by a defined reduction of noise emission in a particular frequency range, is simulated in different failure and fatigue scenarios. These include sensor and actuator degradation, debonding or position tolerances (misplacement), and malfunction. The influences of the design parameters and the different control strategies with respect to the performance robustness of the active oil pan system were able to be quantitatively analyzed through experimental as well as numerical sensitivity analyses [22,23].

10.4.1 Performance Evaluation

Figure 10.15 shows an FE model of the oil pan including piezoelectric (PZT) sensors and actuators (top) and the experimental setup (bottom) used for lab experiments. PZT patch actuators induce a bending deformation of the oil pan bottom which counteracts the vibration depending

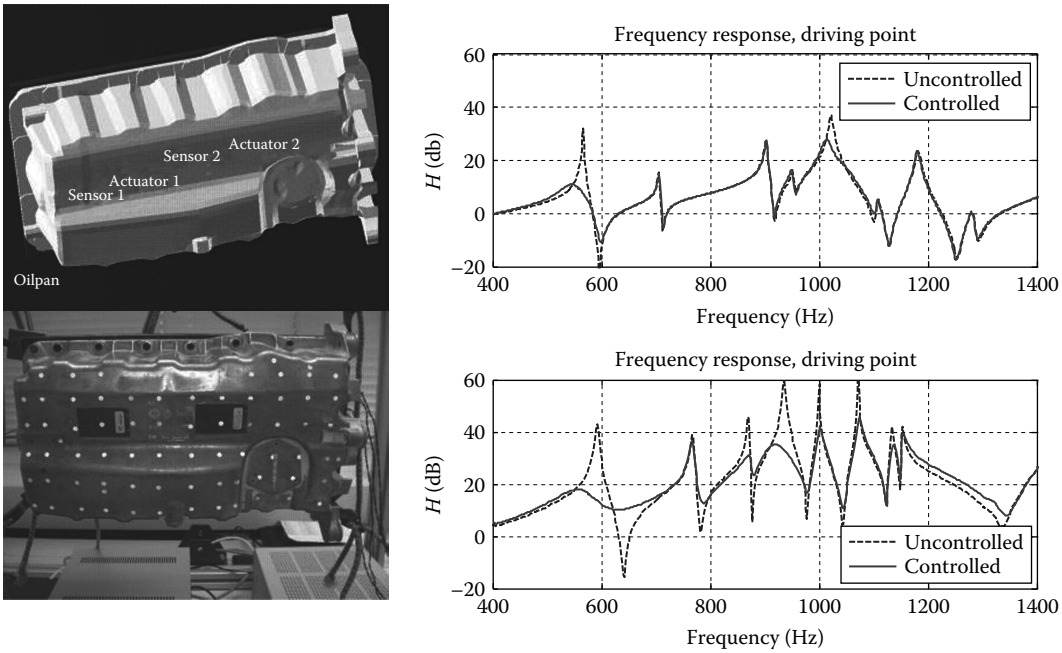

FIGURE 10.15 Numerical (top) and experimental (bottom) evaluation of the active system performance of oil-pan setup.

on the applied control algorithm. Frequency response plots of the oil pan subject to harmonic excitation are shown on the right-hand side of Figure 10.15 for numerical (top) and experimental (bottom) evaluation. The performance of the adaptive systems considered is typically defined as reduction of noise emission or vibration level of the uncontrolled (dashed line) vs. the controlled system (solid line) in some particular frequency range. Accordingly, the failure of the active system implies that the requirement for noise reduction within that range is not matched and the performance index falls below a specified critical limit. The performance index determines the difference in loudness or overall vibration level between the active (controlled) and passive (uncontrolled) system.

10.4.2 Sensitivity Analysis

A number of mathematical techniques are summarized under the expression SA [20]. When we mention SA in this context, we refer to variance-based sensitivity analysis. The aim of this type of SA is to determine the influence of uncertain, distributed input parameters on the output of a system. The parameters will generally be represented by distribution functions which are characterized by, for example, an expected value and a corresponding variance schematically depicted in Figure 10.16. As shown, distribution functions of the input parameters may be arbitrary, e.g., normal distributions, Weibull or uniform distributions, etc. and the variation of the input parameters results in a variation of the output function, e.g., the performance index. A simulation model serves to determine the output function of the system. In our case, the numerical FE model of the oil pan is used to generate the frequency response, which is then evaluated in designated frequency bands to generate a numerical value for the noise reduction performance of the system. The model could as well be an approximated response surface, identified from experimental data. Via the variance decomposition, the output function of the model is analyzed regarding the sensitivity of the output variance with respect to the input parameters.

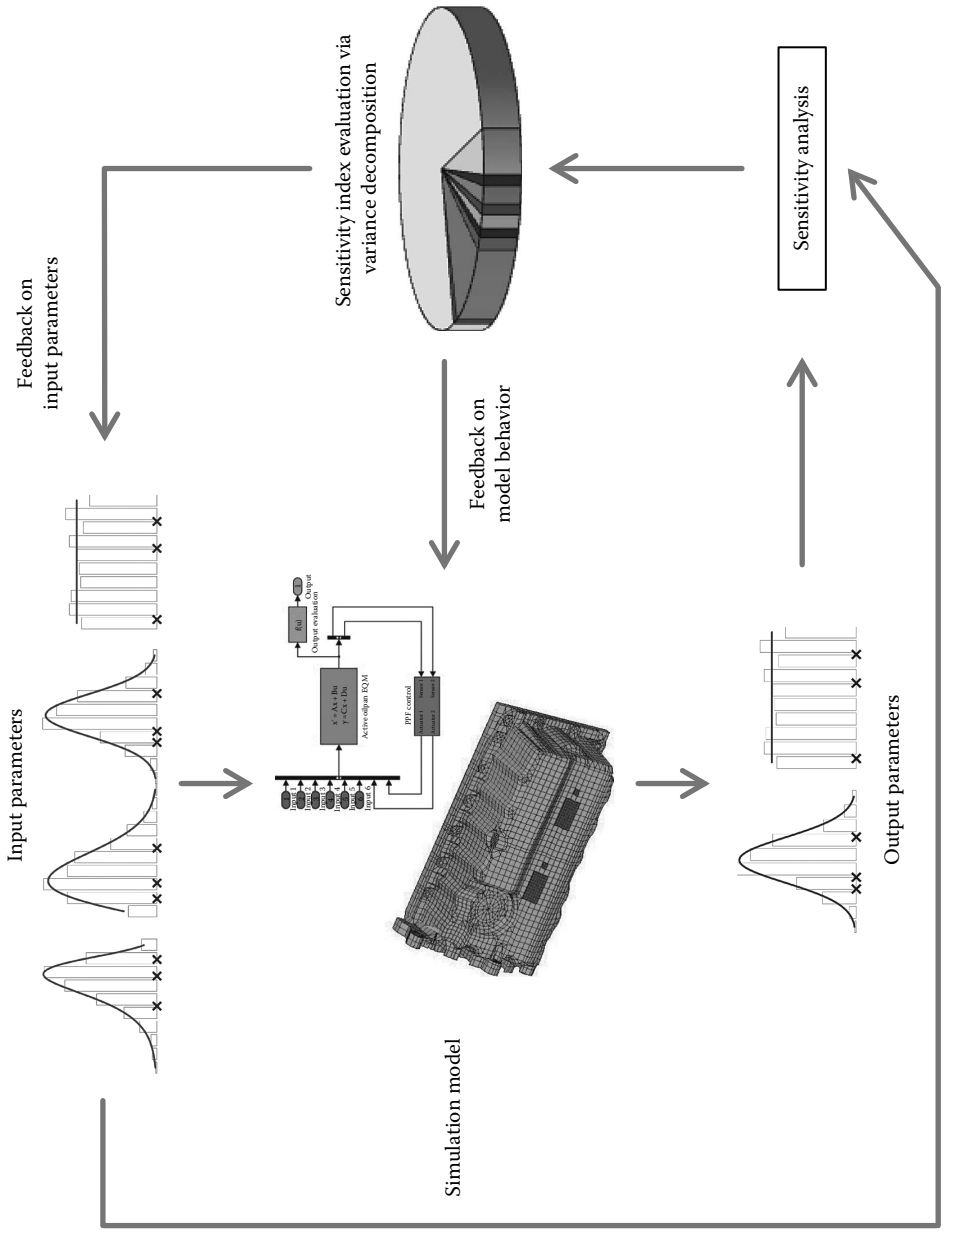

FIGURE 10.16 Variance-based sensitivity analysis of simulation model.

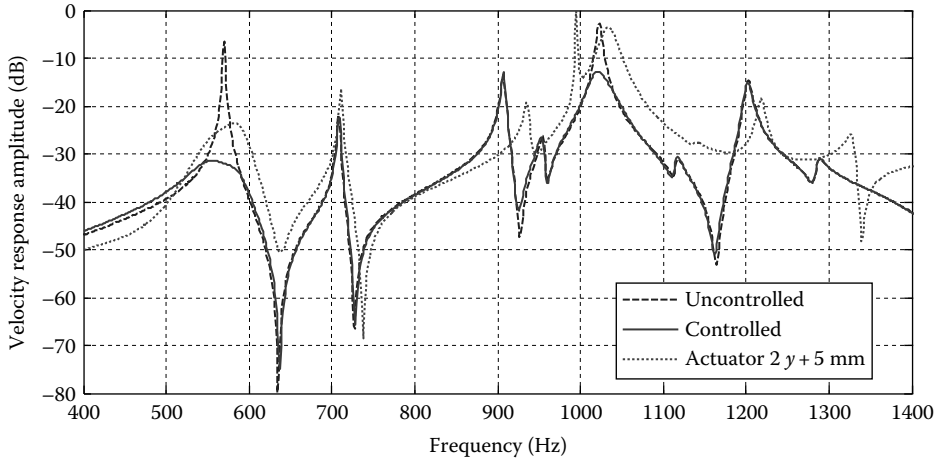

FIGURE 10.17 Vibration response of active system undergoing variation of actuator position.

Suitable sensitivity measures quantify not only the influence of single input parameters but also (higher order) interactions between them. Generally speaking, SA helps to find answers to the questions as follows:

- Which of the input parameters have the largest influence on variance of the output of the system?
- Which of the parameters have very little influence and may be eliminated from the model for simplification?
- How much variance of which input parameters is allowed to keep the output within specified limits?
- If there are "preferred" and "undesired" regions of the system output function, which of the input parameters have major influences on the output values in either region?

The absence of accurate data is a challenging issue when performing SA. For example, data describing degradation of actuators, accuracy of cutting tools, etc. are rarely available. Carefully designing and estimating the scattering of the input parameters are essential steps for the purpose of SA. This presents great potential for modern engineering design. Due to this large amount of uncertainty, the worst-case scenario is often taken into consideration, leaving enormous potential for an optimized reliable design.

As can be seen in Figure 10.17, the performance of the adaptive system dramatically changes with variations of the actuator position. The dashed line represents the calculated frequency response of the uncontrolled, the solid line the response of the controlled system, while the dotted line is the frequency response of the controlled system with one PZT actuator displaced from its nominal position by 5 mm.

The results of the SA carried out for actuator position and degradation are shown in Figure 10.18, according to the performance measures defined in Section 10.3.1. It is seen that a variation of the y-position of actuator 2 has the largest influence on the system performance.

10.4.3 Factors Influencing Reliability

Numerous quantities may be identified that influence the performance of the adaptive system and therefore may also contribute to the failure probability. For the presented method, the factors of interest are those that can be accounted for in the numerical model, such as

- Load spectra
- Design variations, tolerances

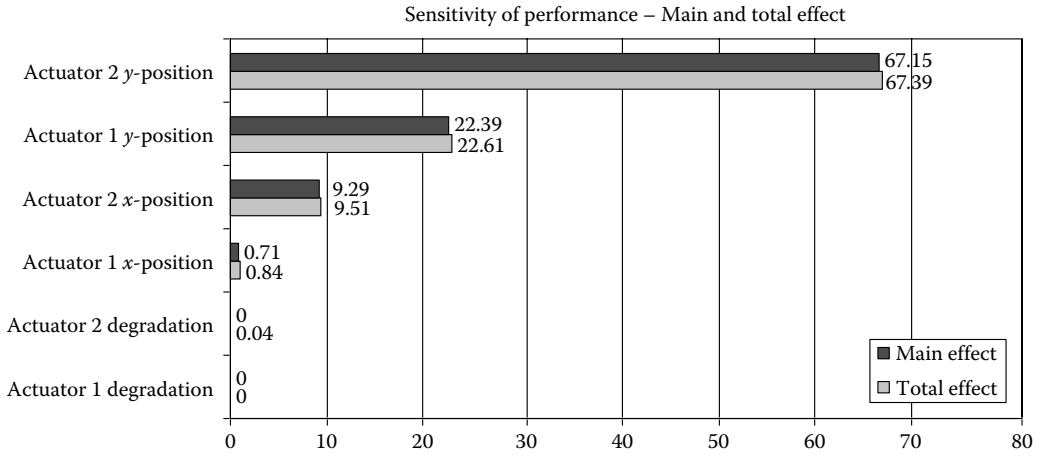

FIGURE 10.18 Results of SA for actuator position and degradation.

- Operating conditions
- Failure modes and degradation

All these quantities may be given as probability distributions and fed into the SA of the model. The outcome of the SA yields the importance of input quantities with respect to the variance of the output.

10.4.4 Lifetime Estimation

Based on the most relevant scenarios for system failure, which are identified via a SA, threshold values for input parameters can be given that assure system performance within specified limits. As the SA shows that variations in the position of actuator 2 have the largest influence on system performance, debonding or cracking of actuators should be one of the failure mechanisms to be closely investigated. In other system configurations, degradation of actuators and sensors has been identified to be likely cause of system failure. A focused reliability test aimed only at the most relevant failure mechanisms can now yield the required probability of a system component exceeding the input parameter threshold that depends on the applied number of load cycles. Based on this reliability function, a lifetime estimation of the system can be given. Collecting this reliability data is the subject of ongoing research.

10.5 CONCLUSION

Failure probability of components in mechatronic systems can be described using the Weibull distribution. Existing knowledge of component failure probabilities and the system structure may be combined to obtain a quantitative reliability prediction on a statistical basis. Systematic analysis of possible failure scenarios in an FMEA is a well-established procedure to identify and then reduce the vulnerability of a device with respect to various failure causes. With increasing complexity of mechatronic systems and shorter cycles of innovation, more reliability analysis must be based on simulation. Facing a multitude of model parameters influencing performance and reliability of mechatronic systems, current research efforts address the reduction of computational cost of these simulations.

11.1 INTRODUCTION

This chapter aims to present the theoretical foundations on which a vehicle is to be conceived and constructed, given the dynamic performance to be attained. The fundamental vehicle construction paradigms are presented and commented.

Apparently simple questions are addressed like why cars have four wheels at the four corners of the body or why suspension systems are basically composed by a spring nearby the ground (pneumatic tire) plus a spring and a damper between the wheel and the body. Other basic questions refer to the construction principles of pneumatic tires, active safety, and powertrain/driveline architecture.

In order to deal with such fundamental issues, theoretical investigations have been performed; some of the presented derivations are unreferenced. Only simple mechanical models, able to give general results, have been used. Alternatively, experimental data have been analyzed.

The theoretical analyses have shown that—necessarily—passive suspension systems must rely on a vertical massless spring in contact with the ground (pneumatic tire) to run properly on an irregular road. The hysteresis of such massless spring causes rolling resistance, such a phenomenon is explained in the chapter. Additionally, the compliance of the pneumatic tire in lateral direction, combined with the inertial and geometric characteristics of the vehicle, is the origin of many problems related to active safety (handling and cornering). Such problems are analyzed in this chapter from the conceptual design perspective.

The general conclusion of this chapter is that, given the constraints that have been set or inherited from the past and given the sustainable technologies available today, it is quite difficult to conceive road vehicles that are *completely* different morphologically from the ones we know, as today's road vehicles are the result of a huge optimization and system integration activity that started about 5000 years ago. The main result of the chapter is to have derived or gathered and emphasized a set of mathematical relations that underpin the design of today's road vehicles.

This chapter deals with a number of fundamental issues referring to the basic design of road vehicles, directly or indirectly related with dynamics. The aim of the chapter is to highlight why vehicles (and their subsystems) are constructed and shaped like we know them today.

A number of apparently naïve questions are addressed and answered with theoretical reasoning based on mathematical models. Such questions are as follows:

Is there a historical origin for today's dimensions of road vehicles?
Is today's architecture of road vehicles (cars) dictated by some specific reason?
Is there any necessary reason why the suspension system of road and off-road vehicles is combined by a pneumatic tire plus a spring and a damper?
Which must be the basic features of pneumatic wheels matching with their functions?
Which must be the basic features of road vehicle's suspension systems matching with active safety requirements?
Which must be the basic features of powertrain and driveline?
How do the geometric and inertial characteristics of a vehicle influence the active safety?
Which are the mass properties of road vehicles?

To answer the aforementioned addressed questions, simple models and analytical formulae have been used, whenever possible, to make the analyses as general as possible.

There are in the literature many books that deal with fundamental topics related with the performance of road or off-road vehicles and their subsystems [1–18,108]. In such books, the dynamic behavior of vehicles is explained in a very accurate and informative way by means of refined mathematical models that take into account the *existing* mechanical systems (vehicles and their subsystems). In this chapter, an attempt is made to explain why—if one or more reasons exists—the vehicles (and their subsystems) are constructed and shaped as the common experience would suggest. The mathematical models used in the literature to describe the motion of an existing vehicle are used here to investigate why such a vehicle had to be conceived and constructed in that particular way in order to attain some prescribed dynamic performance.

The addressed issues refer to the probable historical origin of today's dimensions and architecture of road vehicles, to the car body architecture as influenced by basic functional and technological requirements, to the arrangement of the suspension of road vehicles that is composed by a pneumatic tire plus a spring and a damper (or by an active system), to the basic dimensions and features of pneumatic wheels matching with their functions, to the driveline layout related to (urban) mobility and power losses, to the geometric and inertial features of cars and vans influencing active safety, to the basic features of road vehicle's suspension systems matching with active safety requirements, and to the mass properties of road vehicles.

11.2 BRIEF HISTORY OF GROUND (ROAD) VEHICLES

It is believed that ground vehicles became an important tool for carrying heavy goods when humans started agricultural activities and stopped from being nomadic hunters–gatherers [19]. This seems to be happened roughly in the time interval 15,000–5,000 BC, mainly in the Mesopotamic area. An important factor that contributed to the development and employment of ground vehicles was the possibility to exploit locomotion energy provided by domesticated animals, such as onagers (a kind of wild ass). This might explain why, before European colonization, in the Americas vehicles were not in use; actually animals strong enough were not available. The early vehicles in Asia and Europe were simply sleds or log sleds (Figure 11.1), running on grass or sand/rocky surfaces, sloped (mainly) or horizontal. The architecture of the sleds was strictly related to the power and the force available (for today's horse maximum values that are about 0.5 kW and 600 N, surely the early horses, being smaller [20], provided much lower mechanical power).

It is believed that, to reduce the friction and thus the traction force, rollers (e.g., logs) were used. Using a plank to carry a load would have suggested the idea of connecting the logs to the plank, thus leading to the invention of the wheel (Figure 11.2) [19,21]. The wheel has been one of the main inventions of the mankind (not a discovery). No structure is similar to a wheel in nature.

The history of wagons and carts has been documented in [1,19,21–28]. One of the very first vehicles employed for war is depicted in Figure 11.3, dating back about 2500 BC. Two-piece solid wheels can be seen.

The architecture of the early carts running in the Mesopotamic area (and possibly later in the Mediterranean area before the fifth century BC) refers to two-axle vehicles (wagons) with non-steering wheels. The observation that wheels dug ruts during repeated runs on the same path eventually suggested to build paved roads with ruts deliberately made. This happened in Ur, Babylon, and ancient cities of Assyria and implies that trains came before cars. The Prophet Isaiah in the eighth century BC refers about Assyria that the crooked were made straight and the rough places plain [22].

The importance of the road in defining the size (track) of carts was clearly known by Romans. Romans built many roads departing from Rome toward the borders of the empire, as the army—based in Rome—had to reach the far crisis areas as soon as possible. The roads were built to allow standard war carts to run without interfering with the other ones and produce traffic troubles. It is argued (no written documents stating this are today available) that the size

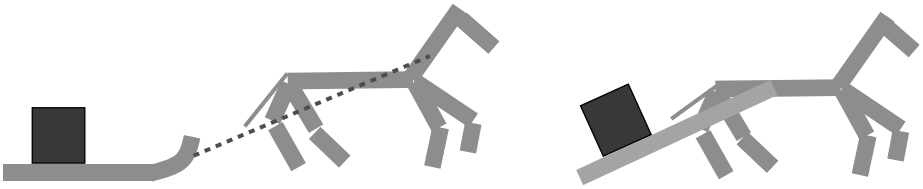

FIGURE 11.1 Schematic view of a sled (a) and a log sled (b) towed by an onager.

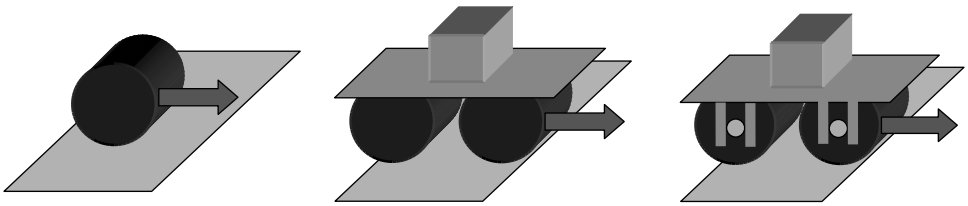

FIGURE 11.2 Logical process possibly leading to the invention of the wheel. Two-axle vehicles (wagons) were firstly developed. See Figure 11.6 showing how logs (could) have been linked to the plank.

FIGURE 11.3 The Standard of Ur, British Museum, 2600–2400 BC.

(cross width) of the cart was defined by the cross width of two horses pulling side by side the cart itself, as shown in Figures 11.4 and 11.5. The connection of the horses to the cart (harness system [24]) was made by means of proper structures resting on the necks. (There is some literature dealing with Roman harness system. In [19,21], authors state that until the Middle Age and after, the maximum power delivered by horses was about 0.12 kW, due to horses towing

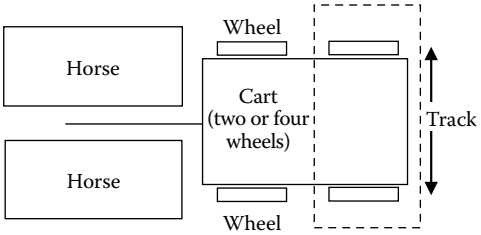

FIGURE 11.4 Hypothesis on Roman cart architecture. The cart track was related to the width of two horses. The cart had two or four wheels (wagon). Notice the only shaft along the middle axle of the cart.

FIGURE 11.5 Ruts left by ancient Roman carts in Pompeii, Italy, 59 BC. The track is about 1.4 m.

vehicles by a yoke resting on the throat and limiting the oxygen inspired by the animal. Such a thesis seems wrong according to [20].)

The track of early road vehicles (about 1.4 m) that were developed in Europe at the end of the nineteenth century AD (Benz, 1885, 1889) is related to the track of carts running in Europe since the Renaissance (1400 AD), when the ancient Roman roads (width about 3 m) were reused for trade. So we may argue that today's cross width of cars (track) is somehow related to the layout of very ancient carts running in Europe 2000 years ago.

The first known steering wagons were the Celtic carts found in Dejbjerg, Denmark, and dated first century BC [19]. Such carts were possibly used for ceremonies and they were obtained simply by connecting two single-axle carts. There is no evidence in carvings that ancient Roman four-wheel carts had a steering front axle [19]; however, after relatively recent studies, Röring [27] concluded that Roman wagons did have a pivoting front axle. Surprisingly, in the Middle Age in Europe, wagons appear not having a pivoting front axle. Pivoting front axles were reintroduced in Europe after 1300 AD and then extensively used [19,21]. Wagons with a pivoting front axle are easily recognized as they often have the front wheels smaller than rear ones.

Suspended vehicles were widely used in the Roman Empire [27], as an extreme luxury. Imperator Adrianus had a suspended system for playing with dice on his wagon [29]. Again in the Middle Age, the wagons were not suspended anymore. A suspension system very similar to the Roman one, based on leather strips, was reinvented during the mid-1400 AD in Hungary [19], apparently in the town of Kocs, which gave the name to suspended vehicles named "coaches."

During the Roman age, weight limits were specified for the Roman Imperial Post service (*De Cursu Publico*, Codex Theodosianus) and were related to the different types of vehicles (carts) [20,29]:

Angaria—1500 Roman lb, 492 kg
Raeda (wagon—four wheels, passenger)—1000 Roman lb, 330 kg
Carrus (wagon—four wheels, goods)—600 Roman lb, 198 kg
Vereda—300 Roman lb, 99 kg
Birota (cart—two wheels)—200 Roman lb, 66 kg

For more information on different types of carts in the Roman age, see [29]. The weights were limited also to avoid damaging the roads.

In ancient times, the shape of the wheels was strictly related to the stress they were subjected and to the unevenness they had to traverse. Taking into account the Hertz contact theory, a guess can be made on how the shape of wheels had evolved (actually Hertz developed his theory in the late nineteenth century eventually referring to railway wheels). Let us consider [30] Young's modulus of wood $E = 10$ GPa, Poisson's modulus of wood $\nu = 0.3$, the admissible compressive stress of wood $\sigma_{adm} = 8$ MPa (for loading perpendicular to grain), and a load $F_z = 1000$ N. The Hertz maximum stress P_0 in the contact area of a transverse log like the one depicted in Figure 11.6 (radius $R = 0.1$ m, length $l = 1$ m) is

$$P_0 = \left(\frac{F_z E^*}{l \pi R} \right)^{1/2} = 6\,\text{MPa}$$

where

$$\frac{1}{E^*} = \frac{1 - \nu^2}{E}$$

The result of the computation shows that such a structure (transverse log) may safely work as $P_0 < \sigma_{adm}$. Small-radius wheels are unable to run on obstacles, so bigger-diameter wheels had to be, and

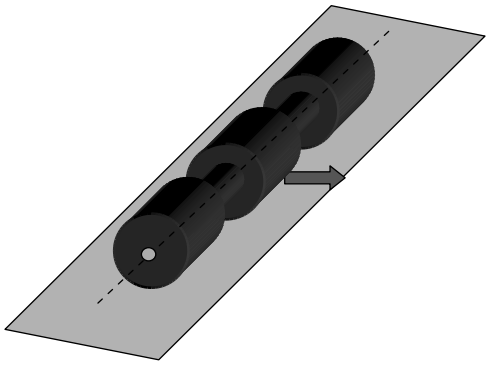

FIGURE 11.6 Log with grooves for linking it to an above plank on which goods could be carried.

were, adopted. Such an increase of diameter, due to weight reasons, implied *thin wheels*; fortunately, the Hertz contact pressure decreases as the radius increases. A 0.5 m diameter wheel (R = 0.25 m, width l = 0.18 m) implies the Hertz contact pressure to be about 8 MPa. Wheels dating 2750 BC had a diameter of approximately 0.5 m [19]. Diameters ranging from 0.5 to 1 m were in use in ancient times [19], up to the end of the nineteenth century. To decrease the weight of the wheels, spoked structures were used by Egyptians (1500 BC) [19] and much later by the Celts (200–100 BC). The manufacture of spoked structures requires an in-depth knowledge of technology and material science; a comprehensive explanation on how wheels were manufactured can be found in [19,20].

To limit the wear of the wheels, a number of treads were attached to the wheel rims [19] (see, e.g., the carvings in the Louvre museum, Near Eastern Antiquities pavilion). Celts, Greeks, and Romans mounted metal rims on wheels. Romans used steel rims (the steel was similar to today's low carbon steel) in only one piece hot shrink fitted on the wooden wheel (such a technology was rediscovered after the Middle Age) [19,20]. Noise produced by steel wheels was a major concern in the ancient city of Rome [29].

The wheels were at first connected to each other rigidly (like today's railway wheelsets). Greeks had such a construction scheme [19], but the mentioned earlier Egyptian carts had independently rotating wheels. Celts used cylindrical roller bearings (first century BC [19]), but up to the twentieth century, all of the wheel bearings were plain (roller or ball bearings were introduced at the beginning of the twentieth century).

Spoked wheels were prone to failures due to shocks acting in lateral direction. In order to diminish the flexure in the spokes due to such shocks, starting from the fifteenth century, a number of engineering solutions were adopted. Such solutions are depicted in Figure 11.7. One solution was to

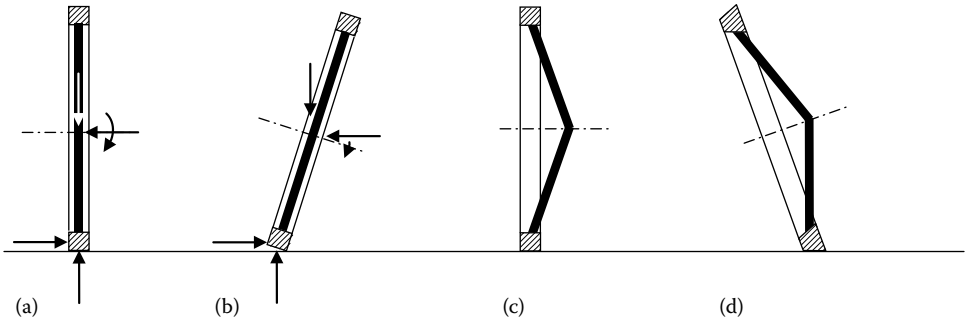

FIGURE 11.7 Cross section of spoked wheels, (a) spokes subject to flexure caused by a lateral shock, (b) spokes less subject to flexure (with respect to case (a)) due to the cambered wheel, (c) cambered spokes (less subject to flexure due to shock but subject to flexure due to radial load), and (d) sloped wheel axis (less subject to flexure due to shock and less subject to flexure due to radial load).

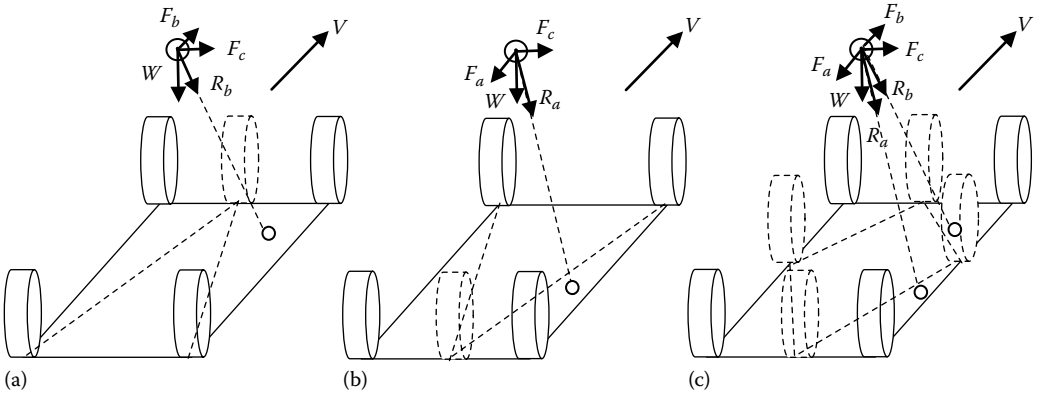

FIGURE 11.8 Comparison of rollover propensity of non-tilting vehicles with different arrangements of the wheels. The arrangement of four wheels at the four corners of the base rectangle is always better with respect to other arrangements with three wheels or with four wheels. (a) Three-wheeled vehicle during braking and cornering, (b) three-wheeled vehicle during acceleration and cornering, and (c) four-wheeled vehicle (rhomb arrangement) during braking or acceleration while cornering. Symbols: W weight, F_a acceleration force, F_b braking force, F_c centrifugal force, R_a resultant of W, F_a, F_c forces, and R_b resultant of W, F_b, F_c forces.

set the wheel axis not parallel with respect to the ground [21] (Figure 11.7b), but this implied a very large track. To reduce the track, the spokes were sloped (cambered) with respect to the horizontal (Figure 11.7c), but this implied the flexure in the spokes due to the payload. A sloped wheel axis together with a wheel with sloped (cambered) spokes was a solution (Figure 11.7d). Later carts or wagons had big spoked wheels (about 1.5 m diameter) to improve the running on road irregularities.

Historically, vehicles were conceived since the very beginning (see Figure 11.3) with four wheels at the corner of a flat rectangular plank used as vehicle body. This appears to be still today the more rational way to define the position of the wheels; actually for static reasons, this is the better way to prevent rollover (non-tilting vehicles are considered). Figure 11.8 shows the advantages of such a layout considering forces applied to the center of gravity during braking or acceleration while cornering. If the resultant force at the center of gravity points outside the area defined by the lines connecting the wheel–ground contact points (respective central points of tire–ground contact areas), the vehicle becomes prone to roll over. At least one attempt to place wheels at the vertexes of a rhomb has been made [31]. A vehicle with rhomboid arrangement of the four wheels suffers similar rollover problems of three-wheeled vehicles, unless tilting is implemented [32].

11.3 BASIC ISSUES ON ROAD VEHICLE (CAR) DESIGN

11.3.1 Road Vehicle Dimensions

The track of early automobiles was possibly inherited from ancient Roman standards (see Section 11.2 and also [112]). Nowadays, there are national and international laws, as well as standards that rule not only the track but also the length and the height (as well as the mass) of vehicles allowed to run freely on public roads (see ISO 3833 [33]).

In [3,4,34,35], the basic issues referring to the conceptual definition of the dimensions of road vehicles—with particular reference to automobiles—are given. According to [35], the parameters for the design of a vehicle (automobile) can be classified into the three groups, *anthropometry, customer requirements*, and *technical equipment*.

The anthropometric data useful for the design of automobiles refer primarily to the ones of the seated person (references for the human dimensions are given in [4,35,36]); the automobile is actually designed (somehow "tailored") around the passengers. The starting point is defining the

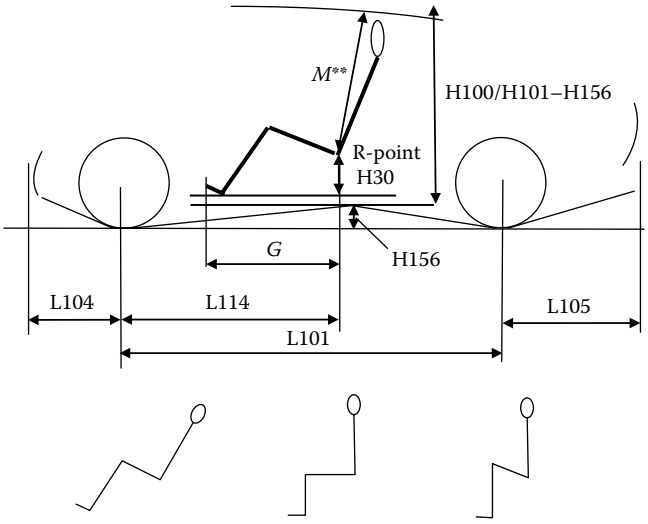

FIGURE 11.9 Main dimensions of an automobile (referring to SAE J1100 and/or [35]) and different body postures influencing directly the body shape of a car.

height of the so-called H point (hip point) located at the rearmost position of the seat (R point) [36–38] (Figure 11.9) with respect to the floor (H30). A rough relationship exists between H30 and G (Figure 11.9; H30 = 1770 – 1.622 × *G*, [35]). Higher H30 implies smaller G (H30 ranges between 170 and 390 mm [35]). Experience and research activity [37] show that the ride comfort (see Chapter 36; [38–41]) is related to the posture, so the definition of *G* and H30 is of crucial importance for vehicle character. The angles between body segments that are expected to provide posture comfort are given in [5,6,42–45] mainly referring to static condition. The height *M*** is set (according to [35]) for some vehicles of a given manufacturer equal to 993 mm (Figure 11.9). In [35], details are given on pedal positioning, steering wheel positioning, and cross width dimensions.

As the passenger room is defined, the internal boot dimensions have to be defined (according to customer requirement); if possible, as a multiple of the cuboid defined by ISO 3832, this helps preventing a too irregular inner shape of the boot. In front engine road vehicles (the greatest majority of cars), the front length (from front passenger feet to the foremost point) is defined by the bigger motor type that has to be fitted into the engine compartment [35]. The total length of the vehicle is thus defined according to such requirements.

Additional details on the interiors, the doors, and the visibility of an automobile can be found in [3,5,6,46–51]. Additional details on how designing the shape of an automobile can be found in [3,5,6,52–60].

From the analysis of the literature, it appears that, starting from the requirements referring to anthropometry, customer, and technical equipment, *there is not a well-defined constraint to set the wheelbase and the positioning of the front and rear axles* (L101, L104, and L105 in Figure 11.9). So these parameters are chosen according to the designer's preferences. There are many different possible preferences; the considerations based on vehicle dynamics are addressed as follows.

11.3.1.1 Wheelbase

The wheelbase length has effects on a number of vehicle performances, namely, acceleration and braking (see Section 11.3.5), handling (see Sections 11.4.1.2 and 11.4.1.3), and ride comfort (see Section 11.3.2.2). Also, (off-road) mobility performance is greatly influenced by the wheelbase (see Chapter 12). Additionally, the setting of the wheelbase has direct effects on the mass and stiffness of the car body (see Chapter 26) and on inertia properties (see Section 11.5). There is not a generally accepted rule to set the wheelbase of an automobile, due to the many different dynamic performances it affects.

11.3.1.2 Track

Also the track, as the wheelbase, has effects on a number vehicle performances, namely, rollover (see Section 11.4.2), handling (see Sections 11.4.12 and 11.4.1.3), and ride comfort (see Section 11.3.2.2).

11.3.2 Suspension System

Let us consider how the wheels can be connected to the car body and whether or not a suspension system has to be fitted into the vehicle. Experience obviously states that a suspension system is necessary; here, we will focus on the basic paradigm of suspension systems. Let us consider a vehicle like an ancient single-axle cart, for example, the one represented in Figure 11.10a. Such a vehicle does not have any suspension, that is, it is unsprung. As the road profile is rough, vibrations are excited, mainly in the vertical direction. The question arises if, given a certain level or road irregularity, there is a limit speed, above which such a vehicle cannot run, due to the wheel leaving the ground.

The statistical description of random road profiles has been given in [2,61–63]. Referring to Figure 11.10, the displacement ξ (road irregularity) may be represented by a random variable defined by a stationary and ergodic stochastic process with zero mean value and Gaussian distribution [61,64]. A concise but complete summary of the theory of random vibration and related stochastic processes is given in [65]. The mean square spectral density of an uneven road profile is given by

$$S_{\xi 1} = \frac{A_b v}{\omega^2} \ [\mathrm{m^2\,s}] \tag{11.1}$$

or

$$S_{\xi 2} = \frac{A_v s_c}{s_c^2 + \omega^2} \ [\mathrm{m^2\,s}] \tag{11.2}$$

where

v is the vehicle speed

ω is the circular frequency (rad/s)

A_b, A_v, s_c are the parameters referring to the irregularity (typically for medium roads) $A_b = 1.4 \times 10^{-5}$ m, $a = s_c/v = 0.4$ rad/m, and $A_v = 3.5 \times 10^{-5}$ m^2; a comprehensive treatment is reported in [2,66]

Equation 11.1 represents the simplest way to describe with sufficient accuracy a random road profile, but it has the drawback that the irregularity amplitude grows to infinity as ω approaches zero. Such a drawback is absent in Equation 11.2. For reasoning about basic issues, Equation 11.1 is often sufficient.

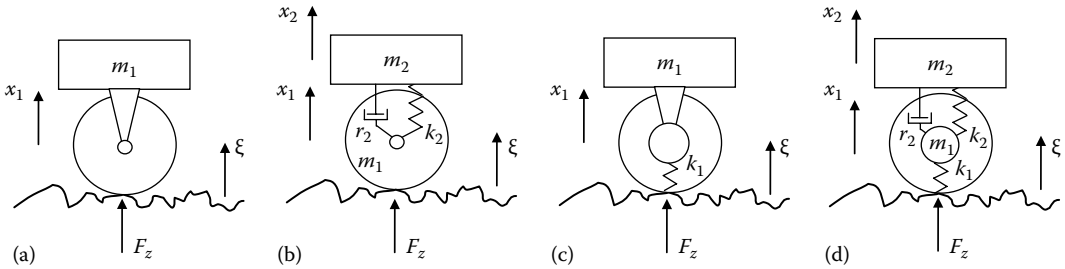

FIGURE 11.10 System models representing vehicles running on an uneven road profile. (a) 1 d.o.f. unsprung vehicle model, (b) 1 d.o.f. sprung vehicle model with stiff wheel, (c) 1 d.o.f. unsprung vehicle model with elastic wheel, and (d) 2 d.o.f. sprung vehicle model with elastic wheel.

The performances that are relevant for studying the vertical vibrations of the unsprung vehicle in Figure 11.10a are

- The body vertical acceleration (represented by $\ddot{x}_1$ in Figure 11.10a) and related to passenger discomfort and rattling of carried goods
- The force at the wheel–road contact area (represented by F_z)

Notice that for the vehicle model in Figure 11.10a, $m_1\ddot{x}_1 = F_z$, that is, the body vertical acceleration and the vertical force at the ground are strictly related. As the distribution of the irregularity ξ is Gaussian, the distribution of $\ddot{x}_1$ and F_z is Gaussian (if the wheel does not leave the ground). Referring to Tchebycheff's inequality, for a Gaussian distribution, if $3\sigma_{F_z} = F_{z,static} = m_1 g$ (g gravity acceleration), there is the probability that 0.3% of the time the wheel leaves the ground, that is, $F_z < 0$. This condition of the wheel not touching the ground is obviously a condition to be avoided. In order to compute the standard deviation of the vertical force σ_{F_z} (and the standard deviation of the vertical acceleration $\sigma_{\ddot{x}_1}$), let us consider that $\ddot{\xi} = \ddot{x}_1$ and that

$$S_{\ddot{\xi}1} = \omega^4 S_{\xi 1} = \omega^4 \frac{A_b v}{\omega^2} = \omega^2 A_b v \tag{11.3}$$

so (see [2,65,67])

$$\sigma_{F_z} = m_1 \sigma_{\ddot{x}_1} = m_1 \sqrt{\frac{1}{2\pi} \int_{-\infty}^{\infty} \omega^4 S_{\xi 1} d\omega} = m_1 \sqrt{\frac{1}{2\pi} \int_{-\infty}^{\infty} \omega^4 \frac{A_b v}{\omega^2}\, d\omega} = m_1 \sqrt{\frac{1}{2\pi} \left[A_b v \frac{\omega^3}{3} \right]_{-\infty}^{\infty}} = \infty \tag{11.4}$$

Additionally, for

$$S_{\ddot{\xi}2} = \omega^4 S_{\xi 2} = \omega^4 \frac{A_v s_c}{s_c^2 + \omega^2}$$

$$\sigma_{F_z} = m_1 \sigma_{\ddot{x}_1} = m_1 \sqrt{\frac{1}{2\pi} \int_{-\infty}^{\infty} \omega^4 S_{\xi 2} d\omega} = \infty \tag{11.5}$$

For an unsprung vehicle represented by the model in Figure 11.10a, the standard deviations of the vertical force σ_{F_z} and the standard deviation of the vertical acceleration $\sigma_{\ddot{x}_1}$ are, respectively, *unbounded*. This implies that, unless the vehicle speed is vanishing or the road profile is perfectly smooth (i.e., $A_b \to 0$ or $A_v \to 0$), both high vertical forces (and wheels missing the contact with the ground) and high vertical accelerations can arise. So, theoretically, for an unsprung vehicle, the limit speed—to avoid the wheel leaving the ground—is *zero*. Actually, it is well known that unsprung vehicles can run only at very low speed.

Let us now consider the vehicle system model depicted in Figure 11.10b, representing a sprung vehicle, that is, a vehicle fitted with a suspension system. The equation of motion of such a simple 1 d.o.f. system is

$$m_2\ddot{x}_2 + r_2\dot{x}_2 + k_2 x_2 = r_2\dot{\xi} + k_2\xi \tag{11.6}$$

the frequency response of the amplitude $x_2 = X_2 e^{j\omega t}$ due to the inputs $\xi = \Xi e^{j\omega t}$, $\dot{\xi} = i\omega t \Xi e^{j\omega t}$ is, for $\Xi = 1$

$$X_2 = \frac{j\omega r_2 + k_2}{-\omega^2 m_2 + j\omega r_2 + k_2} = H_{x_2} \tag{11.7}$$

and

$$\ddot{X}_2 = -\omega^2 \frac{j\omega r_2 + k_2}{-\omega^2 m_2 + j\omega r_2 + k_2} = H_{\ddot{x}_2} \tag{11.8}$$

For $S_{\xi 1}$ excitation, the standard deviation of $\ddot{x}_2$ is [2,67]

$$\sigma_{\ddot{x}_2} = \sqrt{\frac{1}{2\pi}\int_{-\infty}^{\infty} \left|H_{\ddot{x}_2}\right|^2 S_{\xi 1} d\omega} =$$

$$= \sqrt{\frac{1}{2\pi}\int_{-\infty}^{\infty} (j\omega)^2 \frac{j\omega r_2 + k_2}{(j\omega)^2 m_2 + j\omega r_2 + k_2} (-j\omega)^2 \frac{(-j\omega) r_2 + k_2}{(-j\omega)^2 m_2 + (-j\omega) r_2 + k_2} A_b v \frac{1}{j\omega} \frac{1}{(-j\omega)} d\omega} = \infty \tag{11.9}$$

In fact, rearranging Equation 11.9

$$\sqrt{\frac{1}{2\pi}\int_{-\infty}^{\infty} A_b v \left[j\omega \frac{j\omega r_2 + k_2}{(j\omega)^2 m_2 + j\omega r_2 + k_2} \right] \left[(-j\omega) \frac{(-j\omega) r_2 + k_2}{(-j\omega)^2 m_2 + (-j\omega) r_2 + k_2} \right] d\omega} =$$

$$= \sqrt{\frac{1}{2\pi}\int_{-\infty}^{\infty} A_b v A(\omega) A(-j\omega) d\omega}$$

one can easily see that $\lim_{i\omega \to \infty} A(\omega) = -r_2/m_2$, that is, the function $A(\omega)$ to be integrated has a horizontal asymptote for $\omega \to \infty$ that implies $\sigma_{\ddot{x}_2} = \sqrt{(1/2\pi)\int_{-\infty}^{\infty} \left|H_{\ddot{x}_2}\right|^2 S_{\xi 1} d\omega} = \infty$.

With similar reasoning, for $S_{\xi 2}$ excitation, the standard deviation of $\ddot{x}_2$ is

$$\sigma_{\ddot{x}_2} = \sqrt{\frac{1}{2\pi}\int_{-\infty}^{\infty} \left|H_{\ddot{x}_2}\right|^2 S_{\xi 2} d\omega} = \infty \tag{11.10}$$

The acceleration of mass m_2 is *unbounded*; this is due both to the power spectral density of the excitation ($S_{\xi 1}$ or $S_{\xi 2}$) that decreases according to $1/\omega^2$ and to the presence of the damping r_2.

Similarly, to what was written for the model in Figure 11.10a, for the model in Figure 11.10b, we can write $m_1 \ddot{x}_1 + m_2 \ddot{x}_2 = F_z$, so (from 11.3–11.9)

$$\sigma_{F_z} = \sqrt{\frac{1}{2\pi}\int_{-\infty}^{\infty} \left(m_1^2 \omega^4 + m_2^2 \left[(j\omega)^2 \frac{j\omega r_2 + k_2}{(j\omega)^2 m_2 + j\omega r_2 + k_2} \right] \left[(-j\omega)^2 \frac{(-j\omega) r_2 + k_2}{(-j\omega)^2 m_2 + (-j\omega) r_2 + k_2} \right] \right) S_{\xi 1} d\omega = \infty}$$

The same result is found for $S_{\xi 2}$ excitation. The standard deviation of the vertical force σ_{F_z} is *unbounded*. The *sprung* model in Figure 11.10b suffers the same problem of the *unsprung* model in Figure 11.10a, that is, the limit speed—to avoid the wheel leaving the ground—is *zero*.

Surprisingly, for the sprung vehicle model in Figure 11.10b, the standard deviation of the vertical body acceleration $\sigma_{\ddot{x}_2}$ and the standard deviation of the vertical force at the ground σ_{F_z} are *unbounded*. On the contrary, the amplitude response σ_{x_2} is bounded:

$$\sigma_{x_2} = \sqrt{\frac{1}{2\pi}\int_{-\infty}^{\infty} \left|H_{x_2}\right|^2 S_{\xi 1} d\omega} = \sqrt{\frac{1}{2}\frac{A_b\left(m_2 k_2 s_c r_2^2 + m_2\left(m_2 s_c + r_2\right)k_2^2\right)}{m_2 k_2\left(m_2 k_2 s_c + \left(m_2 s_c + r_2\right)k_2\right)}} \tag{11.11}$$

Let us now consider the vehicle model in Figure 11.10c. It behaves almost like the one in Figure 11.10b, provided that $x_1 = x_2$, $k_1 = k_2$, $r_2 = 0$.

For $S_{\xi 1}$ excitation, the standard deviation of $\ddot{x}_1$ is

$$\sigma_{\ddot{x}_1} = \sqrt{\frac{1}{2\pi}\int_{-\infty}^{\infty}\left(j\omega\right)^2 \frac{k_1}{\left(j\omega\right)^2 m_1 + k_1}\left(-j\omega\right)^2 \frac{k_1}{\left(-j\omega\right)^2 m_1 + k_1} A_b v \frac{1}{j\omega}\frac{1}{\left(-j\omega\right)} d\omega} = \infty \tag{11.12}$$

In fact, for $\omega = \pm\sqrt{k_1/m_1}$, the integrand is unbounded. Also $\sigma_{F_z} = m_1\sigma_{\ddot{x}_1} = \infty$.

Summarizing the results of the aforementioned analyses, we can state that *one single suspension system is not efficient for filtering the excitation coming from uneven road profile* and two stages of suspension (like the ones represented in Figure 11.10d) are far more efficient, as experience suggests and as we will show as follows. This may explain why today's road vehicles are equipped with two suspension systems, one represented by the pneumatic tire and one represented by what is properly called the suspension system, that is, the system composed basically by a spring and a damper.

Let us now consider Figure 11.10d. Such a model may represent vehicles with different suspension configurations. In [2], it is shown how the model in Figure 11.10d can represent actual four-wheel vehicles. The performances that are relevant for studying the vertical vibrations are

- The body vertical acceleration (represented by $\ddot{x}_2$)
- The force at the wheel–road contact area (represented by F_z)
- The relative displacement wheel to body (represented by $x_2 - x_1$)

The discomfort of passengers carried by the vehicle in Figure 11.10d is evaluated by computing the standard deviation of the vertical vehicle body acceleration. The higher the standard deviation, the higher is the *discomfort*. This approach seems to provide very good correlation with subjective ride comfort ratings [68]. The standard deviation of the tire radial force is related to *road holding*. The variation of tire radial force can lead to a loss of contact with the ground and poor handling and braking ability [2,68]. The standard deviation of the relative displacement between the wheel and vehicle body, that is, the rattlespace or *working space*, is related to design and packaging constraints, as well as to wheel lateral vibrations. Discomfort, road holding, and working space are the *performance indices* to which reference will be made in the sequel.

The linear equations of motion of the system model in Figure 11.10d are

$$\begin{aligned} m_1\ddot{x}_1 - r_2\left(\dot{x}_2 - \dot{x}_1\right) - k_2\left(x_2 - x_1\right) + k_1 x_1 &= k_1\xi \\ m_2\ddot{x}_2 + r_2\left(\dot{x}_2 - \dot{x}_1\right) + k_2\left(x_2 - x_1\right) &= 0 \end{aligned} \tag{11.13}$$

The mass m_1 represents approximately the mass of the wheel plus part of the mass of the suspension arms, and m_2 represents approximately 1/4 of the body mass (m_2 could be computed more precisely as shown as follows). The damping parameter r_2 represents the first-order coefficient of the damper

characteristic, the stiffness parameter k_2 represents the first-order coefficient of the stiffness characteristic, and the stiffness parameter k_1 represents the tire radial stiffness at static loading. For more detail on the system model and its components, see [1,2,69,70].

The frequency response of the amplitudes $x_1 = X_1 e^{j\omega t}$, $x_2 = X_2 e^{j\omega t}$ due to the input $\xi = \Xi e^{j\omega t}$, $\Xi = 1$ is [68]

$$X_1(j\omega) = \frac{k_1\left(k_2 + jr_2\omega - m_2\omega^2\right)}{D(j\omega)} \tag{11.14}$$

$$X_2(j\omega) = \frac{k_1\left(k_2 + jr_2\omega\right)}{D(j\omega)} \tag{11.15}$$

$$\begin{aligned} D(j\omega) &= k_1k_2 + jk_1r_2\omega - \left(k_2m_1 + k_1m_2 + k_2m_2\right)\omega^2 \\ &\quad - jr_2\left(m_1 + m_2\right)\omega^3 + m_1m_2\omega^4 \end{aligned} \tag{11.16}$$

The frequency response of $\ddot{x}_2 = -\omega^2 X_2 e^{j\omega t}$ due to the input $\xi = \Xi e^{j\omega t}$, $\Xi = 1$ is [68]

$$H_1(j\omega) = -\omega^2 X_2(j\omega) \tag{11.17}$$

The frequency response of $F_z = \bar{F}_z e^{j\omega t}$ due to the input $\xi = \Xi e^{j\omega t}$, $\Xi = 1$ is [68]

$$H_2(j\omega) = k_1\left(1 - X_1(j\omega)\right) \tag{11.18}$$

The frequency response of $x_2 - x_1 = (X_2 - X_1)e^{j\omega t}$ due to the input $\xi = \Xi e^{j\omega t}$, $\Xi = 1$ is [68]

$$H_3(j\omega) = X_2(j\omega) - X_1(j\omega) \tag{11.19}$$

For $S_{\xi 1}$ excitation, the standard deviations of $\ddot{x}_2$, F_z, $x_2 - x_1$ are, respectively,

$$\sigma_{\ddot{x}_2} = \sqrt{\frac{1}{2\pi}\int_{-\infty}^{\infty}\left|H_1\right|^2 S_{\xi 1}d\omega}, \quad \sigma_{F_z} = \sqrt{\frac{1}{2\pi}\int_{-\infty}^{\infty}\left|H_2\right|^2 S_{\xi 1}d\omega}, \quad \sigma_{x_2 - x_1} = \sqrt{\frac{1}{2\pi}\int_{-\infty}^{\infty}\left|H_3\right|^2 S_{\xi 1}d\omega}$$

and, from [68],

$$\begin{aligned} \sigma_{\ddot{x}_2}^2 &= \frac{1}{2}A_b\upsilon\bar{\sigma}_{\ddot{x}_2}^2 \\ \bar{\sigma}_{\ddot{x}_2}^2 &= \frac{1}{m_2^2}\left(\frac{\left(m_2 + m_1\right)k_2^2}{r_2} + k_1r_2\right) \end{aligned} \tag{11.20}$$

$$\sigma_{F_z}^2 = \frac{1}{2} A_b \upsilon \bar{\sigma}_{F_z}^2$$

$$\bar{\sigma}_{F_z}^2 = \left(m_2 + m_1\right)^2 \left(P\right)$$

$$P = \left(\frac{\left(m_2 + m_1\right) k_2^2}{m_2^2 r_2} - \frac{2k_1 k_2 m_1}{m_2 r_2 \left(m_2 + m_1\right)} + \frac{k_1^2 m_1}{r_2 \left(m_2 + m_1\right)^2} + \frac{k_1 r_2}{m_2^2} \right) \tag{11.21}$$

$$\begin{aligned} \sigma_{x_2 - x_1}^2 &= \frac{1}{2} A_b \upsilon \bar{\sigma}_{x_2 - x_1}^2 \\ \bar{\sigma}_{x_2 - x_1}^2 &= \frac{\left(m_2 + m_1\right)}{r_2} \end{aligned} \tag{11.22}$$

For $S_{\xi 2}$ excitation, the standard deviations of $\ddot{x}_2$, F_z, $x_2 - x_1$ are, respectively,

$$\sigma_{\ddot{x}_2} = \sqrt{\frac{1}{2\pi} \int_{-\infty}^{\infty} \left|H_1\right|^2 S_{\xi 2} d\omega}, \quad \sigma_{F_z} = \sqrt{\frac{1}{2\pi} \int_{-\infty}^{\infty} \left|H_2\right|^2 S_{\xi 2} d\omega}, \quad \sigma_{x_2 - x_1} = \sqrt{\frac{1}{2\pi} \int_{-\infty}^{\infty} \left|H_3\right|^2 S_{\xi 2} d\omega}$$

and from [68]

$$\sigma_{\ddot{x}_2}^2 = c_{r\upsilon} \frac{\left[k_1^2 r_2^2 \left(k_2 + r_2 s_c + m_2 s_c^2\right) + k_1 k_2^2 \left(\left(m_1 + m_2\right) \left(k_2 + r_2 s_c\right) + m_1 m_2 s_c^2 \right) \right]}{\left(m_2^2 r_2 \left(D_S\right) \right)}$$

$$D_S = k_1 k_2 + k_1 r_2 s_c + k_2 \left(m_1 + m_2\right) s_c^2 + k_1 m_2 s_c^2 + \left(m_1 + m_2\right) r_2 s_c^3 + m_1 m_2 s_c^4$$

$$s_c = a\upsilon, \quad c_{r\upsilon} = \frac{1}{2 A_\upsilon a \upsilon} \tag{11.23}$$

$$\sigma_{F_z}^2 = c_{r\upsilon} \frac{\left(A_{2S} + B_{2S} + C_{2S}\right)}{k_1^2 m_2^2 r_2^2 \left(D_S\right)}$$

$$A_{2S} = k_1^4 \left(m_1 + m_2\right) r_2 \left(-2k_2 m_1 m_2 + m_1 r_2^2 + m_2 r_2^2\right) \left(k_2 + r_2 s_c + m_2 s_c^2\right)$$

$$B_{2s} = k_1^3 k_2^2 \left(m_1 + m_2\right)^2 r_2 \left(k_2 m_1 + k_2 m_2 + m_1 r_2 s_c + m_2 r_2 s_c + m_1 m_2 s_c^2\right)$$

$$C_{2s} = k_1^4 m_1 m_2^2 r_2 \left(k_1 k_2 + k_1 r_2 s_c + k_1 m_2 s_c^2 + k_2 m_2 s_c^2 + m_2 r_2 s_c^3\right) \tag{11.24}$$

$$\sigma_{x_2 - x_1}^2 = c_{r\upsilon} \frac{k_1 \left(k_2 m_1 + k_2 m_2 + m_1 r_2 s_c + m_2 r_2 s_c + m_1 m_2 s_c^2\right)}{r_2 \left(D_s\right)} \tag{11.25}$$

The formulae 11.20 through 11.25 state that the dynamic response of a vehicle model like the one in Figure 11.10d is *bounded*, due to either excitation $S_{\xi 1}$ or excitation $S_{\xi 2}$. The configuration in Figure 11.10d seems also the *simplest possible* to obtain a good filtered dynamic response for

a generic wheeled vehicle. This may explain why today's road vehicles are configured the way we commonly experience them, that is, a body connected by a suspension system to wheels with a built-in suspension system.

The engineering question arose before on the limit speed can be easily answered now by setting Equation 1.21 (or alternatively, Equation 11.24) equal to $p\sigma_{F_z} = F_{z,static} = (m_1 + m_2)g$ and then derive, for $p = 3$, the speed at which the wheel leaves the ground with 0.3% probability (obviously one may seek higher or lower probabilities, by changing properly the value of p).

The aforementioned reasoning shows that, for a wheeled vehicle running on a rough road profile, *a double-stage suspension system is necessary*. However, a word of caution is in order. The stochastic processes $S_{\xi 1}$ and $S_{\xi 2}$ are the idealization of real processes, and the aforementioned statements have to be taken as an engineering science contribution. For example, farm tractors are, still today, often unsprung, despite the acceleration on the body that is theoretically unbounded, yet they run mostly at vanishing speed, often on soft soil, and imperatively, the driver seat has always been sprung!

In Table 11.1, a fundamental sensitivity analysis is presented, based on Equations 11.20 through 11.22.

TABLE 11.1
Limits of the Three Respective Performance Indices $\sigma_{\ddot{x}_2}$, σ_{F_z}, $\sigma_{x_2-x_1}$ Computed by Equations 11.20 through 11.22, Respectively

	$\sigma_{\ddot{x}_2}$	σ_{F_z}	$\sigma_{x_2-x_1}$

$r_2 \to \infty$	∞	∞	0
$k_1 \to 0$	$\sqrt{\frac{A_b v}{2}\left[\frac{1}{m_2^2}\left(\frac{k_2^2 (m_1 + m_2)}{r_2}\right)\right]}$	$\sqrt{\frac{A_b v}{2}\left[\frac{1}{m_2^2}\left(\frac{k_2^2 (m_1 + m_2)^3}{r_2}\right)\right]}$	$\sqrt{\frac{A_b v}{2}\left[\left(\frac{m_1 + m_2}{r_2}\right)\right]}$
$k_1 \to \infty$	∞	∞	$\sqrt{\frac{A_b v}{2}\left[\left(\frac{m_1 + m_2}{r_2}\right)\right]}$
$k_2 \to 0$	$\sqrt{\frac{A_b v}{2}\left[\frac{1}{m_2^2} k_1 r_2\right]}$	$\sqrt{\frac{A_b v}{2}\left[\frac{1}{m_2^2}\left(\frac{k_1 (k_1 m_1 m_2^2 + r_2^2 (m_1 + m_2)^2)}{r_2}\right)\right]}$	$\sqrt{\frac{A_b v}{2}\left[\left(\frac{m_1 + m_2}{r_2}\right)\right]}$
$k_2 \to \infty$	∞	∞	$\sqrt{\frac{A_b v}{2}\left[\left(\frac{m_1 + m_2}{r_2}\right)\right]}$

Several consideration can be made by inspection of Table 11.1 and related Equations 11.20 through 11.22; $\sigma_{\ddot{x}_2}$, σ_{F_z}, $\sigma_{x_2-x_1}$ increase monotonically with v, A_b.
For what concerns $\sigma_{\ddot{x}_2}$, one may see that

- Reducing to zero the unsprung mass m_1 does not imply the vanishing of $\sigma_{\ddot{x}_2}$; an important increase of m_1 causes an important increase of $\sigma_{\ddot{x}_2}$.
- Reducing to zero the sprung mass m_2 implies very high $\sigma_{\ddot{x}_2}$; an important increase of m_2 causes the vanishing of $\sigma_{\ddot{x}_2}$.
- Reducing to zero the damping r_2 implies a strong increase of $\sigma_{\ddot{x}_2}$; increasing the damping r_2 implies a strong increase of $\sigma_{\ddot{x}_2}$; this means that there is an optimum damping that can be computed by setting $d\sigma_{\ddot{x}_2}/dr_2 = 0$, which gives

$$r_{2,opt} = \frac{k_2}{k_1}\sqrt{k_1\left(m_1 + m_2\right)}$$

In-depth analyses on the influence of the damping on the sprung mass accelerations have been given in the fundamental paper by Bourcier de Carbon [71] and in [2,67,68].

- Reducing to zero the tire stiffness k_1 does not imply the vanishing of $\sigma_{\ddot{x}_2}$ (this depends on the fact that the lower frequency mode becomes undamped as $k_1 \to 0$ and the frequency response function has a high peak near to the null frequency); on the contrary, an important increase of k_1 causes an important increase of $\sigma_{\ddot{x}_2}$; this means that an extremely strong reduction of tire stiffness is not beneficial for making $\sigma_{\ddot{x}_2}$ vanish.
- Reducing to zero the stiffness k_2 does not imply the vanishing of $\sigma_{\ddot{x}_2}$; an important increase of k_2 causes an important increase of $\sigma_{\ddot{x}_2}$; this means that an extremely strong reduction of suspension stiffness is not beneficial for making $\sigma_{\ddot{x}_2}$ vanish.

For what concerns σ_{F_z}, one may consider that $F_z = m_1\ddot{x}_1 + m_2\ddot{x}_2$, so the results are related to the ones already presented for $\sigma_{\ddot{x}_2}$; we can state that

- Reducing to zero the unsprung mass m_1 does not imply the vanishing of σ_{F_z}; on the contrary, an important increase of m_1 causes an important increase of σ_{F_z}.
- Reducing to zero the mass m_2 implies a strong increase of σ_{F_z}; increasing the mass m_2 implies a strong increase of σ_{F_z}; this means that there is an optimum m_2 that can be computed by setting $d\sigma_{F_z}/dm_2 = 0$, which gives involved analytical solutions that cannot be displayed here.
- Reducing to zero the damping r_2 implies a strong increase of σ_{F_z}; increasing the damping r_2 implies a strong increase of σ_{F_z}; this means that there is an optimum damping that can be computed by setting $d\sigma_{F_z}/dr_2 = 0$, which gives

$$r_{2,opt} = \frac{1}{k_1(m_1 + m_2)}\sqrt{k_1\left(k_2^2\left(m_1 + m_2\right)^3 + m_1m_2\left(m_2k_1^2 - 2m_2k_1k_2 - 2m_1k_1k_2\right)\right.}$$

- Reducing to zero the tire stiffness k_1 does not imply the vanishing of σ_{F_z}; on the contrary, an important increase of k_1 causes an important increase of σ_{F_z}; this means that an extremely strong reduction of tire stiffness is not beneficial for making σ_{F_z} vanish.
- Reducing to zero the stiffness k_2 does not imply the vanishing of σ_{F_z}; on the contrary, an important increase of k_2 causes an important increase of σ_{F_z}; this means that a strong increase of suspension stiffness is detrimental for a limited σ_{F_z}.

For what concerns $\sigma_{x_2-x_1}$, one may see that

- Reducing to zero the unsprung mass m_1 does not imply the vanishing of $\sigma_{x_2-x_1}$; on the contrary, an important increase of m_1 causes an important increase of $\sigma_{x_2-x_1}$.
- Reducing to zero the sprung mass m_2 does not imply the vanishing of $\sigma_{x_2-x_1}$; on the contrary, an important increase of m_2 causes an important increase of $\sigma_{x_2-x_1}$.
- Reducing to zero the damping r_2 implies a strong increase of $\sigma_{x_2-x_1}$; increasing the damping r_2 implies the vanishing of $\sigma_{x_2-x_1}$.
- $\sigma_{x_2-x_1}$ does not depend on k_1 and k_2, respectively.

All of the aforementioned considerations refer only to a fundamental parameter sensitivity analysis devoted to conceptual vehicle design considerations, referring to how many suspension stages have to be adopted for a ground vehicle. An in-depth sensitivity analysis referring to suspension system can be found in [2,68]. The optimal tuning of vehicle parameters is another additional question and does require much more theoretical concepts that are given in Chapter 8. Just one fundamental theoretical issue on optimal suspension parameter setting is highlighted here. By comparing Equation 11.20 with Equation 11.23 and Equation 11.21 with Equation 11.24 and Equation 11.22 with Equation 11.25, it follows that if the excitation is $S_{\xi 1}$, then the optimal suspension parameter setting is independent on the vehicle speed. Actually, in Equations 11.20 and 11.21, A_b and v are not mixed with the parameters m_1, m_2, k_1, k_2, r_2. On the contrary, for excitation $S_{\xi 2}$, the parameters A_v, s_c are mixed with the parameters m_1, m_2, k_1, k_2, r_2. The performance computed by means of Equations 11.20 through 11.22 is not much different with respect to the ones computed by means of Equations 11.23 through 11.25 [68] (we leave to the reader the proper analysis). From a theoretical point of view, the relevant point is that with $S_{\xi 1}$ excitation, the suspension tuning is independent from vehicle speed; on the contrary, with $S_{\xi 2}$ excitation, the suspension tuning is dependent from vehicle speed, which is an important issue for vehicle architecture.

Summarizing the issues of this section, we have stated that a passive suspension system is necessary only if a vehicle have to move at relatively high speed. *If vehicles were running on a perfectly smooth surface, no suspension system would be necessary.* No road is smooth enough to avoid excitation of vibration in the vertical direction, unless the vehicle speed is vanishing. Double-stage suspensions were (and are) adopted for vehicles to cope with the vibrations induced by road irregularity.

The aforementioned considerations have been referred to passive suspension systems. The results hold for adaptive suspensions. The results do not hold for ideal active suspensions (see Chapter 31).

Referring to passive suspensions, the question arises on how setting the parameters of the suspension systems in Figure 11.10d, in order to obtain the best performance in terms of minimum $\sigma_{\ddot{x}_2}$, minimum σ_{F_z}, and minimum $\sigma_{x_2-x_1}$. In [68] and in Chapter 8, the question is answered.

The aforementioned considerations were made referring to a randomly uneven profile. In a real environment, excitation is produced by either continuous or isolated obstacles or a combination of them. Taking into account such isolated obstacles (curbs, potholes, etc.), the main general results would have been the same. The description of isolated obstacles and how modeling a pneumatic wheel hitting them is given in [2,7].

In [2], the addition of a spring in series to the damper is discussed with reference to the influence on vibration filtering.

11.3.2.1 Lumped Mass Car Body

The considerations made earlier refer to a so-called quarter-car model [1,2,7,69]. Actually, the quarter-car model is often a sufficient approximation of a full-car model [2] when studying vertical

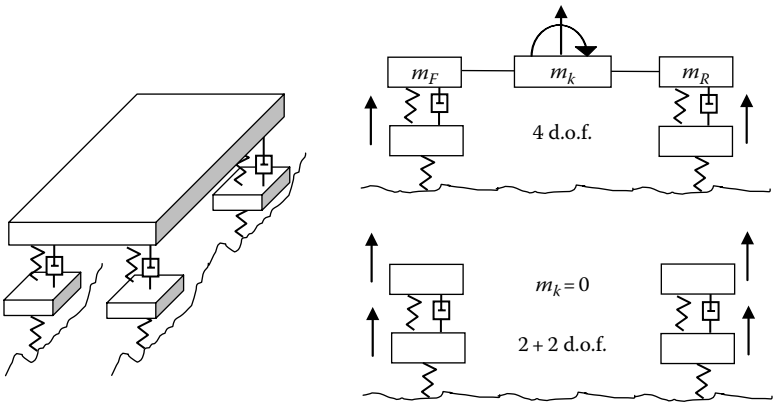

FIGURE 11.11 Lumped mass car models.

vibrations. The unsprung mass m_2 in Figure 11.10d can be determined after considering the half-car model depicted in Figure 11.11; its mass can be partitioned in three parts, such that

$$m_F + m_R + m_k = M$$

$$J = m_F l_F^2 + m_R l_R^2$$

where

M is the mass of the car body
J is the pitch moment of inertia around the center of gravity
m_k is the coupling mass at the center of gravity
m_F, m_R are the sprung masses of the fore and rear quarter models in Figure 11.11
l_F and l_R are the respective horizontal distances of the center of gravity from the front and rear axles

Introducing the condition of linear momentum $0 = m_F l_F - m_R l_R$, the three unknowns m_F, m_R, m_k can be found and read

$$m_F = \frac{J}{(l_F + l_R) l_F}$$

$$m_R = \frac{J}{(l_F + l_R) l_R} \tag{11.26}$$

$$m_k = \frac{M l_F l_R - J}{l_F l_R}$$

If $J = M l_F l_R$, then $m_k = 0$, that is, the front and rear parts of the half model are *decoupled* and $m_F = M l_R / l$, $m_R = M l_F / l$ where l is the wheelbase, $l = l_F + l_R$. If $J = 0$, then $m_k = M$. Often $m_k \approx 0$ in actual cars, so quarter-car models allow to investigate the dynamics of vehicles with the minimum number of variables and parameters.

In this reasoning, roll motion has been disregarded; the complete treatment on how a quarter-car model can be derived is given in [2]; the conclusion is that the reasoning presented earlier can be adopted often with reasonable accuracy for conceptual design investigations.

11.3.2.2 Ride Comfort and Road Holding Influenced by Main Vehicle Dimensions

The wheelbase and the track dimensions influence the performance of the vehicle while running on a road with a random unevenness.

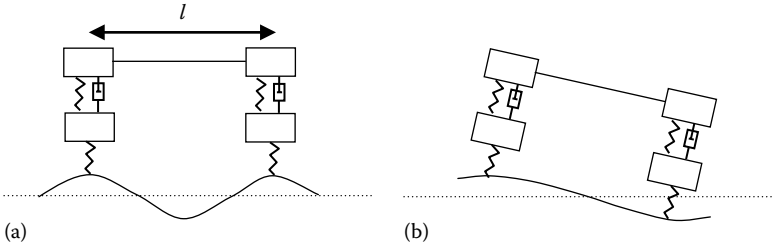

FIGURE 11.12 Heave and pitch motions. (a) Heave excited only and (b) pitch excited only.

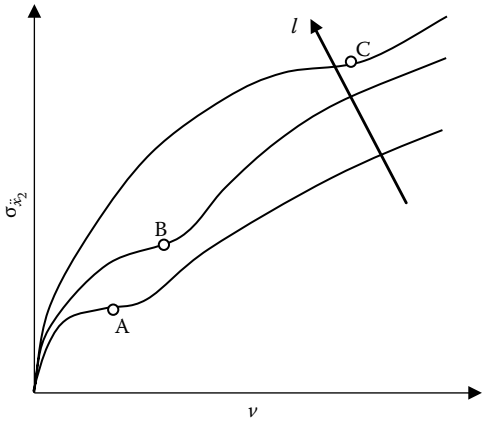

FIGURE 11.13 Typical ride discomfort of an automobile as function of wheelbase l and vehicle speed v.

The wheelbase l influences the ride comfort as, depending on the wavelength of the road unevenness, the heave or the pitch can be or cannot be excited; a simple explanation of this fact can be argued by inspection of Figure 11.12 [2]. Such an occurrence is called *wheelbase filtering*.

Due to wheelbase filtering, the ride discomfort as defined in Section 11.3.2 (and in a more general way in [2)]) depends on vehicle speed v and wheelbase l as shown in Figure 11.13. If a given speed would be attained more frequently than other ones, the wheelbase could be set in order to exploit the bends A, B, or C; more details are reported in [2].

Referring to Figure 11.9, the position of the seat (L114) is of crucial importance for the ride comfort of the passenger, as shown in Figure 11.14 [2]. The seat nearby the center of gravity (mid-wheelbase) is better than a seat on an axle; details on how computing the ride comfort are given in [1,2,66] and in Chapters 29 and 36.

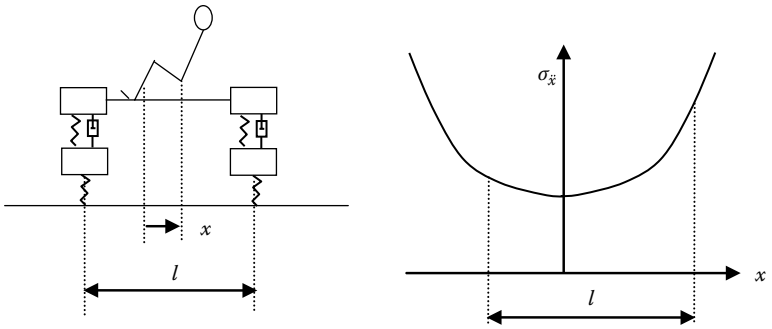

FIGURE 11.14 Ride discomfort as function of the position of the seat along the wheelbase.

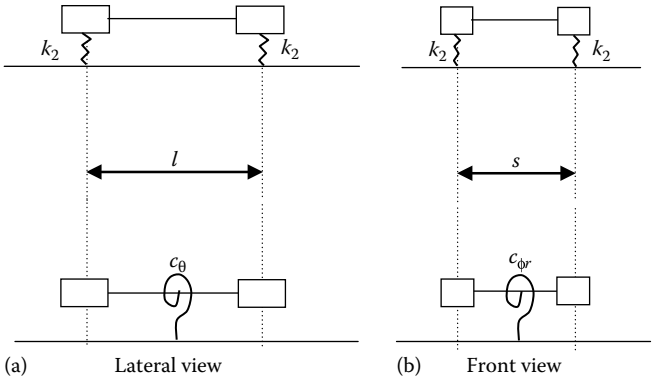

FIGURE 11.15 (a) Anti-dive effect of the wheelbase l and (b) antiroll effect of the track s.

A given amount of pitch stiffness is required to avoid car body dive during braking. The complete and comprehensive theory of anti-dive and anti-squat is given in [2,72]; see Chapter 21. Referring to Figure 11.15, the pitch stiffness is $C_\theta = k_2 l^2/2$, that is, the pitch stiffness depends on the square of the wheelbase l. At a given pitch stiffness, a slight increase of the wheelbase allows a substantial decrease of the suspension stiffness, thus improving ride comfort (which is positively affected by a low k_2).

The road holding is not influenced directly by the wheelbase, at least if $m_k = 0$, which is a reasonable assumption for automobiles.

The total roll stiffness $c_\phi = c_\phi + c_{\phi b}$ depends on the square of the track s, where $c_{\phi r}$ is related to the effect of the suspension springs $c_{\phi r} = k_2 s^2/2$ (such an effect is similar to the one referring to pitch; Figure 11.15) and $c_{\phi b}$ is related to the effect of antiroll bars (see [1,2,7]) $c_{\phi b} = k_b s^2/b^2$ (see Figures 11.15 and 11.16). At a given roll stiffness, a slight increase of the track allows a substantial decrease of the suspension stiffness, thus improving ride comfort (which is positively affected by a low k_2).

In [2], the coherence function γ is effectively introduced to relate the power spectral density of the random vertical unevenness at the track center (see Equations 11.1 and 11.2) $(1/2)(1 + \gamma)S_\xi i(\omega)$ $(i = 1, 2)$, with the power spectral density of roll unevenness (antisymmetrical unevenness at the left and right wheel), and $(2/s^2)(1 - \gamma)S_{\xi i}(\omega)$ $(i = 1, 2)$. The last power spectral density states that the excitation of the roll motions is *inversely proportional to the square of the track*.

11.3.3 Pneumatic Wheel

We have seen that *a double-stage suspension system is necessary* (if the common technology is exploited) and that the first suspension stage can be simply a spring. We dare state that the first suspension stage *must* be simply a spring as a mass in contact with the ground would be subject to unbounded inertia forces; actually the system in Figure 11.17 is the sum of the model in Figure 11.10a plus the model in Figure 11.10d (for the sake of space, the proof of this statement is omitted here).

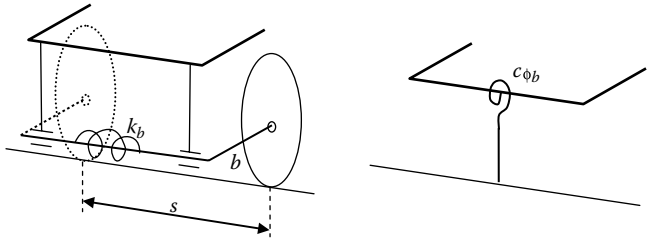

FIGURE 11.16 Antiroll bar. Torsion beam stiffness k_b and equivalent roll stiffness $c_{\phi b}$ (compare with Figure 11.15b).

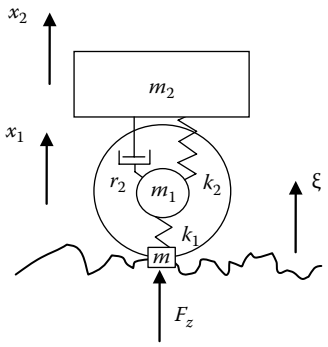

FIGURE 11.17 Model depicted in Figure 11.10d, with the additional mass m.

The pneumatic tire can be modeled [1,2,69] by means of a massless spring, as Figure 11.10d shows. It is the well-known solution referring to Thomson and Dunlop inventions [9].

The main functions of the pneumatic wheel are four; in addition to cushioning (i.e., the first stage of the suspension system), the other three functions are simply carrying the load F_z, applying to the ground the traction/braking forces F_x and applying to the ground the cornering forces F_y.

11.3.3.1 Load Carrying and Radial Stiffness

The load-carrying function of the pneumatic wheel is in principle fulfilled as shown in Figure 11.18 where a torus is pressed against a hard ground. If the torus is made from a membrane (unable to resist flexural moments), the part of the torus in contact with the ground is loaded, respectively, in vertical direction by the double opposing pressures p_i and, in horizontal direction, by distributed tension t. Considering the equilibrium in the vertical direction, the vertical force is $F_z = p_i A_c$ and the pressure on the ground is equal to the inner pressure p_i. The ideal pneumatic tire of Figure 11.18 *is not subject to the Hertz contact pressure*; actually the contact pressure is *constant*. In such an ideal case, the load-carrying capacity of the pneumatic tire is given only by the inner pressure. Unfortunately, the compliance of the torus would be very weak in the horizontal direction, that is, the deformations associated to forces F_x, F_y would be too high (Figure 11.18). So a kind of a stiff ring at the outer portion of the torus has been conceived and applied as shown in Figure 11.19 where a cross section of a radial tire is shown [8,10,73,74] (in the sequel, a "radial tire"—no "run-flat" type—will be considered; older types of pneumatic tires (bias) behave similarly to a stiffened torus, approaching the behavior of radial tires).

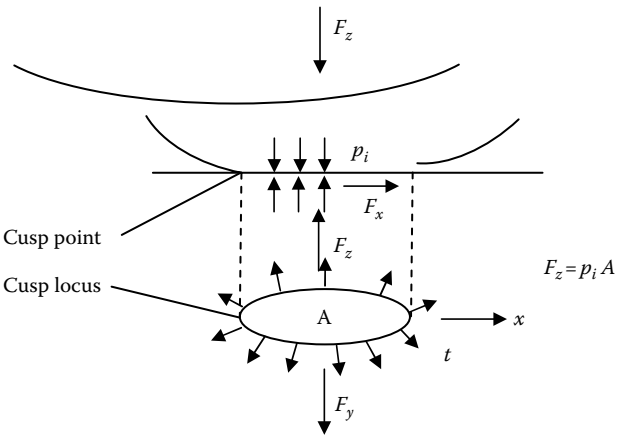

FIGURE 11.18 Membrane torus pressed on hard ground.

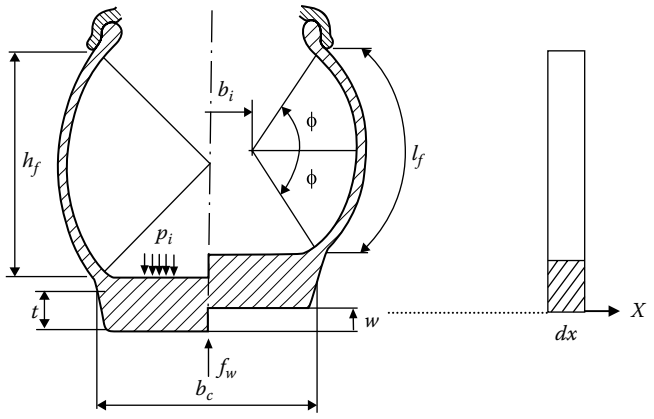

FIGURE 11.19 Cross section of a pneumatic tire (radial type). (Adapted from Mastinu, G. and Fainello, M., Study of the pneumatic tyre behaviour on dry and rigid road by finite element method, *Vehicle System Dynamics*, 21, 143, 1992, http://www.informaworld.com/smpp/title~db=all~content=t713659010~tab=issueslist~branches=27-v271.)

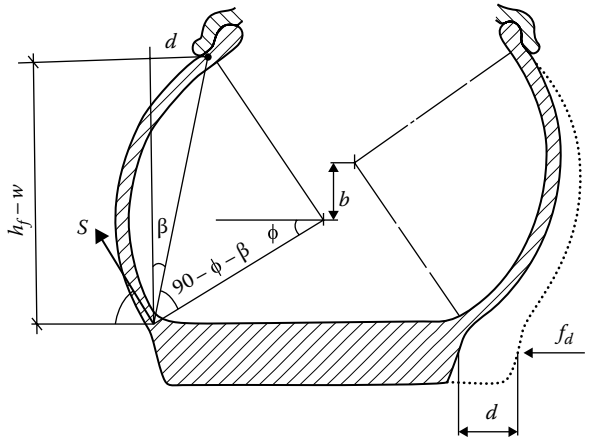

FIGURE 11.20 Section of a pneumatic tire deflected laterally. (From Mastinu, G. and Fainello, M., Study of the pneumatic tyre behaviour on dry and rigid road by finite element method, *Vehicle System Dynamics*, 21, 143, 1992, http://www.informaworld.com/smpp/title~db=all~content=t713659010~tab=issueslist~branches=27-v271.)

Let us consider Figures 11.19 and 11.20 [109]. The respective meanings of the introduced symbols are as follows:

h_f is the height of the sidewall
b_c is the cross width of the belt
w is the vertical (radial) displacement
l_f is the length of the sidewall
f_w is the radial force per unit length (in radial direction)
f_d is the lateral force per unit length (in x direction, i.e., circumferential direction)
p_i is the inner pressure

By inspection of Figure 11.21, the equilibrium in vertical direction of the belt is given by (forces are given per unit length dx along the direction of motion of the wheel)

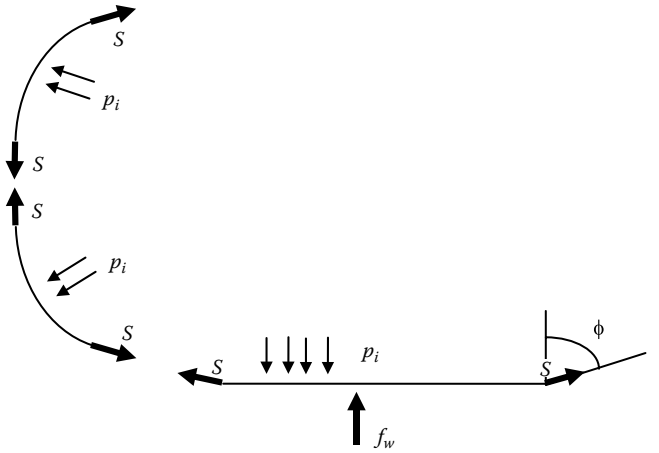

FIGURE 11.21 Cross section of a pneumatic tire with internal and external forces.

$$2S\cos(\phi) - p_i b_c + f_w = 0 \quad \text{additionally}$$

$$\tan(\phi) = \frac{(h_f - w)/2}{(b_c - b_i)/2} = \frac{S\sin(\phi)}{S\cos(\phi)} = \frac{p_i(h_f - w)/2}{S\cos(\phi)}$$

Thus, $S\cos(\phi) = p_i(b_c - b_i)/2$, which implies

$$f_w = p_i b_i \tag{11.27}$$

In order to compute f_d, for small displacements, let us consider that $\tan(\beta) = \dfrac{d}{h_f - w} \cong \sin(\beta) \cong \beta$ and that

$$S_{ys} = S\cos(90 - \phi + \beta)$$

$$S_{yd} = S\cos(90 - \phi - \beta)$$

$$f_d = S_{ys} - S_{yd}$$

Remembering that $S\cos(\phi) = p_i(b_c - b_i)/2$, and using the known trigonometric transformation rules, we can write

$$f_d = 2S\cos(\phi)\sin\frac{d}{h_f - w} = p_i\frac{b_c - b_i}{h_f - w}d \tag{11.28}$$

From (11.27), if $f_w = 0$, then $b_i = w = 0$, and $f_d = p_i(b_c/h_f)d$, which states that the lateral stiffness per unit length (along the circumference direction) of a pneumatic tire (f_d/d) is higher if the *aspect ratio* $a_r = h_f/b_c$ is lower. This explains why the torus-like tire (whose aspect ratio $b_c/h_f = 1$) has been soon abandoned for stiffer pneumatic tires in lateral direction, with lower aspect ratio (a_r = 0.70–30). Less stiff tires in lateral direction have the so-called relaxation length too high that implies a lazy response of the tire in producing lateral forces due to steering input (see [1,2,8,10]).

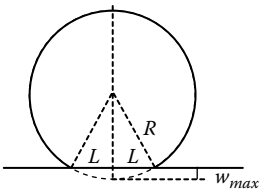

FIGURE 11.22 Approximated contact patch length of a pneumatic tire model whose cross section is shown in Figure 11.19.

Equation 11.27 states that the load-carrying capacity of the tire is related not only to *inner pressure* but also to *geometry*. The pressure does not increase substantially with the increasing load (due to the very limited variation of volume). By inspection of Figure 11.22, the vertical force F_z could be computed summing all of the contributions $f_w(x) = p_i b_i(x)$ at a different coordinate x along the contact patch [10,75]:

$$F_z = \int_{-L}^{L} f_w(x)\,dx = p_i \int_{-L}^{L} b_i(x)\,dx \tag{11.29}$$

The higher the pressure, the higher the load that can be carried.

An analytical formula for Equation 11.29 is reported in [76]:

$$\begin{aligned}
F_z &= 2p_i\left(A\left(w_{max}\right)+B\left(w_{max}\right)+C\left(w_{max}\right)\right)+k_{carc}w_{max}\\
A &= \sqrt{2Rw_{max}}\left(b_c-b_{v0}\right)\\
B &= \frac{1}{2}\sqrt{\frac{1}{3}Ra_rk_{ar}b_c}\left(-\frac{\pi}{2}-\arctan\left(\frac{w_{max}+a_rb_c-a_rk_{ar}b_c}{2\sqrt{w_{max}}\sqrt{a_rk_{ar}b_c-a_rb_c}}\right)\right)a_rk_{ar}b_c\\
C &= \frac{1}{4}\sqrt{3Ra_rk_{ar}b_c}\\
&\quad\times\left(\left(a_rk_{ar}b_c-a_rb_c+w_{max}\right)\left(\frac{\pi}{2}+\arctan\left(\frac{w_{max}+a_rb_c-a_rk_{ar}b_c}{2\sqrt{w_{max}}\sqrt{a_rk_{ar}b_c-a_rb_c}}\right)\right)+2\sqrt{w_{max}}\sqrt{a_rk_{ar}b_c-a_rb_c}\right)
\end{aligned} \tag{11.30}$$

where the respective meanings of the introduced symbols are

R is the outer radius (half of the overall diameter)
$a_r = h_f/b_c$ is the aspect ratio
$a_f = a_rk_{ar} = l_f/b_c$
w_{max} is the maximum tire deflection
b_{v0} is the geometric parameter related to the hoop tension inside the belt
k_{carc} is the radial stiffness of the carcass when $p_i = 0$

Typical tire data are reported in Table 11.2.

A is roughly half of the contact area $A_c = 2A = 2b_cL$ at the tire–ground interface, so $F_{zi} = 2p_ib_cL$ represents the vertical force that would be carried by an ideal tire made from a membrane (see Figure 11.18) whose contact area was rectangular. The force F_{zi} is very high, so other

TABLE 11.2
Typical Tire Data of Equation 11.30, Internal Pressure p_i = 2 Bar

	165/70R14	205/55R16	265/50R19
l_f (mm)	97.8	89	113.5
b_c (measured) (mm)	134.4	177.8	230.5
h_f (mm)	88.7	79.8	103.5
b_{v0} (mm)	41.2	100.3	116.4
R (measured) (mm)	294.3	317.3	379.9
k_{carc} (kN/m)	36.1	51.6	61.9

terms (*B, C*, etc.) reduce such a high force to a value close to the real one F_z. The terms *B* and *C* refer to the forces *S* exerted by sidewalls as shown in Figure 11.21, such *S* forces act in order to reduce F_{zi} (see Figure 11.21).

By inspection (and analysis) of Equation 11.30, the *load-carrying capacity of a tire appears to be proportional to the inner pressure p_i and approximately proportional to the cross width b_c and to $\sqrt{R}$.*

This means that given the static load $F_{z,stat}$, the dimensions of the wheel will have approximately to be proportional to the product $p_i b_c \sqrt{2R}$ (see Equation 11.30). For resisting lateral forces, additional reasoning is needed, which is given in Section 11.4.1.1.

Another formula (referring to old tires) for the tire load-carrying capacity is reported in [18].

The radial stiffness at static condition can be computed from Equation 11.30 taking the derivative $\partial F_z/\partial w_{max}$ at $w_{max} = w_{max,stat}$ (i.e., at the statical w_{max}). The radial stiffness is *proportional to the inner pressure p_i and, with very good approximation, proportional to the cross width b_c and to $\sqrt{R}$.*

This is almost consistent with the formula reported in [18,77] for tire stiffness K_z (kg/mm):

$$K_z = 0.00028\,P\sqrt{OD\,W} + 3.45$$

where

P is the tire inflation pressure (kPa)
W is the tire footprint width (mm)
OD is the outside diameter (mm)

Given the load to be carried, the combination pressure–diameter is defined by the tire manufacturer relying on many aspects (safety, durability) that cannot be dealt with here [10,18]. The basic mathematical relation between the load-carrying ability, the inner pressure, and the cross width is suggested by Equation 11.30. Obviously, the contact of the tire with the ground is much more complicated than addressed here (see, e.g., Chapters 17 through 19 [8–10,78,79,110]).

11.3.3.2 Rolling Resistance

Tire rolling resistance is dealt with in [10] and particularly in [18]. In this section, we will give basic concepts arguing that rolling resistance is related to the tire elasticity necessary for running on non-smooth road. There are several phenomena that more or less qualitatively explain such resistance. Some simple phenomena are presented hereafter (for other phenomena, see "Tire Dynamics" chapter in [8] and [10]).

One simple phenomenon for rolling resistance can be explained qualitatively by means of the model in Figure 11.23a. In the contact patch, the radial force *F* starts from zero at the leading edge and comes back to zero at the trailing edge. The force *F* is directly related to the displacement in radial direction *s* of the generic element of the tire that is in contact with the ground; *s* (together with *F*) is null at both

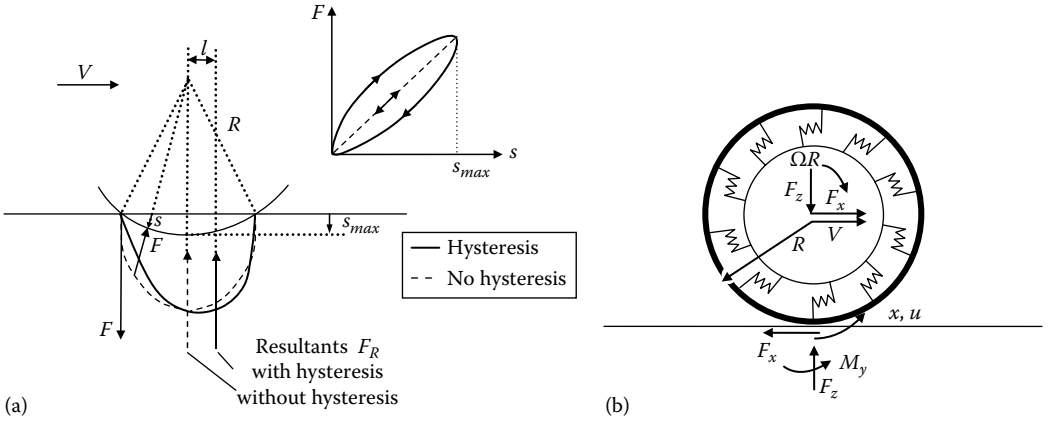

FIGURE 11.23 Tire models suitable for describing basic phenomena associated to rolling resistance: (a) hysteresis in radial direction, (b) hysteresis in circumferential direction.

the leading and trailing edges. There is a linear relationship $F = F(s)$ for hysteresis-free material. If the loading phenomenon is free from hysteresis, the resulting shape of the pressure at the contact area is symmetrical and the resultant force is applied at the center of the contact area. Otherwise, if the loading phenomenon is not hysteresis-free, then the resultant shape of the pressure at the contact area is *not* symmetrical and the resultant force is displaced from the contact area center toward its leading edge. This causes a moment $F_R l$ opposing the rotation of the wheel.

Another mechanism for describing rolling resistance is related simply to rolling. Let us consider Figure 11.23b where a curved bar of small (infinitesimal) thickness in radial direction is connected via a distributed stiffness k to a rigid disk. The curved reference coordinate x is attached to the disk whose center runs at constant forward speed V. The local displacement $u = u(x)$ of the bar is due to the force F_x that is applied to the only contact point between the tire and ground. Due to equilibrium, a moment $M_y = F_x R$ *must* be applied at the tire–ground contact point.

Let us imagine that the deformed part of the bar is located nearby the contact point. Let us write the equilibrium for a section dx of the bar

$$N - N - dN - kdxu = 0, \quad \text{that is, } \frac{dN}{dx} = -ku$$

where N is the compression force inside the bar. Hook's law states that $\sigma = N/A = E(-du/dx)$, where A is the cross section of the curved bar and E is Young's modulus (we have assumed positive compression force N, so the deformation ε reads $\varepsilon = -du/dx$). Taking the first derivative of Hook's law $dN/dx = -EA(d^2u/dx^2)$ and remembering that $dN/dx = -ku$, the differential equation governing the displacement $u = u(x)$ is derived

$$EA\frac{d^2u}{dx^2} - ku = 0$$

The solution of such a differential equation is $u = u(x) = U_0 e^{\lambda x}$. Substituting $u = U_0 e^{\lambda x}$ into the differential equation, the expression for λ can be derived, that is,

$$\lambda = \pm\sqrt{\frac{k}{EA}}$$

The boundary conditions are

$u = 0 \ @ \ x \to \pi R \sim \infty$

$u = 0 \ @ \ x \to -\pi R \sim -\infty$

thus,

$u = u(x) = U_0 e^{|\lambda| x} \ (x < 0)$

$u = u(x) = U_0 e^{-|\lambda| x} \ (x > 0)$

Additionally, at the contact point between the wheel and the ground, the contact force F_x is divided into two equal parts acting at the two bar tips (see Figure 11.24). At $x = 0^+$ ($x > 0$), $N = -F_x/2$, so applying Hook's law at such a bar tip and remembering that $u = u(x) = U_0 e^{-|\lambda| x}$,

$$-\frac{F_x}{2} = EA\left(-\frac{du}{dx}\right) = EA\left(-(-|\lambda|)U_0 e^{|\lambda|0}\right) = EA\lambda U_0 \quad \text{with} \quad \lambda = \sqrt{\frac{k}{EA}}$$

and so

$$U_0 = -\frac{F_x}{2EA\lambda}$$

that is, the bar has a negative displacement U_0 at the contact point. U_0 is "small," that is, the two points O and A in Figure 11.24 are separated by an infinitesimal distance.

Let us imagine that the rigid movement of the disk occurs around an axis through point O′ (Figure 11.25). As the curved bar can be deformed in circumferential direction, and point B must remain stuck at point O to the ground, the bar is elongated toward left by the amount *du*. In other words, during the motion, due to the bar elasticity, point B will remain at point O and will not reach the position shown in Figure 11.25.

The absolute velocity of point O with respect to the ground is $\vec{v}_{abs} = 0$; the relative velocity of point O (belonging to the curved bar) with respect to the disk is $\vec{v}_{rel} = du/dt < 0$ (*du* points in opposite

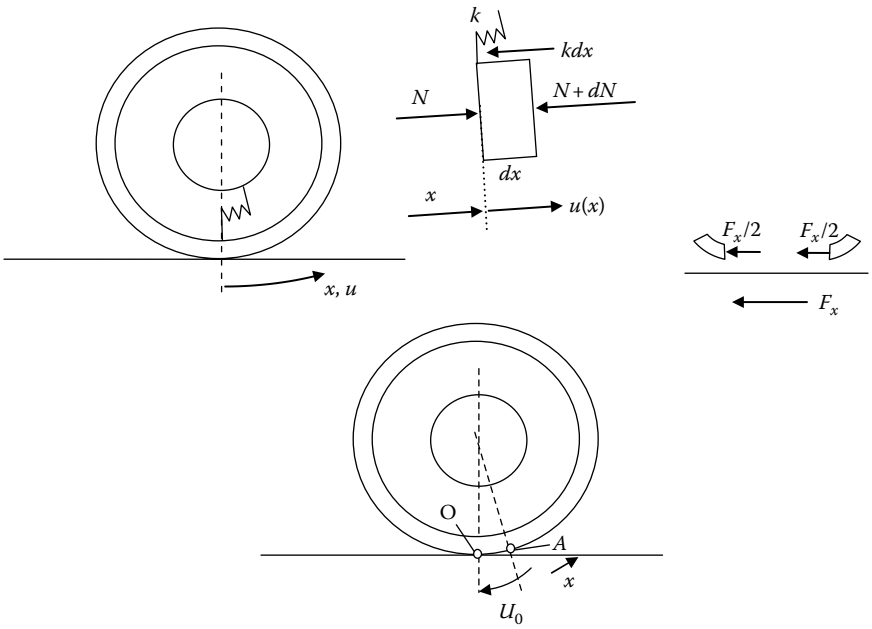

FIGURE 11.24 Tire model for describing the basic features of a non-stiff rolling wheel (see also Figure 11.23b).

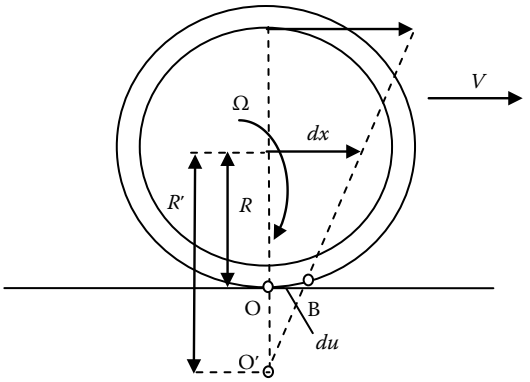

FIGURE 11.25 Rolling of a non-stiff wheel (see also Figure 11.23b). All displacements are small (infinitesimal).

direction with respect to *x*), and the velocity of the point O as it was attached to the disk is $\vec{v}_t$ whose projection along the *x*-axis is $\Omega(R' - R) = V - \Omega R$.

Let us consider that at point O,

$$\frac{du}{dt} = \left.\frac{du}{dx}\right|_{x=-U_0} \frac{dx}{dt}$$

and (remembering that $u = u(x) = U_0 e^{|\lambda| x}$ for $x < 0$) with $\lambda = \sqrt{k/EA}$
$du/dt = \lambda U_0 e^{\lambda U_0} \cdot V \cong \lambda U_0 V$ (as $dx/dt = V$ and $e^{\lambda U_0} \cong 1$ being $U_0 \cong 0$); thus,

$$\vec{v}_{rel} = \frac{du}{dt} = \lambda\left(\frac{-F_x}{2EA\lambda}\right)V = \frac{-F_x}{2EA}V < 0$$

At point O,

$$\vec{v}_{abs} = \vec{v}_{rel} + \vec{v}_t = \frac{-F_x}{2EA}V + V - \Omega R = 0$$

and rearranging,

$$F_x = 2EA\frac{V - \Omega R}{V}$$

The last expression states that the force F_x depends on both EA and the longitudinal slip $s_x = V - \Omega R/V$, that is, the longitudinal force can only develop if slip occurs. Since $F_x = M_y R$ (Figure 11.23b), if M_y is null, F_x is null and the wheel rolls at zero slip (ideal case). If hysteresis is present in the elastic bar, some power is needed to make the wheel rolling. In this case, neither M_y nor F_x is null and slip occurs. The rolling resistance is related to how much material is present in the elements that are deformed during rolling; hysteresis power is proportional to the volume of the deformed material. The cross area A can be expressed as $A = b_c t$ where b_c is the cross width of the tread (Figure 11.19) and t is the tread height (Figure 11.19). If E were extremely high, the deformations would be vanishing and the rolling resistance would be vanishing. *Inherently, not perfectly stiff wheels are prone to rolling resistance*. Material hysteresis is directly related to the rolling resistance. The displacements of the bar and related deformations are reported in Figure 11.26.

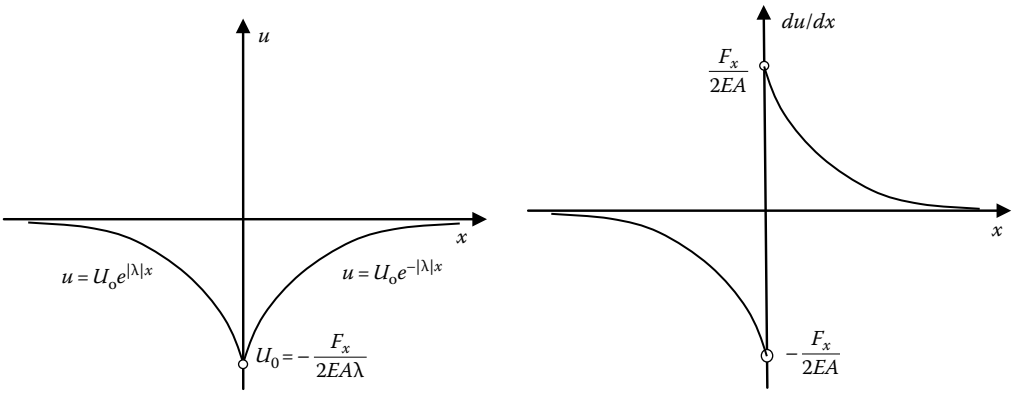

FIGURE 11.26 Displacement (u) and deformation (du/dx) of the elastic curved bar (wheel rim).

11.3.4 Powertrain Concept

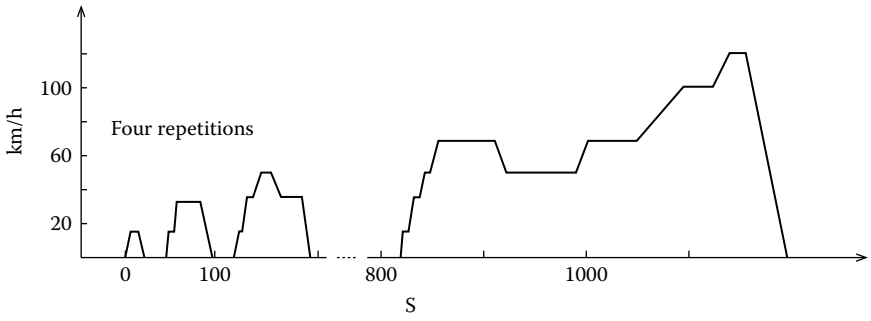
In the preceding sections, we have seen that an elastic wheel is necessary for a vehicle to run on an uneven road and that the hysteresis associated with such an elasticity causes wheel rolling resistance. In this section, we will deal with the energy required to travel and the related impact on the concept of the powertrain.

In Chapter 27 Section 27.2, the longitudinal dynamic behavior of vehicles has been presented. In particular, driving resistances have been dealt with referring to straight driving.* Starting from such a modeling of vehicle dynamics, the conceptual design of the powertrain has to take into account the actual operation conditions, that is, the *mission* of the vehicle.

The reference cycle (criticized) describing the mission of European vehicles is the *New European Driving Cycle* (NEDC, also denoted as MVEG-95, Motor Vehicle Emission Group-95; Figure 11.27). In the United States, the corresponding cycle FTP-75 is used. For cars, design and construction solutions depend directly from the considered reference cycle.

In [80], a contribution to the conceptual design of powertrains is given. Taking into account the NEDC, the energy E required to travel 100 km is computed by considering the actual energy spent for running at different speeds:

$$E = A \cdot C_x \cdot 1.9 \times 10^4 + m \cdot f_R \cdot 8.4 \times 10^2 + m \cdot 10 \text{ kJ/100 km} \tag{11.31}$$



where

A is the cross-sectional area of the vehicle
C_x is the drag coefficient
m is the vehicle mass
f_R is the rolling resistance of tires

Introducing the proper parameter values in Equation 11.31, it appears that all of the three terms of the sum are of the same order of magnitude.

---

* During cornering, an additional rolling resistance appears due to the components of the lateral forces in the direction of forward motion of the car. Such a resistance is $F_{rx} = \frac{mv_x^2}{Rl}(l_F\alpha_R + l_R\alpha_F)$; the meaning of the symbols can be argued by inspection of Figure 11.31. Since the lateral slip at the axle is proportional to the lateral force at the same axle, that is, $\alpha_i \propto F_{yi}$ ($i = F, R$), and since $F_{yi} \alpha v_x^2$, it follows that $F_{rx} \alpha v_x^4$! The only way to reduce rolling resistance during cornering is to have low α_i, that is, high cornering stiffness.

	Unit	ECE 15	EUDC
Distance	[km]	4 × 1.013 = 4.052	6.955
Duration	[s]	4 × 195 = 780	400
Average speed	[km/h]	18.7 (with idling)	62.6
Maximum speed	[km/h]	50	120

FIGURE 11.27 NEDC (or MVEG-95), composed by four repetitions of ECE 15 driving cycle and one repetition of EUDC. (From Guzzella, L. and Sciarretta, A., *Vehicle Propulsion Systems*, Springer Verlag, Berlin, Germany, 2005, ISBN-10 3-540-25195-2.)

The relationship between the cross-sectional area A and the mass of today's cars can be taken as linear. The linear interpolation of the available data gives $A = a{\cdot}m + b$, where a and b (see [2]) are constants ($a = 5.7 \times 10^{-4}$ m^2/kg and $b = 1.172$ m^2).

The sensitivity of E with respect to the aerodynamic drag coefficient $p_1 = C_x$, to the tire rolling resistance $p_2 = f_R$, and to the vehicle mass $p_3 = m$ can be defined as

$$\lim_{\delta p_i \to 0} \frac{\left[E\left(p_i + \delta p_i\right) - E\left(p_i\right)\right]/E\left(p_i\right)}{\delta p_i / p_i} = \frac{\partial E}{\delta p_i}\frac{p_i}{E} \quad i = 1,3 \tag{11.32}$$

where

$$\frac{\partial E}{\delta p_1} = \frac{\partial E}{\partial C_x} = A \cdot 1.9 \times 10^4 \text{ kJ/100 km} \cdot \text{m}^2$$

$$\frac{\partial E}{\delta p_2} = \frac{\partial E}{\partial f_R} = m \cdot 8.4 \times 10^2 \text{ kJ/100 km}$$

$$\frac{\partial E}{\delta p_3} = \frac{\partial E}{\partial m} = a \cdot C_x \cdot 1.9 \times 10^4 + f_R \cdot 8.4 \times 10^2 + 10 \text{ kJ/100 km} \cdot \text{kg}$$

Expression (11.32) defines the normalized variation of E due to a unitary normalized variation of p_i. In Table 11.3, the E percent variations for 10% variation of p_i are reported for actual vehicles of different sizes. It is immediately evident that the highest sensitivity is related to mass. Reducing the vehicle mass by 10% can reduce by slightly less than 10% the energy required to travel 100 km at the different speeds defined by NEDC.

In Section 11.5, the mass distribution of different cars is introduced. By inspection of Table 11.3, it appears that reducing vehicle mass by a certain percent amount means reducing the mass of almost every subsystem by the same percent amount.

TABLE 11.3
Variation of E (Equation 11.32) due to Single Parameter Variation (for Different Vehicles)

	Data					Percent Variation of E due to 10% Variation Of		
Vehicle Type	Rated power (kW)	A (m²)	C_x	f_R	m (kg)	Aerodynamic drag coeff. $p_1 = C_x$	Rolling resistance $p_2 = f_R$	Vehicle mass $p_3 = m$
Midrange	140	2.2	0.26	12×10^{-3}	1560	2	4	9
Compact	55	2.0	0.29	10×10^{-3}	1120	4	3	8
Sports	310	1.95	0.29	12×10^{-3}	1650	2	4	9
SUV	200	2.3	0.41	14×10^{-3}	2640	2	4	9

Vehicle mass reduction is a more effective way to reduce the energy required to travel. Thus, mass reduction is a need for green mobility and a target (challenge) for the present and future of automotive technology.

Mass reduction allows vehicles to accelerate more rapidly, which is an important customer demand. For cars with internal combustion engine, an approximated formula for obtaining the acceleration time t_{vx} to reach the speed v_x from still is $t_{v_x} \cong v_x^2 \cdot m/P_{max}$ where P_{max} is the maximum rated power of the engine and m the vehicle mass.

In Table 11.4, referring to different vehicles, the ratio $E/\Delta T$ for completing the NEDC is reported, where E has been defined before and ΔT is the time to drive the NEDC for 100 km (10,720 s). $E/\Delta T$ can be interpreted as a mean power. Additionally in Table 11.4, the maximum power output of the vehicle during the NEDC and the maximum rated power are shown. $E/\Delta T$ is dramatically lower than the maximum rated power of the engine. The maximum acceleration that a vehicle can have is about two to four times (up to five to seven for sports cars) the acceleration required for the NEDC. It appears that the NEDC is rather mild in terms of acceleration and power required. Driver/customers require extremely high acceleration and power.

In [80], referring to the NEDC, the energy required to travel 100 km has been computed in case the recuperation of the kinetic energy could be obtained with perfect efficiency ($\eta = 1$) and with our increasing mass of the vehicle due to the fitting into the vehicle of the recuperation system. The formula reads

$$E_{rec} = A \cdot C_x \cdot 2.2 \times 10^4 + m \cdot f_R \cdot 9.81 \times 10^2 \text{ kJ/100 km} \tag{11.33}$$

TABLE 11.4
Mean Power Required to Complete the NEDC, Maximum Power during the NEDC and Maximum Rated Power

Vehicle Type	$E/\Delta T$ for NEDC (Mean Power) (kW)	Maximum Power during NEDC (kW)	Maximum Rated Power (kW)
Midrange	4	14	140
Compact	3	13	55
Sports	4	16	310
SUV	7	28	200

Data in Table 11.3.

Computing E_{rec}/E, it appears that, even in the ideal case, such a ratio is not lower than 80%. Considering the actual reduced efficiency of recuperation ($\eta = 0.6$) and the mass increment of the vehicle for the presence on board of the recuperation system (≈100 kg), $E_{rec}/E \approx 90\%$. In this case, only a 10% saving could be expected, that is, we cannot expect a dramatic reduction of fuel consumption from hybrid vehicles.

The aforementioned Equations 11.31 and 11.32 are fundamental for the concept design of the powertrain of vehicles with either internal combustion engine or electric or hybrid powertrain.

More information on powertrain can be found in [2,4,5,12,13,81–83].

11.3.5 Traction and Braking

Let us consider Figure 11.28. A generic two-axle vehicle with mass m and wheelbase l is shown. The center of gravity is at height h from the ground. The vehicle runs at speed v. The horizontal distances of the center of gravity from, respectively, the front and rear axles are l_F, l_R. The inertial forces are ma_x and mg.

Let us consider Figure 11.28a; the vehicle is braking, and the longitudinal deceleration is a_x. On the front axle, the forces F_{xF} and F_{zF} are acting, respectively, in longitudinal and vertical directions; correspondingly, F_{xR} F_{zR} act at the rear axle.

In the following derivations, the vectors are positive if directed as shown in Figure 11.28a.

Let us write the rotation equilibrium equation around an axis passing by point A and divide by l:

$$F_{zR} = mg\frac{l_F}{l} - ma_x\frac{h}{l}$$

When locking (at braking) or full slip (traction) is reached,

$$F_{zR} = \frac{F_{xR}}{\mu_{max}} \quad \text{and} \quad F_{zF} = \frac{F_{xF}}{\mu_{max}}$$

μ_{max} is the *maximum* friction coefficient between tire and ground; by hypothesis, it is *equal* for rear and front axle tires. Then

$$F_{zR} = mg\frac{l_F}{l} - ma_x\frac{h}{l} = \frac{F_{xR}}{\mu_{max}} \tag{11.34}$$

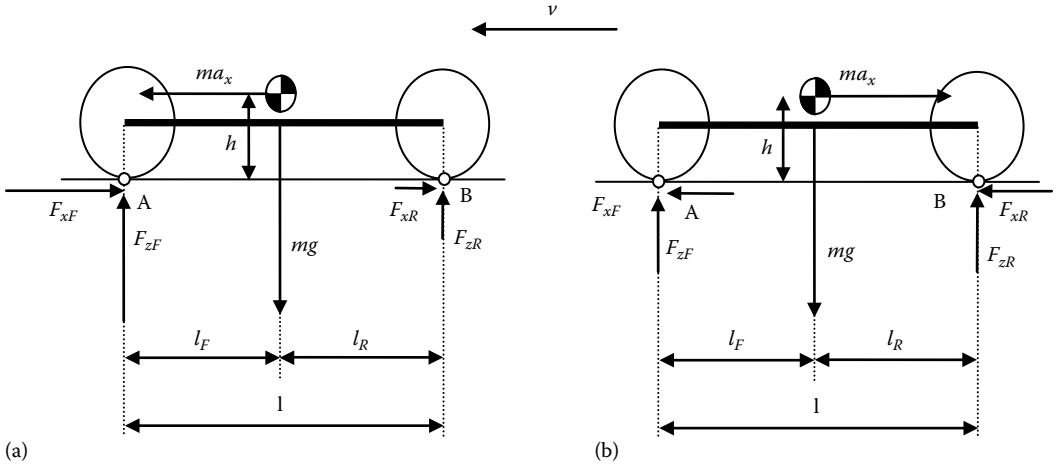


FIGURE 11.28 Forces in longitudinal and vertical direction acting on a vehicle. Aerodynamic forces are neglected. (a) Braking and (b) traction.

Repeating the aforementioned derivation with reference to point B,

$$F_{zF} = mg\frac{l_R}{l} + ma_x\frac{h}{l} = \frac{F_{xF}}{\mu_{max}} \tag{11.35}$$

Summing up Equations 11.34 and 11.35,

$$mg\frac{l_F}{l} + mg\frac{l_R}{l} = \frac{F_{xF}}{\mu_{max}} + \frac{F_{xR}}{\mu_{max}}$$

but as

$$l_F + l_R = l \quad mg = \frac{F_{xF}}{\mu_{max}} + \frac{F_{xR}}{\mu_{max}}$$

that is

$$\mu_{max} = \frac{F_{xF} + F_{xR}}{mg} \tag{11.36}$$

or $F_{xF} + F_{xR} = mg\mu_{max}$, that is, the longitudinal forces at the tires are equal to $\mu_{max}mg$.

Let us now write the equilibrium in longitudinal direction:

$$F_{xF} + F_{xR} = ma_x \tag{11.37}$$

$$a_x = \frac{F_{xF} + F_{xR}}{m} \tag{11.38}$$

Dividing Equation 11.36 by Equation 11.38, we obtain

$$\frac{\mu_{max}}{a_x} = \frac{m}{mg}$$

so

$$a_x = \mu_{max}g \tag{11.39}$$

that is, the limit longitudinal acceleration of a vehicle is $\mu_{max}g$.

Subtracting Equation 11.35 from Equation 11.34

$$mg\frac{l_F}{l} - mg\frac{l_R}{l} - 2ma_x\frac{h}{l} = \frac{F_{xR}}{\mu_{max}} - \frac{F_{xF}}{\mu_{max}}$$

eliminating μ_{max} by Equation 11.36, and rearranging

$$mg\left(\frac{l_F}{l} - \frac{l_R}{l}\right) - 2ma_x\frac{h}{l} = \frac{F_{xR} - F_{xF}}{F_{xF} + F_{xR}}mg$$

eliminating a_x by Equation 11.38

$$mg\left(\frac{l_F}{l}-\frac{l_R}{l}\right)-2\left(F_{xF}+F_{xR}\right)\frac{h}{l}=\frac{F_{xR}-F_{xF}}{F_{xR}+F_{xR}}mg$$

then (if $F_{xF}+F_{xR}\neq 0$)

$$mg\left(\frac{l_F}{l}-\frac{l_R}{l}\right)\left(F_{xF}+F_{xR}\right)-2\left(F_{xF}+F_{xR}\right)^2\frac{h}{l}=\left(F_{xF}-F_{xR}\right)mg$$

that is,

$$\begin{aligned}\left(F_{xF}+F_{xR}\right)^2&=\frac{l}{2h}\left(mg\left(\frac{l_F}{l}-\frac{l_R}{l}\right)\left(F_{xF}+F_{xR}\right)-\left(F_{xF}-F_{xR}\right)mg\right)\\&=\frac{mgl}{2h}\left(F_{xF}\frac{l_F}{l}+F_{xR}\frac{l_F}{l}-F_{xF}\frac{l_R}{l}-F_{xR}\frac{l_R}{l}-F_{xR}+F_{xF}\right)\\&=\frac{mgl}{2h}\left(F_{xF}\left(\frac{l_F}{l}-\frac{l_R}{l}+\frac{l}{l}\right)+F_{xR}\left(\frac{l_F}{l}-\frac{l_R}{l}-\frac{l}{l}\right)\right)\end{aligned}$$

As $-l_R+l=l_F$ and $l_F-l=-l_R$, then

$$\frac{mgl}{2h}\left(F_{xF}\left(\frac{2l_F}{l}\right)+F_{xR}\left(\frac{-2l_R}{l}\right)\right)\text{ and, finally,}$$

$$\left(F_{xF}+F_{xR}\right)^2=\frac{mg}{h}\left(l_FF_{xF}-l_RF_{xR}\right)\tag{11.40}$$

Equation 11.40 represents *the relationship that has to hold between longitudinal forces at, respectively, the front and rear axles when the friction at the tire–ground interface is exploited at the maximum extent* and the maximum friction coefficient is equal at the front and rear axles. Equation 11.40 has been obtained just manipulating equilibrium equations (Equations 11.34 through 11.37) and considering the limit conditions $F_{zF}=F_{xF}/\mu_{max}$, $F_{zR}=F_{xR}/\mu_{max}$. Notice that μ_{max} nor a_x appears in Equation 11.40. To plot Equation 11.40, let us write

$$F_{xR}^2+2F_{xR}F_{xF}+\frac{mg}{h}l_RF_{xR}-\frac{mg}{h}l_RF_{xF}+F_{xF}^2=0$$

F_{xR} can be obtained given F_{xF}. Figure 11.29 shows the plot of Equation 11.40.

The part of the parabola lying in the first quadrant ($F_{xF}>0$, $F_{xR}>0$) refers to braking and has been presented in Chapter 27. In Figure 11.29, not only positive (braking) forces F_{xF}, F_{xR} are plotted but also negative forces appear in the third quadrant (where $F_{xF}<0$, $F_{xR}<0$). Such forces (plotted in Figure 11.28b) are related to *traction for all-wheel-drive vehicles*. (There is no engineering interest in the case in which $F_{xF}>0$, $F_{xR}<0$ and $F_{xF}<0$, $F_{xR}>0$.) Equation 11.40 establishes the ideal torque distribution between front and rear axles to obtain the maximum longitudinal acceleration or deceleration.

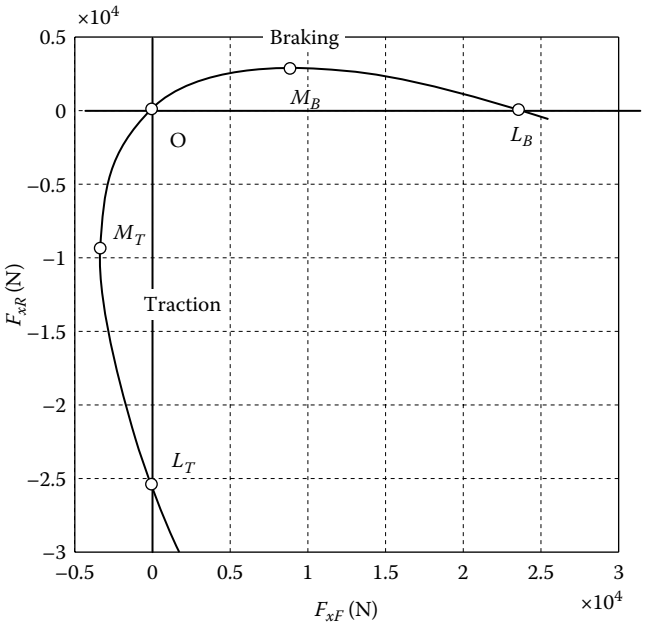

FIGURE 11.29 Plot of Equation 11.40, m = 1000 kg, l_F = 1.2 m, l_R = 1.3 m, and h = 0.5 m.

The coordinates of points O, M_B, L_B, M_T, L_T are given in Table 11.5. Such points are important to define the architecture of both braking systems and all-wheel-drive systems of cars. Usually the limit working conditions for cars are nearby points M_B and M_T; the ratios

$$\frac{F_{xFM_B}}{F_{xRM_B}} = \frac{2 \cdot l_R}{l_F} + 1, \quad \frac{F_{xFM_T}}{F_{xRM_T}} = \frac{l_R}{\left(l_R + 2l_F\right)}$$

give a guess of the maximum forces acting at front and rear axles (for cars). If $l_F = l_R$, then $F_{xFM_B}/F_{xRM_B} = 3$ and $F_{xFM_T}/F_{xRM_T} = 1/3$. The deceleration at point M_B is (Figure 11.29) $a_x = ½l_F g/h$, correspondingly, at M_T $a_x = -½l_R g/h$.

The axis of the parabola is $F_{xR} = -F_{xF} + (mg/4h)(l_F - l_R)$ (see Figure 11.30). If $l_F = l_R$, the axis takes the equation $F_{xF} = -F_{xR}$. Additionally in the origin

$$\frac{dF_{xR}}{dF_{xF}} = -1 + \frac{l}{l_R}$$

TABLE 11.5
Coordinates of Limit Points of Figure 11.29

	O	M_B	L_B	M_T	L_T
F_{xF}	0	$\frac{1}{4}\frac{mg \cdot l_F \cdot (2l_R + l_F)}{h \cdot l}$	$\frac{mg \cdot l_F}{h}$	$-\frac{1}{4}\frac{mg \cdot l_R^2}{h \cdot l}$	0
F_{xR}	0	$\frac{1}{4}\frac{mg \cdot l_F^2}{h \cdot l}$	0	$-\frac{1}{4}\frac{mg \cdot l_R \cdot (l_R + 2l_F)}{h \cdot l}$	$-\frac{mg \cdot l_R}{h}$

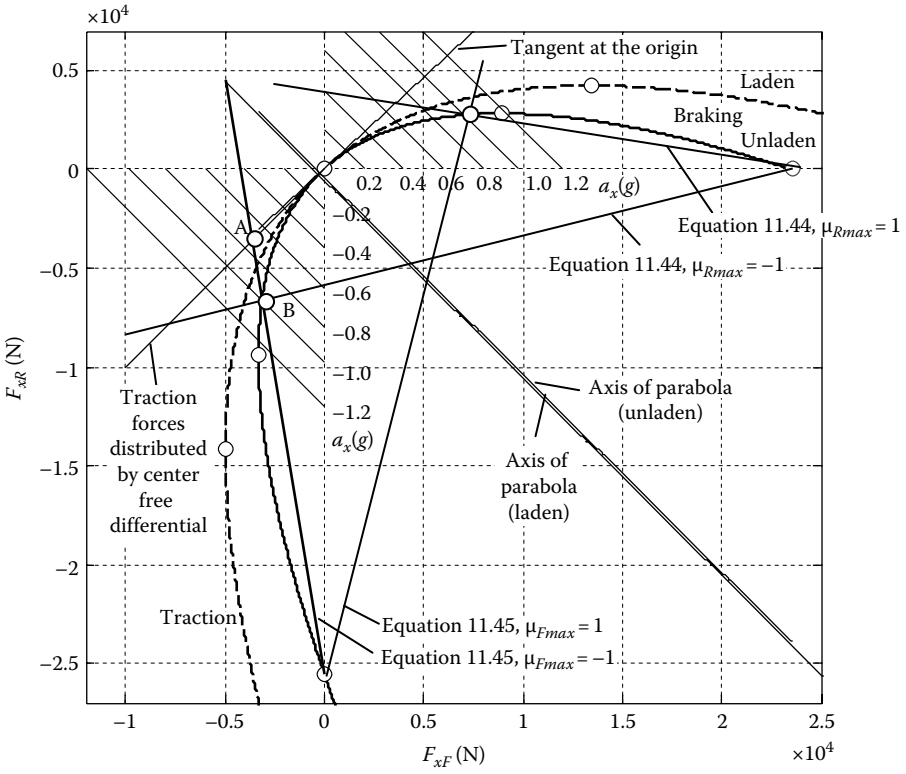

FIGURE 11.30 Traction–braking forces for optimal acceleration–deceleration performance, data in Figure 11.29 (data refer to the unladen vehicle, mass of the laden vehicle m = 1500 kg).

that is, all of the parabolas that can be obtained for different values of m have the same tangent at the origin (see Figure 11.30). If $l = 2l_R$ (or $l_F = l_R$), then $dF_{xR}/dF_{xF} = 1$.

Let us consider how Equation 11.40 is transformed when the friction coefficient is different for front and rear axles. Let us write the moment equilibrium around point A (Figure 11.28a) and divide by $lF_{zR} = mg(l_F/l) - ma_x(h/l)$. At limit condition, $F_{zR} = F_{xR}/\mu_{Rmax}$ and $F_{zF} = F_{xF}/\mu_{Fmax}$, where $\mu_{i\text{-}max}(i = F, R)$ is the maximum friction coefficient at the tire–ground interface. Let us now suppose that at the rear axle, the maximum longitudinal force is always attained, that is, $F_{zR} = F_{xR}/\mu_{Rmax}$, instead at the front axle whichever longitudinal force could be applied $F_{zF} = F_{xF}/\mu_F$ with $0 \le \mu_F < \infty$. Thus,

$$F_{zR} = mg\frac{l_F}{l} - ma_x\frac{h}{l} = \frac{F_{xR}}{\mu_{Rmax}} \tag{11.41}$$

Repeating the same derivations with reference to point B, we find

$$F_{zF} = mg\frac{l_R}{l} + ma_x\frac{h}{l} = \frac{F_{xF}}{\mu_F} \tag{11.42}$$

Summing up Equations 11.41 and 11.42, we obtain

$$mg = \frac{F_{xF}}{\mu_F} + \frac{F_{xR}}{\mu_{Rmax}}$$

that is,

$$\frac{F_{xF}}{\mu_F} = mg - \frac{F_{xR}}{\mu_{Rmax}}$$

and

$$\frac{1}{\mu_F} = \frac{1}{F_{xF}}\left(mg - \frac{F_{xR}}{\mu_{Rmax}}\right)$$

and

$$\mu_F = \frac{F_{xF}}{\left(mg - \left(F_{xR} / \mu_{Rmax}\right)\right)} = \frac{\mu_{Rmax} F_{xF}}{\mu_{Rmax} mg - F_{xR}} \tag{11.43}$$

Recalling the equilibrium equation in longitudinal direction,

$$F_{xF} + F_{xR} = ma_x \tag{11.37}$$

or

$$a_x = \frac{F_{xF} + F_{xR}}{m} \tag{11.38}$$

Subtracting Equation 11.42 from Equation 11.41, we obtain

$$mg\left(\frac{l_F}{l} - \frac{l_R}{l}\right) - 2ma_x \frac{h}{l} = \frac{F_{xR}}{\mu_{Rmax}} - \frac{F_{xF}}{\mu_F}$$

Eliminating μ_F by means of Equation 11.43 and eliminating a_x by means of Equation 11.38, we obtain

$$mg\frac{l_F}{l} - mg\frac{l_R}{l} - 2(F_{xF} + F_{xR})\frac{h}{l} = \frac{F_{xR}}{\mu_{Rmax}} - \frac{F_{xF}}{\left(\mu_{Rmax} F_{xF} / \mu_{Rmax} mg - F_{xR}\right)} = \frac{F_{xR}}{\mu_{Rmax}} - \frac{\mu_{Rmax} mg - F_{xR}}{\mu_{Rmax}}$$

Rearranging,

$$mg\frac{l_F}{l} - mg\frac{l_R}{l} - 2\frac{h}{l}F_{xF} - 2\frac{\mathrm{h}}{\mathrm{l}}F_{xR} = \frac{F_{xR}}{\mu_{Rmax}} - mg + \frac{F_{xR}}{\mu_{Rmax}}$$

and

$$-2\frac{h}{l}F_{xR} - 2\frac{F_{xR}}{\mu_{Rmax}} = -mg - mg\frac{l_F}{l} + mg\frac{l_R}{l} + 2\frac{h}{l}F_{xF}$$

and

$$\left(\frac{1}{\mu_{Rmax}}+\frac{h}{l}\right)F_{xR}=\frac{l_F}{l}mg-\frac{h}{l}F_{xF}$$

and

$$F_{xR}=\left(\frac{l_F}{l}mg-\frac{h}{l}F_{xF}\right)\left(\frac{1}{\mu_{Rmax}}+\frac{h}{l}\right)^{-1} \tag{11.44}$$

Equation 11.44 represents *the relationship that has to hold between longitudinal forces at, respectively, the front and rear axles when the friction at rear is exploited at the maximum extent.*

Let us now suppose that the tire–ground friction limit is reached at the front axle $F_{zF}=F_{xF}/\mu_{Fmax}$, instead, at the rear axle whichever longitudinal force could be applied $F_{zR}=F_{xR}/\mu_R$ with $0\le\mu_R<\infty$. Repeating the aforementioned procedure, we find

$$F_{xR}=\frac{l}{h}\left(\frac{1}{\mu_{Fmax}}-\frac{h}{l}\right)F_{xF}-\frac{l_R}{h}mg \tag{11.45}$$

Equation 11.45 represents *the relationship that has to hold between longitudinal forces at, respectively, the front and rear axles when the friction at front is exploited at the maximum extent.*

Notice that Equations 11.44 and 11.45 have been derived referring to braking. To describe traction (defined by negative forces $F_{xF}<0$, $F_{xR}<0$), in the derivation of Equations 11.44 and 11.15, the relations describing wheel slipping are

$$F_{zF}=-\frac{F_{xF}}{\mu_R},\quad F_{zR}=-\frac{F_{xR}}{\mu_R}$$

that formally imply $\mu_{Fmax}<0$, $\mu_{Rmax}<0$.

Let us derive the maximum acceleration reachable by a rear-wheel-drive car, under fundamental hypothesis that the engine torque is unlimited. From Equation 11.44, setting $F_{xF}=0$ and $F_{zR}=-F_{xR}/\mu_R$, from Equation 11.38, we find $a_x=F_{xR}/m$; combining with Equation 11.44, we find

$$a_{xRmax}=\frac{F_{xR}}{m}=\left(\frac{l_F}{l}g\right)\left(\frac{1}{-\mu_{Rmax}}+\frac{h}{l}\right)^{-1}$$

Sports cars have a very low h, with l_F that is as high as possible. Since l is proportional to the mass m, high l implies high mass, which implies a powerful (and heavy) engine.

Correspondingly, the maximum acceleration reachable by a front-wheel-drive car reads (starting from Equation 11.45)

$$a_{xFmax}=\left(\frac{l_R}{l}g\right)\left(\frac{1}{-\mu_{Fmax}}-\frac{h}{l}\right)^{-1}$$

The last two equations give hints on vehicle architecture to obtain the proper acceleration performance. If the question is comparing the maximum attainable acceleration of a front-wheel-drive car

with the maximum attainable acceleration of a rear-wheel-drive car, if $\mu_{Fmax} = \mu_{Rmax} = \mu$ and if l, h, l_F, and l_R are the same for the two vehicles, then

$$\frac{a_{xFmax}}{a_{xRmax}} = \left(\frac{l_R}{l_F}\right)\left(\frac{l - h\mu}{l + h\mu}\right) \tag{11.46}$$

Only if $l_R/l_F < (l - h\mu/l + h\mu)^{-1}$, the maximum attainable acceleration of the rear-wheel-drive car is the highest.

Figure 11.30 shows the plot of, respectively, Equations 11.37, 11.40, 11.44, and 11.45. Equation 11.40 is plotted referring both to an unladen vehicle and to a laden vehicle; Equations 11.44 and 11.45 are plotted for $\mu_{Fmax} = \mu_{Rmax} = 1$ (braking) and for $\mu_{Fmax} = \mu_{Rmax} = -1$ (traction); Equation 11.37 is plotted referring to longitudinal decelerations or accelerations ($a_x = 0.2\ldots1.2$, or $a_x = -0.2\ldots-1.2$). The line that is tangent at the origin to both of the two curves "laden" and "unladen" is shown, and its slope is almost equal to 1 (as $l \approx 2l_R$). The respective axes of the two parabolas "laden" and "unladen" are shown, and they are very near.

Let us consider Figure 11.30. Let us imagine that $|\mu_{Fmax}| = 1$ and $|\mu_{Rmax}| = 1$. In traction condition for an all-wheel-drive car, point B represents the maximum possible acceleration (provided that the engine power is sufficient; actually the acceleration would be equal to 1 g, a performance hardly achievable even by a very efficient sports car). In this case, both the front and the rear axles come together at a full slip. Let us imagine that the architecture of the all-wheel-drive car is conceived with a central free differential. In this case, the longitudinal force distribution is equal on the front and rear axles, and such a condition is represented by the line equally sloped shown in the third quadrant of the plot in Figure 11.30. Increasing the module of the forces at the axles, point A is reached from the origin; at point A, the slipping of front axle is reached, and the rear axle is still not slipping. Since the maximum longitudinal force at the front axle is reached, the free differential prevents to increase the force at the rear axle even if an additional torque would be applied by the engine (such an additional torque input would imply unsteady motion conditions of the driveline that is not taken into consideration in our model). The maximum acceleration attainable would be about 0.7 g instead of 1 g. Figure 11.30 shows that the distribution of longitudinal forces at the axles during traction to obtain the best performance in terms of maximum acceleration is not the distribution provided by a free differential connecting the front and the rear axle. Actually, the best distribution should be defined by Equation 11.40.

This occurrence has important implications in the conceptual design of the architecture of all-wheel-drive road vehicles. Actually, at least a fixed unequal distribution of longitudinal forces at the front and rear axles is necessary (about 40% at front 60% at rear), as it is often adopted in very powerful cars (for more details on driveline architecture, see [2,85]).

Obviously, the maximum longitudinal acceleration depends on the friction available. In case friction at the tire–ground interface were extremely high, the maximum longitudinal acceleration would be obtained with rear-wheel drive only (i.e., $F_{xF} = 0$).

11.4 ACTIVE SAFETY

11.4.1 Handling

In Chapter 27, the main concepts referring to handling have been given. Here, the influence on handling of some parameters related to vehicle architecture will be highlighted.

Handling of road vehicles (running on even road) depends mostly on

- Tire characteristics
- Inertial and geometric data (mass, center of gravity location, wheelbase)
- Drive axle (front- or rear- or all-wheel drive) and torque vectoring
- Suspension kinematics and elastokinematics

A simplified but extremely powerful way to take into account all of the relevant parameters or nonlinearities influencing the horizontal motion of vehicles is provided by the *handling diagram* theory. Such a theory describes the handling and stability properties of a vehicle running on an even surface. The handling diagram theory is briefly reported in Chapter 27, Section 27.3.3; full details are given in [8]. In the following sections, the handling diagram theory will be used to highlight the influence of parameters related to vehicle architecture on active safety. For further reading on active safety, see [1,2,7,11,86].

11.4.1.1 *Tire Characteristics*

Surely, the nonlinear tire cornering characteristics play *the* fundamental role referring to handling. Let us consider Figure 11.31a; the forces acting on an actual car (left) and the corresponding resultants acting at the axles (right) are shown. Such a correspondence suggests the introduction of the simple two-wheel model depicted in Figure 11.31b (Chapter 27) for studying the handling behavior of road vehicles. Let us consider the well-known tire cornering characteristic (briefly, tire characteristic) at pure lateral slip, that is, let us consider the relation between lateral force and lateral slip $F_y = F_y(\alpha)$. Let us consider the two-wheel model depicted in Figure 11.31b; for the model to be consistent with reality, the resultant lateral force at the rear axle is to be computed as the sum of the lateral forces at the two rear tires of the actual vehicle (e.g., considering the rear axle, $F_{yR} = 2F_y(\alpha)$). Approximately the same holds for the front axle (precisely, the resultant lateral force at the front axle can be computed as the sum of the lateral forces at the two front tires if a vanishing longitudinal force is acting at the front tires and—as it usually occurs—δ_F is small; see Chapter 27). The relationship between axle cornering characteristic (defined as the resultant lateral forces acting at the axle as function of lateral slip at the axle center) and tire characteristic is obvious for the two-wheel model in Figure 11.31b (e.g., considering the rear axle, $F_{yR} = 2F_y(\alpha)$) in linear form $F_{yR} = 2C_{\alpha R}\alpha$ ($C_{\alpha R}$ is the rear tire cornering stiffness; for definition of the cornering stiffness, see Chapters 17 and [8]). The relationship between axle cornering characteristic (briefly, axle characteristic) and tire characteristic is less obvious if the actual vehicle (Figure 11.31a) or a more complex vehicle model is considered. In this case, many different vehicle parameters, such as the axle kinematic or elastokinematic, can have a substantial influence in defining the said relationship (the more relevant among such influences will be dealt with in the subsequent sections). It is anyway a matter of fact that such influences do not modify substantially the original relation between axle characteristic and tire characteristic. Thus, the resultants of lateral forces at the axles are strictly related to tire characteristics.

In the handling diagram theory (see Chapter 27, Section 27.3.3 [8]), reference is made to the so-called effective axle characteristics that are the previously introduced axle characteristic divided by the resultant of the vertical forces at the same axle F_{yi}/F_{zi} ($i = F, R$) (e.g., referring to rear axle and to Figure 11.32, $F_{yR}/F_{zR} = F_{yR}(\alpha)/F_{zR}$, in linear form $F_{yR}/F_{zR} = C_R\alpha/F_{zR} = 2C_{\alpha R}\alpha/F_{zR}$). Referring to Figure 11.31c and considering the effective axle characteristics F_{yF}/F_z, F_{yR}/F_z, (subscripts F = front, R = rear), it is clear how the front and rear effective axle characteristics influence the handling diagram [8]. Actually, by inspection of Figure 11.31c, one can easily see that the curve on the left (the so-called handling curve) is obtained *by subtracting horizontally the two curves on the right (i.e., the effective axle characteristics)*, at a given value of F_{yi}/F_{zi}. Since

$$\frac{F_{yF}}{F_{zF}} = \frac{F_{yR}}{F_{zR}} = \frac{a_y}{g} = \frac{v_x^2}{Rg} \quad \text{and} \quad \alpha_F - \alpha_R = \delta_F - \frac{l}{R} = \delta_F - \delta_{F_0}$$

the handling curve of Figure 11.31c establishes a relationship between the lateral acceleration a_y/g (expressed in nondimensional form as a_y is divided by the ground acceleration g) and the steering angle δ_F. (For the sake of simplicity, the aforementioned formula has been derived neglecting the aerodynamic forces and the rolling resistances—such effects can be introduced with a proper reasoning that is dealt with in Section 11.4.1.3).

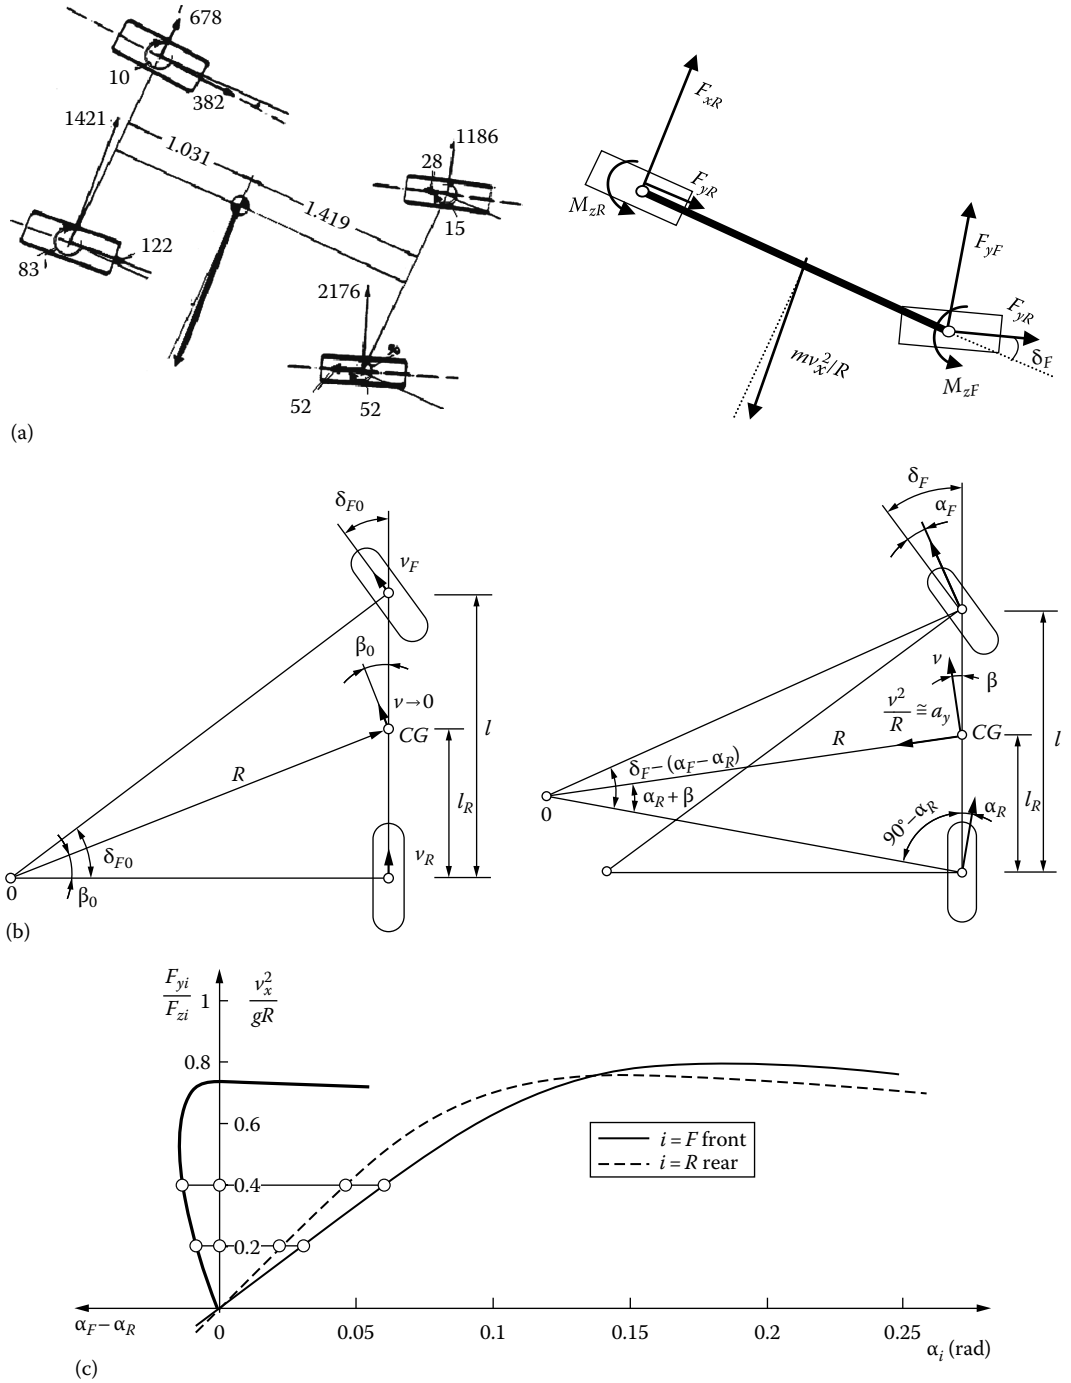

FIGURE 11.31 (a) Forces acting on an actual car (left) and corresponding resultants acting at the axles (right); aerodynamic forces are neglected. (b) Simple car model (see Chapter 27). (c) Front and rear tire characteristics and corresponding handling diagram. (Adapted from Figure 27.30.) The left curve is obtained by subtracting the effective front axle characteristic from the rear one at a given level of lateral acceleration (see, e.g., the segments at 0.2 and 0.4).

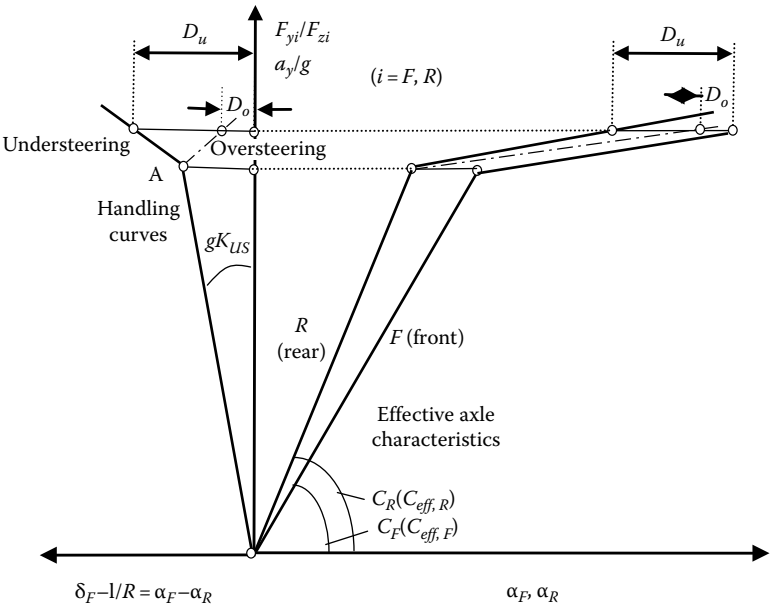

FIGURE 11.32 Substantial variation of the handling curve due to slight variation of the rear effective axle characteristic at high lateral acceleration. F_{yi} resultant of lateral forces at ith axle, F_{zi} resultant of vertical forces at ith axle, a_y centripetal acceleration (g gravity), l wheelbase, R cornering radius, and δ_F front-wheel steer. The effective axle characteristics have been depicted in simplified multi-linear form. K_{US} is the understeering gradient (see Chapter 27 and Equation 11.48).

The front and rear effective axle characteristics can be very much different from the ones depicted in Figure 11.31c. In [8], a number of different combinations of tire characteristics are presented together with the corresponding handling diagrams.

Any parameter (of the vehicle or of the tire) that influences the tire characteristic does influence the axle effective characteristic and consequently the handling diagram, that is the dynamic behavior of the vehicle.

Considering the so-called tire brush model [8], the cornering stiffness C_α can be approximated as

$$C_\alpha = 2 \cdot c_{py} L^2 = 2 \cdot c_{pby} b_c L^2$$

where

c_{py} is the lateral stiffness of the tire tread per unit length
c_{pby} is the lateral stiffness of the tire tread per unit area (the area refers to the contact patch area)
L is the half length of the contact area (see Figure 11.22)
b_c is the tire tread cross width (Figure 11.19)

Higher cross width b_c is related to higher cornering stiffness C_α. When a tire has to be chosen to be fitted into a car, usually, the driving condition is that the tire has to carry the vertical load $F_{z,stat} \cong 2 p_i b_c \sqrt{2 R w_{max}} \cong 2 p_i b_c L$ (Equation 11.30); the tire manufacturers provide different combinations of parameters p_i, b_c, and R, to carry the same vertical force $F_{z,stat}$. Among such a variety of solutions, the designer can choose the tire that best fits the needs, considering not only the cornering stiffness but also the rolling resistance (which is—among other factors—proportional to $b_c t$; see Figure 11.19 and Section 11.3.3.2) and the radial stiffness (which is approximately proportional to $p_i \cdot b_c \cdot \sqrt{R}$; see Section 11.3.3.1).

It is now clear how the dimensions of a tire can influence the tire characteristic, that is, the effective axle characteristic, and finally the handling diagram. In the subsequent sections, the main parameters related to vehicle architecture that influence axle effective characteristics will be taken into account.

Let us consider Figure 11.32; the handling diagram theory immediately highlights that the vehicle handling (and stability) is very much influenced by slight variations of tire characteristics, especially at high lateral acceleration. Let us depict the front and rear effective axle characteristics by means of straight segments; Figure 11.32 represents a simplified version of both the axle characteristics and the handling diagram that are shown in Figure 11.31c. Figure 11.32 shows that a slight variation of rear axle characteristic causes, after point A, the vehicle to change from understeering to oversteering (for the definition of understeering and oversteering, see Chapter 27). This means that at high lateral accelerations, a slight variation of the axle characteristics can cause a huge change of the overall vehicle dynamic behavior. Since the effective axle characteristics are influenced by chassis parameters (e.g., suspension kinematics influence the tire forces that influence effective axle characteristic), at high lateral accelerations, slight variation of even one of those parameters may influence considerably the stability of the vehicle (see Section 11.4.1.4).

11.4.1.2 Inertial and Geometric Data

To assess the handling performance of a car (or more generally of a ground road vehicle), the *understeering gradient* K_{US} (see Figure 11.31) is fundamental

$$K_{US} = \frac{m}{l}\frac{C_R l_R - C_F l_F}{C_R C_F} \tag{11.47}$$

where

m is the vehicle mass

l is the wheelbase

C_i and l_i ($i = F, R$ F = front, R = rear) are, respectively, the effective axle characteristic and the horizontal distance of the center of gravity from the ith axle center

The understeering gradient defines the handling curve at relatively low levels of centripetal acceleration (Figure 11.32); thus, the study of the understeering gradient is directly related to the study of the handling diagram.

Additionally, to assess the active safety, the following indices can be considered (see Chapter 27):
Yaw velocity gain (yaw velocity at steady state per unit of front-wheel steer angle):

$$G_{r,st} = \frac{v_x}{l + K_{US} v_x^2} \tag{11.48}$$

where v_x is the forward vehicle speed.

Damping ratio of *both* the yaw rate r (Figure 11.39) and the sideslip angle β (Figure 11.31b) responses to a steering input:

$$D = \frac{K_1}{\sqrt{K_2}} \tag{11.49}$$

where K_1 and K_2 are taken from the differential equations governing the yaw rate r and the sideslip angle β caused by a steering input

$$\ddot{\beta} + 2K_1\dot{\beta} + K_2\beta = \frac{C_F}{mv_x}\dot{\delta}_F - \frac{C_F\left(l_F mv_x^2 - C_R l_R l\right)}{I_Z mv_x^2}\delta_F$$

$$\ddot{r} + 2K_1\dot{r} + K_2 r = \frac{l_F C_F}{I_Z}\dot{\delta}_F + \frac{C_F C_R l}{I_Z mv_x}\delta_F$$

$$K_1 = \frac{I_Z\left(C_F + C_R\right) + m\left(C_F l_F^2 + C_R l_R^2\right)}{2I_Z mv_x}$$

$$K_2 = \frac{l^2 C_F C_R + \left(C_R l_R - C_F l_F\right)mv_x^2}{I_Z mv_x^2}$$

See Chapter 27 (Equations 27.75 through 27.78) for the meaning of the symbols; the damping ratio by definition is $D = 2K_1 / 2 \cdot 1 \cdot \sqrt{K_2/1}$. The damping ratio gives important information to assess if a vehicle oscillates or not after a disturbance.

Let us consider the influence of the mass m, the wheelbase l, and the center of gravity location $l_F = k_l l$, ($l_R = l - l_F$) (Figure 11.31b), respectively, on the understeering gradient K_{US}, on the yaw rate gain $G_{r,st}$, and on the damping ratio D.

Such a handling assessment can be made with two different perspectives. The first perspective is the one of the designer who performs the *conceptual design* of a vehicle, that is, the perspective of the engineer who has to define the basic architecture of a fully new vehicle. The second perspective is the one of an engineer who has to perform a *robustness assessment*. In the conceptual design phase, typically, the wheelbase, the location of the center of gravity, and the mass have to be decided. In the robustness assessment, given a vehicle, the effects on handling of the loading and related displacement of the center of gravity have to be minimized.

In the following derivations, we will take into account the fact that the mass m and the wheelbase l are inherently related; a linear interpolation based on actual data (see Figure 11.42) gives $m = m(l) = k_{ml}l + q$. The convenient relation between the wheelbase and location of the center of gravity will be introduced by the two equations $l_F = k_l l$, $l_R = l - l_F$ (l_F is the horizontal distance between the center of gravity and the fore axle center; see Figure 11.31b). For a given vehicle that is to be loaded, the location of the center of gravity appears to be related to the mass m; a linear interpolation based on actual data can be used, which gives $l_F = l_F(m) = k_l l$, $k_l = k_m(m - m_0) + k_{l0}$ (see Equation 11.66 for the meaning of symbols). The relation between the moment of inertia around the vertical axis I_z and the mass is $I_z = m \cdot l_R \cdot l_F$ (see Section 11.5 where $J_{zz} = I_z$).

In order to introduce in a simple and effective way the influence on handling of the tires, let us consider two cases referring to the cornering stiffness:

$$1.\ C_F = C_F(F_z) = K_F F_{zF}, \quad C_R = C_R(F_z) = K_R F_{zR} \tag{11.50}$$

$$2.\ C_F = C_F(F_z) = K_{FS} = \text{constant}, \quad C_R = C_R(F_z) = K_{RS} = \text{constant} \tag{11.51}$$

The first case and the second case refer, respectively, to lines (1) and (2) in Figure 11.33. The first case refers to a case in which the tire is not exploited very much; on the contrary, the second case refers to a substantial exploitation of the tire. Roughly, the first case refers to relatively large tires (high cross width) and relatively small (thin) tires work in the second case.

Usually, for cars, K_i ($i = F, R$) can be found in the range $5 < K_i < 25$ (frequently, for car tires, K_i values can be found in the range 10–20; for truck tires, see [8]). K_i ($i = FS, RS$), for cars, can be found in the range 50,000 N/rad $< K_i <$ 200,000 N/rad. Commonly $K_R > K_F$ and $K_{RS} > K_{FS}$.

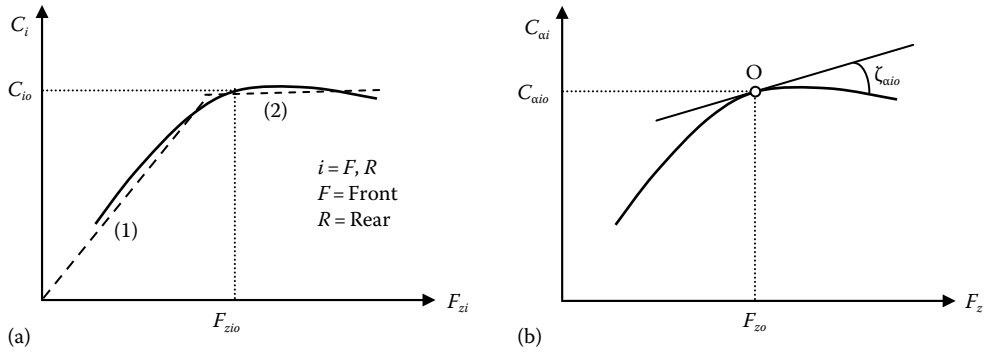

FIGURE 11.33 (a) Approximation of the effective axle characteristic C_i ($i = F,R$) (function of the vertical load at the axle F_{zi} ($i = F,R$)) by means of a multi-linear function composed by line (1) and line (2). (b) Approximation of the tire cornering stiffness by means of linearization about point O.

Referring to the two-wheel model described in Figures 11.31 and 11.35b, the vertical forces at the tires read $F_{zF} = mgl_R/l$, $F_{zR} = mgl_F/l$; so for case (1), we can write $C_F = C_F(F_z) = K_F F_{zF} = K_F(mgl_R/l)$, $C_R = C_R(F_z) = K_R F_{zR} = K_R(mgl_F/l)$.

K_{US} as a function of l, l_F, l_R, and m

Referring to Equations 11.50 and 11.51, we obtain for K_{US}

Case (1)

$$K_{US} = \frac{m}{l}\frac{C_R l_R - C_F l_F}{C_R C_F} = \frac{m}{l}\frac{K_R\left(mgl_F/l\right)l_R - K_F\left(mgl_R/l\right)l_F}{K_R\left(mgl_F/l\right)K_F\left(mgl_R/l\right)} = \frac{1}{g}\frac{K_R - K_F}{K_F K_R} = \frac{1}{gK_F} - \frac{1}{gK_R} \tag{11.52}$$

Case (2)

$$K_{US} = \frac{m}{l}\frac{C_R l_R - C_F l_F}{C_R C_F} = \frac{m}{l}\frac{K_{RS} l_R - K_{FS} l_F}{K_{RS} K_{FS}} = m\frac{K_{RS}\left(1-k_l\right) - K_{FS}k_l}{K_{RS}K_{FS}} = m\frac{K_{RS} - \left(K_{RS} + K_{FS}\right)k_l}{K_{RS}K_{FS}} \tag{11.53}$$

In case (1) (tires are not exploited very much), the understeering gradient *does not depend* on the vehicle parameters (wheelbase, location of the center of gravity, mass) but on tire characteristics only! If $K_F = K_R$, then $K_{US} = 0$.

In case (2) (tires are substantially exploited), the understeering gradient does depend on the vehicle mass and location of the center of gravity and does not depend explicitly on the wheelbase.

From a conceptual design perspective, if the mass is increased (without changing the position of the center of gravity), the understeering (or oversteering behavior) is increased. If the position of the center of gravity is moved toward the rear axle (i.e., k_l increases without increasing the mass), the understeering gradient K_{US} is decreased (oversteering is approached or made worse).

Since mass is linearly related to wheelbase ($m = m(l) = k_{ml}l + q$; see Figure 11.42), K_{US} turns out to increase linearly with the wheelbase, even if the wheelbase does not appear explicitly in Equation 11.53.

From a robustness assessment perspective, loading a given car or a van (except for some sports cars with rear engine) implies that the center of gravity moves toward the rear axle. Considering

Equation 11.66 that gives $l_F = l_F(m) = k_l l$, we can set $k_l = k_m(m - m_0) + k_{l0} = k_m(\Delta m) + k_{l0}$, and substituting into Equation 11.53,

$$K_{US} = m\frac{K_{RS}\left(1-k_m\left(m-m_0\right)-k_{l0}\right)-K_{FS}\left(k_m\left(m-m_0\right)+k_{l0}\right)}{K_{RS}K_{FS}}$$

$$= -k_m\left(\frac{1}{K_{FS}}+\frac{1}{K_{RS}}\right)\left(\Delta m\right)^2+\left(\frac{1-m_0k_m-k_{l0}}{K_{FS}}-\frac{m_0k_m+k_{l0}}{K_{RS}}\right)\Delta m+\left(\frac{m_0\left(1-k_{l0}\right)}{K_{FS}}-\frac{m_0k_{l0}}{K_{RS}}\right)$$

$$= A\left(\Delta m\right)^2+B\Delta m+C \tag{11.54}$$

where

m_0 represents the mass of the unloaded vehicle

$\Delta m = m - m_0$ represents the mass increase when the vehicle is loaded

Equation 11.54 represents a parabola pointing downward and whose vertex abscissa is at

$$\left(\Delta m\right)_v = \frac{-B}{A} = -\frac{K_{RS}\left(m_0k_m+k_{l0}-1\right)+K_{FS}\left(m_0k_m+k_{l0}\right)}{k_m\left(K_{FS}+K_{RS}\right)}$$

Since usually $(\Delta m)_v < 0$ and $C = (m_0(1 - k_{l0})/K_{FS}) - (m_0k_{l0}/K_{RS}) > 0$, K_{US} decreases if Δm increases (i.e., K_{US} decreases if the vehicle is loaded).

$G_{r,st}$ as a function of l, l_F, l_R, and m

Referring to Equations 11.50 and 11.51, we obtain for $G_{r,st}$

Case (1)

$$G_{r,st} = \frac{v_x}{l+v_x^2\left(\frac{1}{gK_F}-\frac{1}{gK_R}\right)} \tag{11.55}$$

Case (2)

$$G_{r,st} = \frac{v_x}{l+v_x^2\left(m\frac{K_{RS}-(K_{RS}+K_{FS})k_l}{K_{RS}K_{FS}}\right)} \tag{11.56}$$

The yaw rate gain $G_{r,st}$ is directly related to the understeering gradient K_{US} (see Equation 11.48), so similar comments can be made here with respect to the ones made earlier.

In case (1), the yaw rate gain does not depend on the location of the center of gravity. The yaw rate gain decreases substantially if the wheelbase increases.

From a conceptual design perspective, increasing the wheelbase implies a linear increase of the mass (see Figure 11.42), so the yaw rate gain decreases substantially if the mass increases, even if the mass does not appear explicitly in Equation 11.55.

From a robustness assessment perspective, the sensitivity to loading is null.

In case (2), the yaw rate gain does depend on the vehicle mass, location of the center of gravity, and wheelbase.

From a conceptual design perspective, if the mass is increased (without changing the wheelbase and position of the center of gravity), the yaw rate gain is decreased. If the position of the center of gravity is moved toward the rear axle (i.e., k_l increases), without increasing the mass, the yaw rate gain is increased.

From a robustness assessment perspective, given a car or a van, inserting Equations 11.54 and 11.66 into Equation 11.56 and rearranging,

$$G_{r,st} = \frac{v_x}{l + v_x^2\left(-k_m\left(\frac{1}{K_{FS}} + \frac{1}{K_{RS}}\right)(\Delta m)^2 + \left(\frac{1 - m_0 k_m - k_{l0}}{K_{FS}} - \frac{m_0 k_m + k_{l0}}{K_{RS}}\right)\Delta m + \left(\frac{m_0(1-k_{l0})}{K_{FS}} - \frac{m_0 k_{l0}}{K_{RS}}\right)\right)} \tag{11.57}$$

By inspection of Equation 11.57 and recalling the discussion about Equation 11.54, one may notice that $G_{r,st}$ increases if Δm increases.

D as a function of l, l_F, l_R, and *m*

Referring to Equations 11.50 and 11.51, we obtain for *D*

Case (1)

$$D = \frac{1}{2}\frac{g\left(K_F + K_R\right)l}{\sqrt{g\left(g \cdot l \cdot K_F K_R + v_x^2 K_R - v_x^2 K_F\right)l}} \tag{11.58}$$

Case (2)

$$\begin{aligned} D &= \frac{1}{2}\frac{\left(K_{FS} l_F + K_{RS} l_R\right)l}{\sqrt{-\left(-l^2 K_{FS} K_{RS} - m v_x^2 K_{RS} l_R + v_x^2 K_{FS} l_F\right) l_F l_R}} \\ &= \frac{1}{2}\frac{\left[\left(K_{FS} - K_{RS}\right)k_l + K_{RS}\right]l}{\sqrt{l\left(-l K_{FS} K_{RS} - m v_x^2 K_{RS} + m v_x^2 K_{RS} k_l + m v_x^2 K_{FS} k_l\right)k_l\left(-1 + k_l\right)}} \end{aligned} \tag{11.59}$$

In case (1), the damping ratio *D* does not depend on the location of the center of gravity and does not depend explicitly on the mass. *D* depends on the wheelbase, but quantitatively the effect is usually small. If $K_F = K_R$, then $D = 1$.

From a conceptual design perspective, the wheelbase and the mass increase accordingly in a linear way, so *D* increases (slightly) with the mass.

From a robustness assessment perspective, the sensitivity to loading is null.

In case (2), the damping ratio *D* depends explicitly on the wheelbase, on the location of the center of gravity, and on the mass.

From a conceptual design perspective, Figure 11.34 shows the influence of the wheelbase on the damping ratio *D* for two different vehicle speeds and two different positions of the center of gravity.

From a robustness assessment perspective, given a vehicle, inserting Equation 11.66 in Equation 11.59 leads to an involved symbolic expression that reads

$$D = \frac{f\left(\Delta m\right)}{\sqrt{g\left(\left(\Delta m\right)^4\right)}} \tag{11.60}$$

where *f* and *g* are two functions. In this case, discussing $D(\Delta m)$ is very difficult and a numerical solution is to be envisaged. Often, increasing the mass (increasing Δm), *D* decreases.

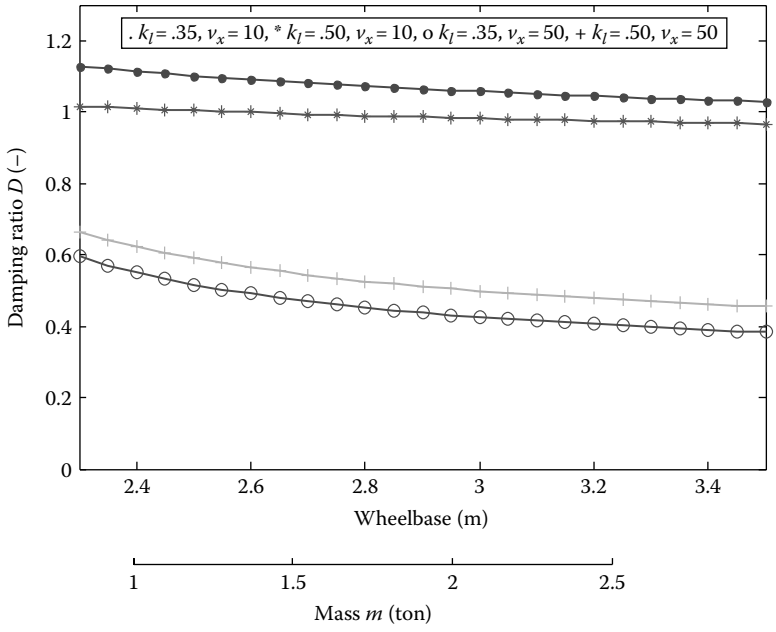

FIGURE 11.34 Plot of Equation 11.59; the damping ratio D depends mostly on the speed v_x ($[v_x]$ = m/s), less on the wheelbase (or mass) and less on the position of the center of gravity (defined by k_l). Understeering vehicle, K_{FS} = 60,000 N/rad, K_{RS} = 110,000 N/rad.

The aforementioned analyses state that working in the part (1) of tire cornering stiffness characteristic (Figure 11.33) allows to conceive a vehicle that is very much less sensitive to mass variation (and related center of gravity migration). On the contrary, a vehicle conceived to work in the part (2) of tire cornering stiffness characteristic (Figure 11.33) is sensitive to all of the vehicle geometric and inertial parameters.

11.4.1.3 Drive Axle and Torque Vectoring

Let us recall Chapter 27, Section 27.3.3, where the handling diagram theory was introduced together with the hypotheses on which such a theory is based on.

Let us consider the simple two-wheel model in Figures 11.31b and 11.35. Let us consider the longitudinal axle of such a vehicle model and the external resultant forces acting on it

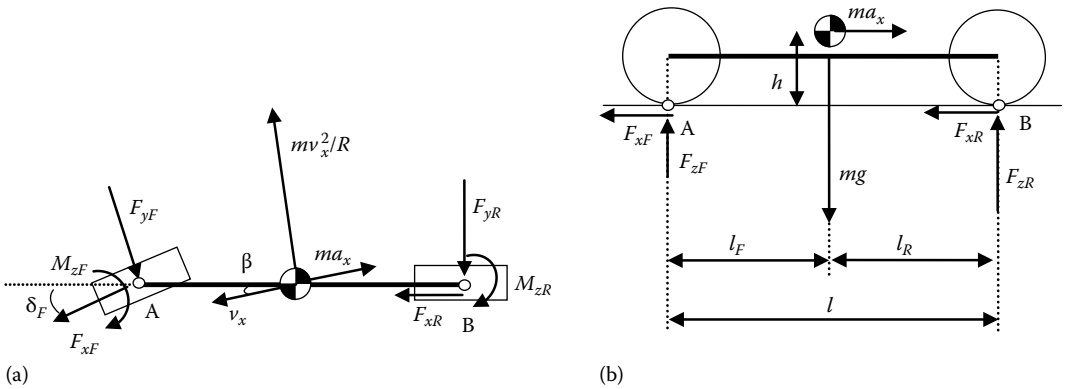

FIGURE 11.35 External resultant forces acting on a two-axle vehicle (aerodynamic effects are neglected). (a) Top view and (b) lateral view.

(aerodynamic effects are neglected). The moments M_{zF} and M_{zR} in Figure 11.35 are introduced as they represent unequal longitudinal forces at the two wheels of the same axle, thus representing a torque vectoring effect.

Let us assume that the steering angle δ_F is small (this assumption is consistent with the hypothesis given in Chapter 27, where the force $F_{xF} \sin \delta_F$ is neglected) and that the β angle is small. The rotation equilibrium around a vertical axis passing by point B (taking into account the forces and moments acting in the horizontal plane) is written in the first equation (11.61). The rotation equilibrium around a vertical axis passing by point A (taking into account the forces and moments acting in the horizontal plane) is written in the second equation (11.61). The rotation equilibrium around a horizontal axis passing by point B (taking into account the forces in the vertical plane) is written in the third equation (11.61). The rotation equilibrium around a horizontal axis passing by point A (taking into account the forces in the vertical plane) is written in the fourth equation (11.61):

$$\begin{aligned} F_{yF} l &= m \frac{v_x^2}{R} l_R + \left(M_{zF} + M_{zR}\right) \\ F_{yR} l &= m \frac{v_x^2}{R} l_F - \left(M_{zF} + M_{zR}\right) \\ F_{zF} l &+ m a_x h = m g l_R \\ \boldsymbol{F}_{zR} l &- m a_x h = m g l_F \end{aligned} \tag{11.61}$$

The first equation (11.62) is obtained by dividing the first equation (11.61) by the third equation (11.61). The second equation (11.62) is obtained by dividing the second equation (11.61) by the fourth equation (11.62). By this way, a mathematical manipulation of the equilibrium equations is performed; thus, the general validity of new relations is not corrupted:

$$\begin{aligned} \frac{F_{yF}}{F_{zF} + m a_x h / l} &= \frac{m v_x^2 / R l_R}{m g l_R} + \frac{\left(M_{zF} + M_{zR}\right)}{m g l_R} \\ \frac{F_{yR}}{F_{zR} - m a_x h / l} &= \frac{m v_x^2 / R l_F}{m g l_F} - \frac{\left(M_{zF} + M_{zF}\right)}{m g l_F} \end{aligned} \tag{11.62}$$

The aforementioned equations can be rearranged considering that

$$F_{zF} + \frac{m a_x h}{l} = F_{zF,st}$$

$$F_{zR} - \frac{m a_x h}{l} = F_{zR,st}$$

where $F_{zF,st}$ and $F_{zR,st}$ refer, respectively, to the static vertical forces at the front and rear axles. So we obtain

$$\begin{aligned} \frac{F_{yF}}{F_{zF,st}} - \frac{\left(M_{zF} + M_{zR}\right)}{m g l_R} &= \frac{v_x^2}{R g} \\ \frac{F_{yR}}{F_{zR,st}} + \frac{\left(M_{zF} + M_{zR}\right)}{m g l_F} &= \frac{v_x^2}{R g} \end{aligned} \tag{11.63}$$

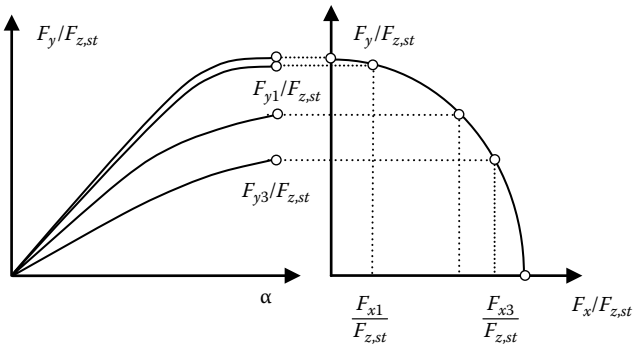

FIGURE 11.36 Left plots lateral forces at different longitudinal forces. Right plots relationship between maximum forces acting, respectively, in longitudinal (x) and in lateral direction (y) on a tire. α is the lateral slip and the suffix "*st*" means that the vertical force at the tire is constant (steady state).

Equation 11.63 corresponds to Equation 27.122 in Chapter 27 if M_{zF} and M_{zR} are neglected. Moreover, such equations have been obtained considering a motion with constant acceleration along the longitudinal axis!

This derivation is very important because it means that the handling diagram theory can give an (approximated) insight of the nonlinear dynamic behavior of vehicles accelerating into a bend. This occurrence will be exploited here to discuss the conceptual design of two-axle vehicles with different driveline architectures (front-, rear-, or all-wheel drive).

Often in the engineering practice, the handling diagrams (relation between $\delta_F - \delta_{F0}$ and centripetal acceleration) are obtained at different longitudinal accelerations.

Let us consider Figure 11.36 where a simplified graphical representation of the relationship between the longitudinal and lateral forces at a tire is given [2] (for the correct relationship, see [8]). Increasing the longitudinal force at the tire from $F_{x1}/F_{z,st}$ to $F_{x3}/F_{z,st}$ leads to the lowering of the tire characteristic $F_y/F_{z,st}(\alpha)$; actually $F_{y1}/F_{z,st}(\alpha)$ is higher than $F_{y3}/F_{z,st}(\alpha)$.

This general conclusion can be used to understand the effects on handling of the architecture of the driveline.

In Figure 11.37a, the effects on handling of front-wheel drive are highlighted. Since the longitudinal force at tires causes a lowering of the tire characteristic (Figure 11.36), the vehicle with front-wheel drive is more understeering (increased understeering gradient K_{US}) than the vehicle with vanishing forces at the front tires. Additionally, the attainable maximum centripetal acceleration is lowered with respect to the case of vanishing forces at the front tires.

In Figure 11.37b, the effects on handling of rear-wheel drive are highlighted. If the longitudinal forces at rear tires are not very high, the vehicle is less understeering (decreased understeering gradient K_{US}) than the vehicle with vanishing forces at the rear tires. If the longitudinal forces at rear tires are very high, the vehicle is oversteering (understeering gradient $K_{US} < 0$). Always the attainable maximum centripetal acceleration is lowered with respect to the case of vanishing forces at the rear tires.

In Figure 11.37c, the effects on handling of all-wheel drive are highlighted. Usually the torque distribution between the front and rear axles is chosen to keep the vehicle almost insensitive to the application of longitudinal forces at the front and rear tires. Always the attainable maximum centripetal acceleration is lowered with respect to the case of vanishing forces at the tires.

In Figure 11.38, the effect on handling diagram of an unequal distribution of the longitudinal forces at the tires of an axle is highlighted. Such an unequal distribution generates the moments M_{zF} and M_{zR} shown in Figure 11.35. If the moments are positive as shown in Figure 11.38, the understeering

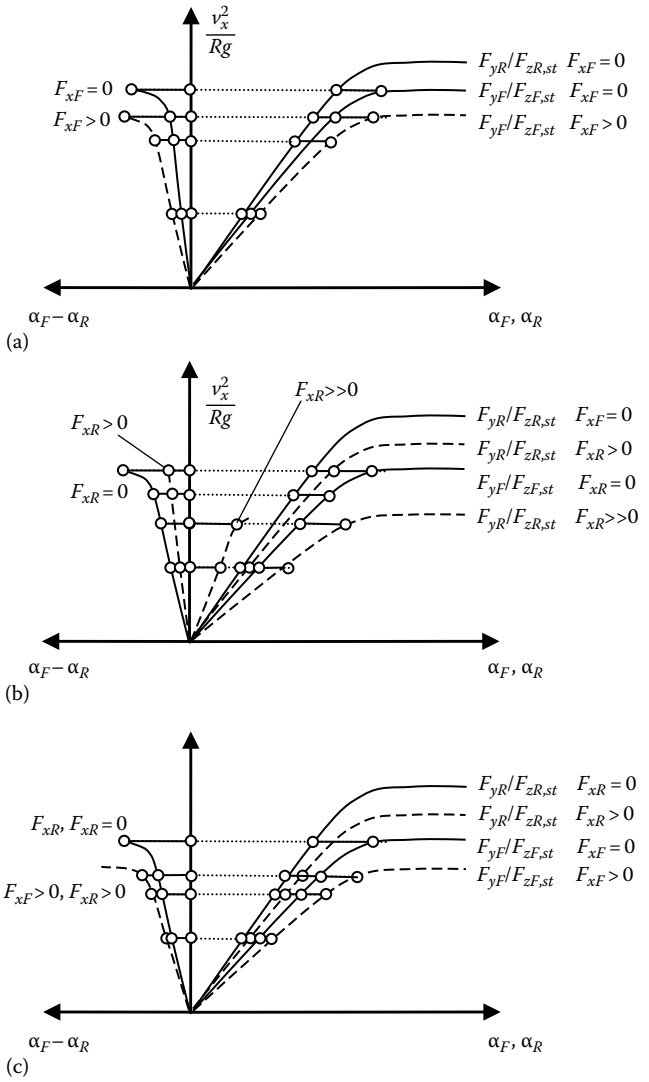

FIGURE 11.37 Effects on the handling diagram of different driveline architectures. (a) Front-wheel drive. (b) Rear-wheel drive. (c) All-wheel drive.

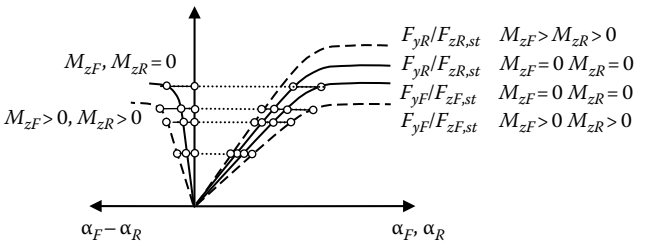

FIGURE 11.38 Effects on the handling diagram of torque vectoring, that is, unequal distribution of longitudinal forces at the two tires of the same axle (the moments M_{zF} and M_{zR} are generated, respectively, at the front and rear axles).

gradient is increased with respect to the case in which $M_{zF} = M_{zR} = 0$. Obviously, it is not necessary that both of the two moments M_{zF} and M_{zR} are to be applied. Again, the attainable maximum centripetal acceleration is lowered with respect to the case of vanishing vertical moments at the axles.

Rear-wheel-drive cars exhibit an oversteering character (see Figure 11.37b), so they get advantage from a torque vectoring like the one depicted in Figure 11.38 that counteracts oversteering with understeering [87–89].

The rolling resistances can be very high during cornering (see footnote; Section 11.3.4). Such a rise of rolling resistance can be introduced by considering the effect on tire characteristic as shown in this section. The aerodynamic drag can be introduced as mentioned for rolling resistance.

In this section, the effect of lateral load transfer has been neglected; in the following section, such an effect is dealt with.

11.4.1.4 Suspension Kinematics and Elastokinematics

In [8], Pacejka has given an inspiring synthesis on the influence of vehicle parameters (depicted in Figure 11.39) on effective axle characteristic (Figure 11.32). Such a contribution is summarized here. The theoretical analysis is linear and limited to low lateral slips. Such analysis is anyway informative to give an idea on the complexity of the handling behavior depending on axle kinematics and elastokinematics at higher lateral slips. Another similar contribution can be found in [2]. The axle characteristics (Figures 11.32 and 11.33) at low lateral slips read (symbols are reported in Figure 11.39)

$$\frac{F_{yi}}{F_{zi}} = \frac{F_{yi,in} + F_{yi,out}}{F_{zi,in} + F_{zi,out}} = \frac{C_i \alpha_{ai}}{F_{zi}} \quad \left(i = F, RF = \text{front}, R = \text{rear}, in = \text{inner wheel}, out = \text{outer wheel}\right)$$

$$C_i = \frac{2C_{\alpha io}}{1 + A + B - C + D}$$

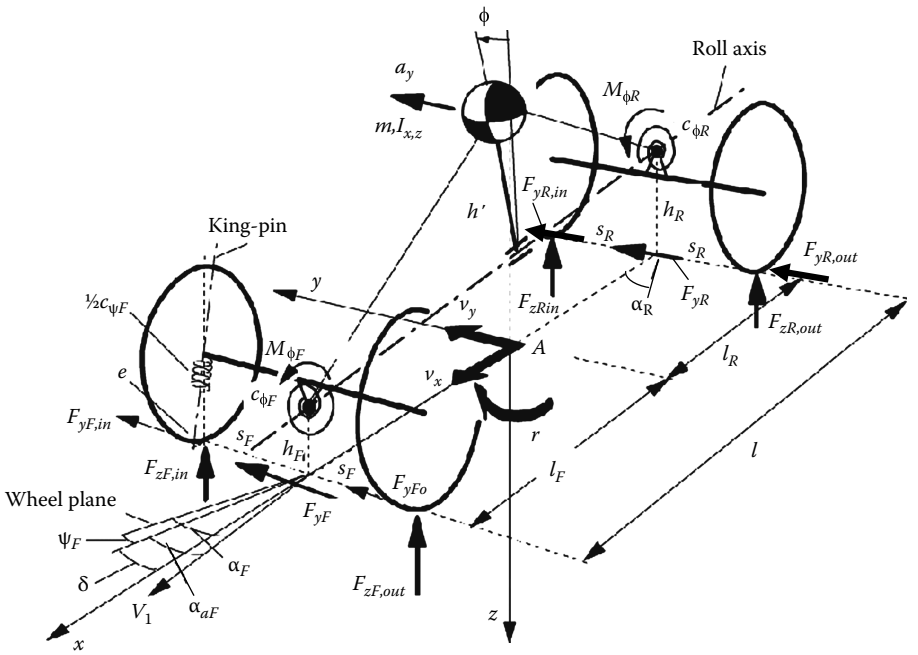

FIGURE 11.39 Vehicle model for cornering behavior. (Adapted from Pacejka, H., *Tyre and Vehicle Dynamics*, SAE International, Warrendale, PA, 2005.)

$$A = \frac{2l\left(\varepsilon_i C_{\alpha io} + \tau_i C_{\gamma io}\right)h'}{\left(l - l_i\right)\left(c_{\phi F} + c_{\phi R} - mgh'\right)}$$

$$B = \frac{2C_{\alpha io}\left(e_i + t_i\right)}{c_{\psi i}} \tag{11.64}$$

$$C = 2C_{\alpha io}c_{sfi}$$

$$D = \frac{2l\sigma_i}{l - l_i}\left(\zeta_{\alpha io}\psi_{io} + \zeta_{\gamma io}\gamma_{io}\right)$$

where

α_{ai} ($i = F, R$; Figure 11.39) represents the lateral slip that the axle would have if ψ_i were zero

$2C_{\alpha io}$ is obtained from the sum of the outer tire cornering stiffness (subscript *out*) plus the inner tire cornering stiffness (subscript *in*) $C_{\alpha i} = C_{\alpha i,\,out} + C_{\alpha i,\,in}$

The tire cornering stiffness depends on the vertical force (see Figure 11.33):

$$C_{\alpha i,out} = C_{\alpha io} + \zeta_{\alpha i}\left(F_{zi,out} - F_{zio}\right) = C_{\alpha io} + \zeta_{\alpha io}\Delta F_{zi}$$

$$C_{\alpha i,in} = C_{\alpha io} - \zeta_{\alpha i}\left(F_{zio} - F_{zi,in}\right) = C_{\alpha io} - \zeta_{\alpha io}\Delta F_{zi}$$

Finally,

$$C_{\alpha i,out} + C_{\alpha i,in} = 2C_{\alpha io}$$

A is related to roll steer (i.e., the steering induced by body roll) and to camber induced by body roll. The steering angle at the two wheels of an axle due to body roll can be linearized as

$$\psi_r = \varepsilon_i \phi$$

The camber angle at the two wheels of an axle due to body roll can be linearized as

$$\gamma_r = \tau_i \phi$$

(the body roll can be computed as $\phi = -ma_y h'/c_{\phi F} + c_{\phi R} - mgh'$ where $c_{\phi F}$ and $c_{\phi R}$ are, respectively, the front and rear roll stiffnesses; see Section 11.3.2.2)

$C_{\gamma io}$ is the axle camber stiffness depending on tire camber stiffness ($F_y = C_\gamma \gamma$), defined as $C_{\gamma i} = C_{\gamma io} + \zeta_{\gamma io}\Delta F_{zi}$.

Other symbols l, l_i, h', m are depicted in Figure 11.39, and their meaning is readily understandable.

B is related to steering compliance that causes the steering of the wheels due to the application of a lateral force, e_i represents the caster arm (Figure 11.39), t_i represents the trailing arm [8], and $c_{\psi i}$ represents the steering stiffness (rotation of the wheel around its steering axis; see Figure 11.39).

C is related to the suspension compliance that causes the steering of the wheels due to the application of a lateral force; the steering angle is

$$\psi_{sfi} = c_{sfi_i} F_{yi}$$

c_{sfi} represents the rotational stiffness of the suspension in lateral direction.

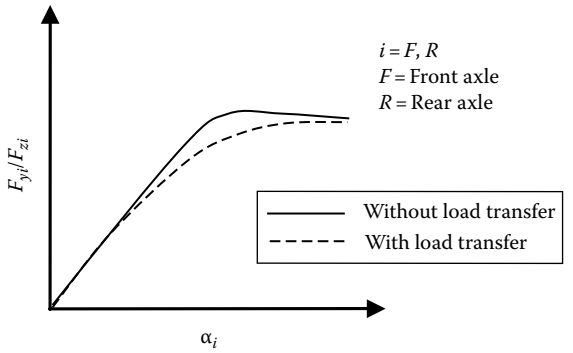

FIGURE 11.40 Effect of load transfer on effective axle characteristic.

D is related to the load transfer effect (at an axle, during steady-state cornering, the vertical force at the outer wheel is higher than the vertical force at the inner one). The vertical force at respective outer and inner wheel is

$$F_{zi,out} = \frac{F_{zi}}{2} + \Delta F_{zi}$$

$$F_{zi,in} = \frac{F_{zi}}{2} - \Delta F_{zi}$$

where F_{zi} is the static vertical load at the ith axle

$$\Delta F_{zi} = \sigma_i m a_y$$

$$\sigma_i = \frac{1}{2s_i}\left(\frac{c_{\phi i}}{c_{\phi F} + c_{\phi R} - mgh'}h' + \frac{l - l_i}{l}h_i\right)$$

ψ_{io} and γ_{io} refer, respectively, to the static toe angle and static camber angle.

Equation 11.64 states that the effective axle characteristic at low lateral slip angle is influenced by many parameters of the vehicle. The influence of the wheelbase and of the center of gravity position is mixed up with the influence of other parameters, so a simple synthesis is not possible. The designer can easily change the axle characteristic combining the many parameters appearing in Equation 11.64. The effect of load transfer is present only if ψ_{io} and γ_{io} are not null. The effect of load transfer is substantial at medium lateral slips (Figure 11.40). More details on load transfer and elastokinematics effects of effective axle characteristic can be found in [8].

11.4.2 *Rollover*

An excellent overview of the main issues referring to rollover has been given in [7,111]. Figure 11.41 shows a vehicle running at steady state into a bend, without suspension and for which both of the two inner wheels miss the contact with the ground at the same time; the rollover threshold is $a_y/g = s/h$, where s is half the track width, h is the height of the center of gravity from the ground, m is the vehicle mass, and a_y and g are the lateral acceleration and the gravitational acceleration, respectively. Rollover threshold is in the range 1.2–1.7 for cars, in the range 0.9–1.1 for pickup truck, and in the range 0.4–0.8 for trucks.

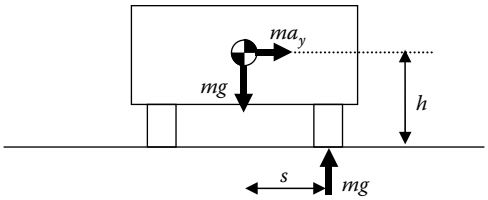

FIGURE 11.41 Simple vehicle model describing rollover initiation.

The actual vehicle is more similar to the one shown in Figure 11.39 than the one in Figure 11.41. In the actual case, during rollover initiation only one of the four wheels leaves the ground. In this case, the rollover threshold is obtained observing (Figure 11.39) that the vertical force at the inner wheel of the ith axle is $F_{zi,\,in} = F_{zi}/2 - \Delta F_{zi} = 0$ where $F_{zi} = mg(l - l_i)/l$ is the static vertical load at the ith axle and $\Delta F_{zi} = \sigma_i m a_y$ is the load transfer at the ith axle, with $\sigma_i = 1/2 s_i((c_{\phi i}/c_{\phi F} + c_{\phi R} - mgh')h' + (l - l_i/l)h_i)$. Thus, the rollover threshold is

$$\frac{a_y}{g} = \frac{s_i}{h_i + \dfrac{c_{\phi i}}{c_{\phi F} + c_{\phi R} - mgh'} \dfrac{l}{l - l_i} h'} \quad \left(i = F, R \; F = \text{front}, R = \text{rear}\right) \tag{11.65}$$

Notice that $h_i + h' \cong h$ (Figures 11.39 and 11.41). Such a threshold is lower (about 5%) than the one previously defined (s/h).

Rollover during transient maneuvers has been studied by simulating a step steer input by means of a model like the one shown in Figure 11.39. A step steer maneuver that produces at its end a lateral acceleration level (a_y/g) below the rollover threshold defined by Equation 11.65 can cause rollover, because of the body roll overshoot. Such an end lateral acceleration level depends on the body roll damping ratio and can be lower by a factor of about 10% to the previously derived rollover threshold.

Under a sinusoidal steer input, the body roll can reach its resonance; in this case, a wheel can leave the ground at a lateral acceleration (at the body center of gravity, a_y/g) lower by a factor 20% with respect to the rollover threshold defined by Equation 11.65. A sinusoidal steer input attaining the lateral acceleration needed for rollover can be hardly reproduced in reality, and so it is of little significance. The coupling of yaw motion with body roll motion somehow moderates the peak lateral acceleration.

The tipping phenomenon is another cause for rollover. Obviously the level of energy dissipated during the impact is important to reduce the energy required for rollover (rotational kinetic energy plus potential energy to raise the center of gravity). The s/h threshold appears to be important in the case of tipping too.

In [7], the analysis of rollover accidents is summarized both for cars and for trucks. It appears that not only the threshold s/h is important but also a number of other factors contribute equally to the rollover occurrence.

Other contributions on rollover are given in [90–99].

11.5 VEHICLE INERTIA PROPERTIES AND DIMENSIONS

The inertia properties of a rigid body are a set of 10 parameters, namely, the mass (1 parameter), the location of the center of mass (3 parameters), and the inertia tensor (6 parameters, usually the inertia tensor is related to the center of mass). The vehicle is composed by a number of bodies (subsystems) that can be considered rigid in the frequency range 0–25 Hz. So the inertia properties of a vehicle refer actually to the ones of each single vehicle subsystem.

The inertia properties of the body of a vehicle depend on design choices. Some design targets are obvious (minimum mass, minimum height of the center of mass). The targets referring to the

Source: Torre, S., The car weight (in Italian), *Autotecnica*, XXI, 9–10, 2002.

inertia tensor are less obvious; some researches have been made on this topic [100–102], but still an in-depth analysis is missing.

The number of parts in a car is the order of 10^4; Table 11.6 gives the mass of main car subsystems. It is clear that to decrease the mass, almost every single part has to be made lighter; actually, more than half part of the mass is given by a plethora of relatively light parts. The only heavy subsystems are the body structure and the suspension system [103].

The relationship between the mass and the wheelbase of today's cars can be taken as linear. In Figure 11.42, the mass and the wheelbase are plotted for European cars sold on the market (year 2008); the linear interpolation gives $m = m(l) = k_{ml}l + q$, where m is the mass, l is the wheelbase, and k_{ml} and q are constants ($k_{ml} = 2042$ kg/m and $q = -3971$ kg).

Given a car or a van, as the mass m increases, the center of gravity moves toward the rear axle; more generally, the position of the center of gravity is a function of the mass m. Given the horizontal distance of the center of gravity from the fore axle as a fraction of the wheelbase, that is, $l_F = k_l l$, the relation between k_l and m is (see, e.g., [84])

$$\Delta k_l = k_m \Delta m \ (k_m \text{ can be set with good accuracy equal to } 2 \times 10^{-4}\ \text{kg}^{-1})$$

or

$$k_l - k_{l0} = k_m \left(m - m_0 \right) \tag{11.66}$$

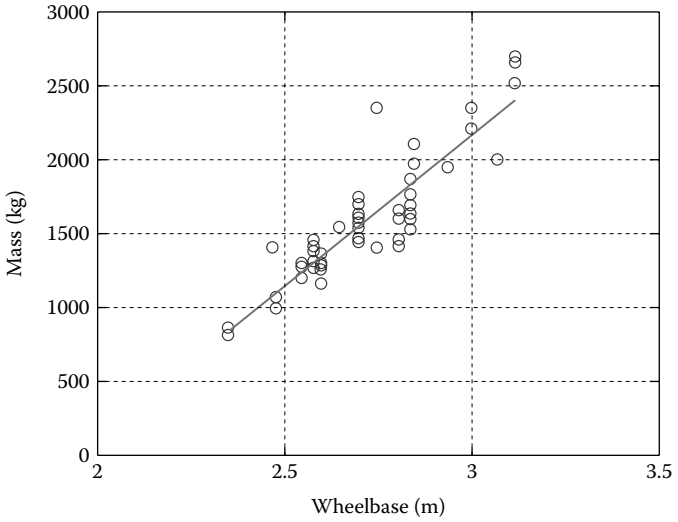

FIGURE 11.42 Relationship between mass (m [kg]) and wheelbase (l [m]) of European cars (as at year 2008). The linear interpolation gives $m = 2042l - 3971$ kg.

where k_{l0} and m_0 refer, respectively, to the center of gravity position and mass of a given unladen vehicle (for cars, k_{l0} is approximately in the range from 0.35 to 0.45, for truck and SUVs, in the range from 0.40 to 0.47).

Given a reference frame as in Figure 11.43, the center of mass R and the inertia tensor J (referred to the origin of the coordinate frame) are defined, respectively, as

$$R = \begin{bmatrix} \bar{x} \\ \bar{y} \\ \bar{z} \end{bmatrix} = \begin{bmatrix} \dfrac{\int_V \rho(r)\, x dV}{\int_V \rho(r) dV} \\ \dfrac{\int_V \rho(r)\, y dV}{\int_V \rho(r) dV} \\ \dfrac{\int_V \rho(r)\, z dV}{\int_V \rho(r) dV} \end{bmatrix}; \quad r = \begin{bmatrix} x \\ y \\ z \end{bmatrix}$$

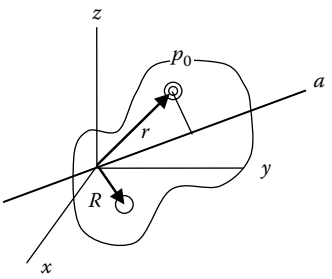

FIGURE 11.43 Reference coordinate frame for defining the inertia properties of a body; p_0 is a generic point of the body, identified by vector r. R identifies the location of the center of mass. The axis a identifies a generic axis of rotation.

$$\boldsymbol{J} = \begin{bmatrix} J_{xx} & J_{xy} & J_{xz} \\ & J_{yy} & J_{yz} \\ simm & & J_{zz} \end{bmatrix} = \int_V \left(\begin{bmatrix} y^2+z^2 & -xy & -xz \\ -yx & x^2+z^2 & -yz \\ -zx & -zy & x^2+y^2 \end{bmatrix} \right) \rho(r) dV$$

where $\rho(r)$ is the density of the body at the point defined by vector r.

The relationship between the moment of inertia around the axis $a(J_a)$ (Figure 11.43) and the inertia tensor $\boldsymbol{J}$ is $J_a = \nu^T J \nu$,where ν is the vector of the direction cosines of the line a.

Due to the aforementioned definition of $\boldsymbol{J}$, the following relationships hold among the components of the inertia tensor $\boldsymbol{J}$ [104]:

$$J_{xx} \geq 0, \quad J_{yy} \geq 0, \quad J_{zz} \geq 0$$

$$J_{xx} + J_{yy} \geq J_{zz}, \quad J_{xx} + J_{zz} \geq J_{yy}, \quad J_{yy} + J_{zz} \geq J_{xx}$$

$$A^2 \leq 1, \quad B^2 \leq 1, \quad C^2 \leq 1$$

$$A^2 + B^2 + C^2 - 2 \cdot A \cdot B \cdot C \leq 1$$

where

$$A = \frac{2|J_{xy}|}{\sqrt{J_{zz}^2 - \left(J_{xx}^2 - J_{yy}^2\right)}}, \quad B = \frac{2|J_{xz}|}{\sqrt{J_{yy}^2 - \left(J_{xx}^2 - J_{zz}^2\right)}}, \quad C = \frac{2|J_{yz}|}{\sqrt{J_{xx}^2 - \left(J_{zz}^2 - J_{yy}^2\right)}}$$

Thus, the six components of the inertia tensor *cannot* take whichever value.

In [84], an extensive survey of measured inertia properties of wheeled ground vehicles is given. The center of gravity height (C_G) divided by the roof height (R_H) is found within the range $0.36 \leq C_G/R_H \leq 0.42$. C_G/R_H increases very slightly as function of the vehicle mass, either for cars, vans, trucks, or SUVs. For cars, the ratio a/W_B (a horizontal distance between the center of gravity and the front axle axis; W_B wheelbase) can be found in the range 0.36–0.40 and raises to the range 0.45–0.49 when the vehicle is fully loaded. In other words, the center of gravity is moved sensibly toward the rear axle when the vehicle is fully loaded.

Relevant statistics among vehicle dimensions and main diagonal inertia tensor components are given in [100] (Table 11.7); in particular, the values of the main diagonal inertia tensor components J_{xx}, J_{yy}, J_{zz} are given as function of the wheelbase W_B, the track width T_W, the roof height $R_H = H_r$, and the weight W_t (the prediction error can be rather large, ±25%, and in some specific cases even more):

$$\begin{bmatrix} J_{xx} \\ J_{yy} \\ J_{zz} \end{bmatrix} = \begin{bmatrix} 10^{k_{1x}} \cdot W_b^{k_{2x}} \cdot T_w^{k_{3x}} \cdot H_r^{k_{4x}} \cdot W_t^{k_{5x}} \\ 10^{k_{1y}} \cdot W_b^{k_{2y}} \cdot T_w^{k_{3y}} \cdot H_r^{k_{4y}} \cdot W_t^{k_{5y}} \\ 10^{k_{1z}} \cdot W_b^{k_{2z}} \cdot T_w^{k_{3z}} \cdot H_r^{k_{4z}} \cdot W_t^{k_{5z}} \end{bmatrix} \tag{11.67}$$

Coefficients of Equation 11.67 (Table 11.6)

$k_{1x} = -2.14 \cdot k_{2x} = -0.16 \cdot k_{3x} = 1.94 \cdot k_{4x} = 0.36 \cdot k_{5x} = 0.94$
$k_{1y} = -2.00 \cdot k_{2y} = 1.53 \cdot k_{3y} = 0.25 \cdot k_{4y} = 0.10 \cdot k_{5y} = 1.02$
$k_{1z} = -1.78 \cdot k_{2z} = 1.43 \cdot k_{3z} = 0.38 \cdot k_{4z} = 0.02 \cdot k_{5z} = 0.98$

Wheelbase, W_B; track width, T_W; roof height, R_H; and weight, W_t.

Very simple and approximate formulae to estimate J_{xx}, J_{yy}, and J_{zz} are, respectively,

$$J_{xx} = \frac{M \cdot s^2}{2}$$

$$J_{yy} \approx J_{zz}$$

$$J_{zz} = M \cdot a \cdot b \text{ or } J_{zz} = k \cdot M' W_b^{3/2}$$

where
M is the mass of the body
s is the track width
a and b are, respectively, the horizontal distances of the center of gravity from the front and rear axles
k is constant (that can be obtained from Equation 11.67)
M' is the mass of the vehicle
W_b is the wheelbase

Under the hypothesis that the powertrain is rigidly connected to the car body, cars with a front engine feature usually a non-negligible J_{xz} [84,101,102]. This occurrence can couple the yaw and roll motions; to alleviate this, the roll axis can be sloped toward the front [2].
In [101], the influence of the inertia tensor on ride and handling of a car was highlighted. Small variations of the components of the inertia tensor may produce significant variations of ride comfort and on center handling of vehicles [2,8]. The inertia tensor plays also a very important role during panic evasive maneuvers involving the dynamic stability of road vehicles.

It is rather hard to compute the inertia properties of ground vehicles (actually there is a huge number of parts to take into account; see Table 11.6), so it is convenient to *measure* them. Also the measurement is not simple and requires special skills [104]. In [84,105,106], an overview of existing methods and facilities to measure the inertia properties of vehicles is given.

In [101,107], the needed measurement accuracy of inertia properties was proposed in order to perform reliable simulations, either for full vehicles or a subsystem such as the engine. Referring to the car body, the mass should be known with an uncertainty <0.5%; the main diagonal components of

FIGURE 11.44 An accurate system for measuring the inertia properties of cars. (From Mastinu, G. et al., A new test rig for the identification of the inertia tensor of a rigid body, SAWE Paper 3315.)

the inertia tensor should be measured with a tolerance <3% and the extra diagonal components within the uncertainty range ±15 kg m^2 (Figure 11.44). Referring to the system engine + gearbox of a car, the appropriate computation of both the natural frequencies and the forces transmitted to the chassis should be performed when the main diagonal components of the inertia tensor are known with an uncertainty <2.5%; the position of the center of gravity is measured with an uncertainty <3 mm; the mass should be known with an uncertainty <1.5%.

11.6 CONCLUSION

The wheel has been invented about 5000 years ago. Employing wood has allowed to shape the wheel from a log-like cylinder to a disk with a relatively low mass and high diameter to run on obstacles. Since the beginning, the vehicles were fitted with wheel couples (i.e., axles, two wheels rotating around the same axis), and two-axle vehicles were used. The track of ancient Roman carts was standardized (possibly the cart track width was related to the cross width of horses), and today's road vehicles have approximately the same track of such ancient vehicles. Extensive implementation of brakes, steering, and suspensions was firstly introduced by Romans.

The dimensions of today's cars are strictly related to anthropometry, customer requirements, and technical equipment. The posture of humans inside the car largely influences the vehicle geometry. However, there is not a well-accepted rule to set the wheelbase.

In non-tilting vehicles, the best way to avoid rollover during cornering and braking is to arrange four wheels at the four corners of the car body.

In order to describe the running of vehicles on irregular road profile, the so-called quarter vehicle model (2 degrees of freedom [d.o.f.]) is very useful; such a simple model can be employed for conceptual design purposes under broad conditions. Ride (dis)comfort, road holding, and working space (rattling of the wheel with respect to body) are the output performance indices of the quarter vehicle model. Pitch body motions can be somehow taken into account by using a couple of the quarter-car models.

A vehicle with a single suspension arrangement (i.e., a simply sprung vehicle whose body is resting on stiff wheels and springs like ancient Roman carts) is not efficient to filter properly the excitation produced by the irregular road profile. Actually, for a simple quarter-car model with 1 d.o.f. excited by a standard irregular road profile, both the variance of the body mass vertical acceleration (discomfort index) and the variance of the vertical force at the wheel–ground interface (road holding index) are unbounded. Providing an additional suspension system (pneumatic tire) and referring to a 2 d.o.f. quarter-car model, the mentioned variances are made bounded, that is, adding a

pneumatic tire to a simply sprung vehicle makes a big difference, both from a theoretical and from a practical point of view. Actually the tire acts as low-pass filter. Two is the minimum number of passive suspension stages to obtain a bounded response of a ground vehicle to common random road irregularity. Such conclusions on suspension system behavior have been obtained by deriving relatively simple analytical formulae.

Providing a vertical massless spring between the vehicle and the ground is necessary (but not sufficient) to obtain a bounded response of the passively suspended vehicle to road irregularity excitations. The pneumatic tire represents the solution to such a technical need.

The working principle of the pneumatic tire surpasses the one of the solid wheel in that the Hertz contact pressure depending on wheel radius is no more the leading phenomenon (if the pneumatic tire were a thin-walled membrane, the contact pressure were simply the inner pressure). The load-carrying capacity of the tire is related not only to inner pressure but also to geometry. With reasonable approximation for concept design, the pneumatic tire load-carrying ability increases both with the square root of the wheel radius and linearly with inner pressure and cross width. The same wheel parameters affect in the same way the pneumatic tire stiffness. Such a synthesis on tire behavior has been obtained by deriving relatively simple analytical formulae.

Inherently, non-perfectly stiff wheels are prone to rolling resistance. Actually, hysteresis implies a moment that counteracts the rotation of the wheel. Such conclusion has been derived by analyzing a simple model featuring a wheel with an elastic tire. There are many different phenomena that lead to rolling resistance, involving both vertical and longitudinal tire compliance.

Rolling resistance is important but not the most important drag force during urban running conditions when inertia resistance is prevailing. Due to this, the powertrain of vehicles delivers often the highest power during acceleration. An analysis based on the NEDC has been introduced. Minimizing the energy to drive the NEDC requires reducing the vehicle mass and, to a less extent, the tire rolling resistance and aerodynamic drag. The recuperation of the kinetic energy does not lead to savings higher than about 20%.

The architecture of the driveline of two-axle road vehicles (front-, rear-, or all-wheel drive) depends—among other relevant aspects—on longitudinal acceleration performance (power on). The optimal torque distribution between the front and rear axles should be tuned (as for braking) as function of the longitudinal acceleration.

The active safety (handling) performance of a two-axle vehicle depends mostly on tire characteristics, inertial and geometric data (mass, center of gravity location, wheelbase), drive axle/torque vectoring, and suspension kinematics (or elastokinematics). All of these factors affecting vehicle architecture can be taken into account by the handling diagram theory. Actually the handling diagram theory allows an insight into the nonlinear phenomena involved within handling and allows to quickly understand the relation between vehicle architecture and vehicle performance. The crucial role of pneumatic tires on handling has been highlighted; actually the relationship between steering angle and centripetal acceleration is directly related to tire characteristics.

In order to investigate the influence on handling of vehicle inertial data and geometry, to simplify the theoretical investigation, the cornering stiffness of tires has been considered constant or linearly dependent on tire vertical load. In this last case, the understeering gradient is insensitive both to the vehicle mass and to the location of the center of gravity. Additionally, in this case, the yaw velocity gain and the damping ratio (of both the yaw rate and the sideslip angle responses to a steering input) do not depend on the location of the center of gravity. On the contrary, if the tire cornering stiffness characteristic is independent on tire vertical load (i.e., constant), the vehicle dynamic performance is very sensitive to all of its geometric and inertial parameters. Such conclusions have been derived by simple analytical formulae.

The effects on handling of drivetrain architecture (front-, rear-, or all-wheel drive) become evident taking into account how the handling diagram is constructed. Always traction forces reduce the maximum centripetal acceleration attainable, and the understeering is, respectively, increased or decreased by front- or rear-wheel drive. Torque distribution affects the handling performance in a way that is easily predicted by a simple and original formula derived in the chapter.

The kinematics and elastokinematic effects on the handling diagram (and on active safety) have been considered with reference to both the low and high levels of centripetal acceleration. At low levels of centripetal acceleration, the influence of lateral load transfer is generally vanishing; at high levels of centripetal acceleration, every single parameter of the suspension system may play an important role in defining the stability of a vehicle.

The inertia properties (mass, center of mass location, and body inertia tensor) are of crucial importance to assess accurately the dynamic behavior of vehicles. Some inertia properties are related to either vehicle geometry or among themselves. The mass is statistically linearly related to the wheelbase; the center of gravity horizontal distance from the front axle increases linearly with the vehicle mass as the vehicle is loaded. There are more or less simple relationships giving the main diagonal inertia tensor components as function of vehicle geometry. The experimental measurement of vehicle inertia properties is relatively quick and accurate.

After the analyses performed in this chapter, a comprehensive set of basic relations has been given to highlight how the vehicle architecture is related to vehicle dynamic performance.

The main issues referring to the conceptual design of road vehicles related to dynamics have been addressed referring to sustainable technology available today. In the future, the paradigms on which vehicle is conceived could change even abruptly provided that new technologies are made available and applied. An investigation on far future road vehicle conceptual design was out of the scope of this chapter.

12.1 INTRODUCTION

Automobiles are, at present, the most widely used means of transport on roads. When there are no roads, cargo and persons must be transported by off-road vehicles, which are designed for this purpose.

This chapter gives a general overview on models and theoretical and practical considerations for wheeled and tracked off-road vehicle systems. In addition to this, relevant elements of off-road vehicles and their influence on mobility are presented. Finally, the human factors and future developments are pointed out.

The *steam engine* was the first power source for vehicles on tracks and later on roads, then finally on terrain (Figure 12.1).

After the invention of the *internal combustion engines*, first according to the *Otto* and later to the *Diesel principle*, the steam engine lost its importance as a propulsion system for road vehicles as well as for off-road vehicles.

Off-road vehicles are used in large numbers, for example, in

- Agriculture
- Military operations
- Expeditions
- Rescue missions
- Construction
- Recreation activities

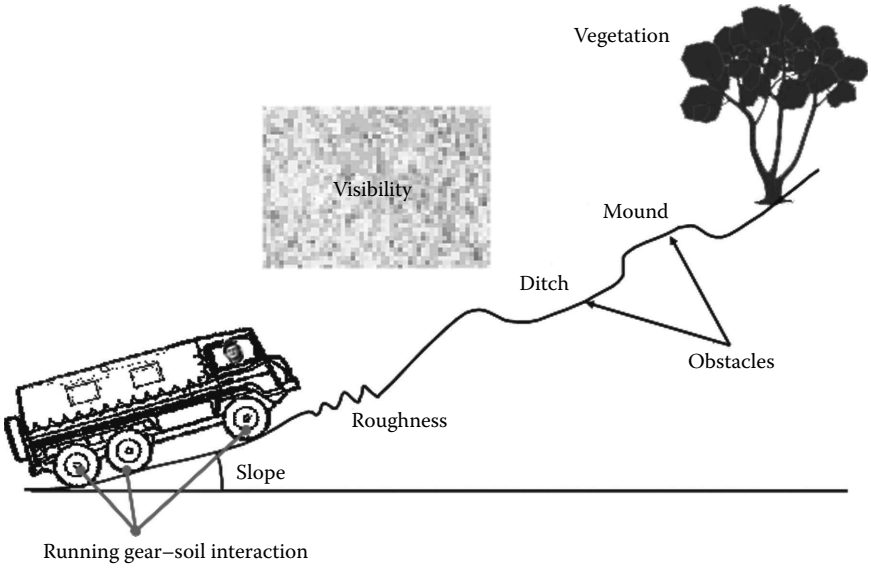

FIGURE 12.2 Vehicle in terrain interaction. (Reproduced from Hohl, G.H. and Corrieri, A., Basic considerations for the concepts of wheeled off-road vehicles, *FISITA World Automotive Congress*, Seoul, Korea, 2000 and based on an idea from *Vehicle Traction Mechanics*, Yong, R.N., Copyright, from Elsevier.)

Off-road vehicles share many components and design principles with commercial vehicles. However, in order to operate on terrain, these vehicles require different considerations, a new design or modifications of components.

The first considerations for a concept of off-road vehicles are to analyze the differences between road and terrain and the resulting influences.

The strength and deformation of terrain material must provide the necessary flotation and traction to keep a vehicle in constant travel and produce the required tractive force. Terrain characteristics can constitute other factors that could restrict vehicle speed or even cause total vehicle immobilization. These factors can be identified in Figure 12.2.

Influence of the terrain on the vehicle–terrain interaction [1]:

1. *Running gear–soil interaction*, "Running gear" *is the umbrella term for wheels a*nd tracks. The term "soil" is used in literature in connection with terrain vehicles to represent all types of transport surface. The determining factors for possible movement of off-road vehicles are the mechanical properties of the soil and the characteristics of the running gear system. The vehicle–terrain interaction is described in Section 12.3.
2. *Slope* can be anything up to a vertical wall, whereas roads rarely exceed 18%. Motion resistance increases because of the gravitational component of the vehicle along the slope. When traversing a slope, the vehicle could come into a dangerous overturning situation.
3. *Obstacles* include surface features, such as mounds, ditches, boulders, stumps, logs, dikes, and potholes, which are impediments to vehicles.
   There must be
   a. No interference between the obstacle and the bottom profile of the vehicle
   b. Enough traction and enough torque at the running gear
4. *Vegetation*, for example, grass-covered surfaces, causes additional resistance in vehicle motion and maneuvering around vegetation, like trees and bushes, requires additional traction forces and small steering radii.

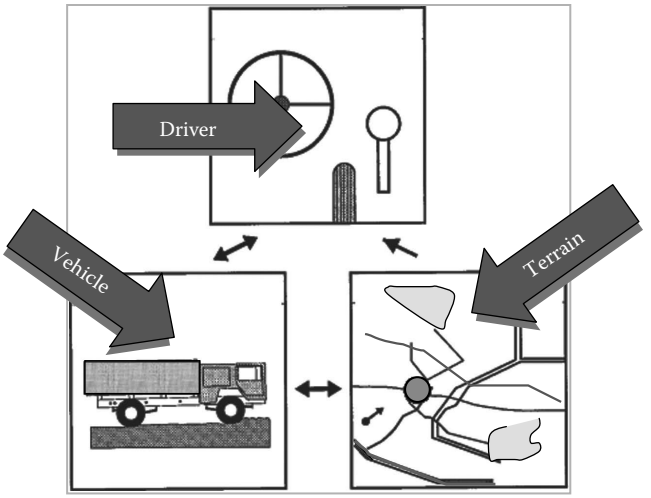

FIGURE 12.3 Driver–Terrain–Vehicle model. (Reproduced and modified from Ruff, K. and Jakobs, R., Interactive simulation of vehicle movement in terrain, *6th European ISTVS Conference*, Vienna, Austria, 1994.)

5. *Visibility* conditions influence the driver's recognition distance. Visibility controls the maximum speed at which the driver may proceed.
6. *Roughness* can be defined as random ground surface irregularities, which are the source of shocks and vibrations to the vehicle body, to the running gear assembly and also to the crew (see Section 12.4).
7. *Water* in brooks, rivers, and lakes can be a hindrance for an off-road mission. It has to be distinguished between having contact with the ground with slow speed and floating, respectively. For the first situation, the vehicle needs a special design, so that water cannot damage any component of the vehicle. For amphibious abilities, even more complicated design concepts are necessary.

For basic considerations of a terrain vehicle, a simple model can be used, the so-called "Driver–Vehicle–Terrain" model. The three elements influence each other (Figure 12.3).

Another more detailed model is described in Ref. [2].

12.2 CLASSIFICATION

12.2.1 General

In technology, one always tries to form categories. These attempts have also been made for terrain and vehicles (see Sections 12.3 and 12.5).

Irrespective of unconventional off-road vehicles in niches, such as marsh screws, air cushion vehicles, and slides [3], conventional terrain vehicles can be divided with respect to their suspension systems into two main categories:

- Wheeled vehicles
- Tracked vehicles

Concerning the structure, there are two further categories:

- Non-armored (or soft-skinned) vehicles
- Armored vehicles

It is a fact that in soft ground conditions and for good ditch crossing ability, tracked vehicles are superior to wheeled vehicles. Generally, Main Battle Tanks (MBTs) are based on tracked suspension systems. Armored personnel carriers (APC) with infantry on board that fight together with MBT must, therefore, have the same level of mobility and are tracked vehicles. The disadvantage, in comparison with armored wheeled vehicles (AWV), is the higher price and the lower road speed.

For other purposes, as in reconnaissance and peace-keeping missions, wheeled armored vehicles have higher road speed and thus offset the lower off-road mobility. Due to the lower price, more vehicles can be introduced in military units.

12.2.2 Wheeled Non-Armored Vehicles

Wheeled non-armored (soft-skinned) vehicles are used for transport of persons and goods in poor terrain situations as well as on paved roads. The structure is a frame (see Section 12.5). These types of vehicles have a range from *S*port *U*tility *V*ehicles (SUV) to extreme heavy vehicles with a gross weight of up to 40 t and thus can be divided into light, medium, and heavy versions (Figure 12.4).

Two principal concepts in developing soft-skinned vehicles can be pointed out. The one group is specially designed for off-road purposes. The other category is based on civilian utility vehicles and modified in details for their terrain missions like greater fuel tanks, all-wheel drive, and differential locks.

12.2.3 Wheeled Armored Vehicles

Wheeled armored vehicles have an armored hull, which is the structure of the vehicle. The hull is the structure and can be regarded as an over dimensioned torsion-resistant tube frame (see Section 12.5.1)

They are equipped with small caliber arms and are used for transport of infantry men, reconnaissance, peace-keeping and police missions, and ambulance operations (Figure 12.5).

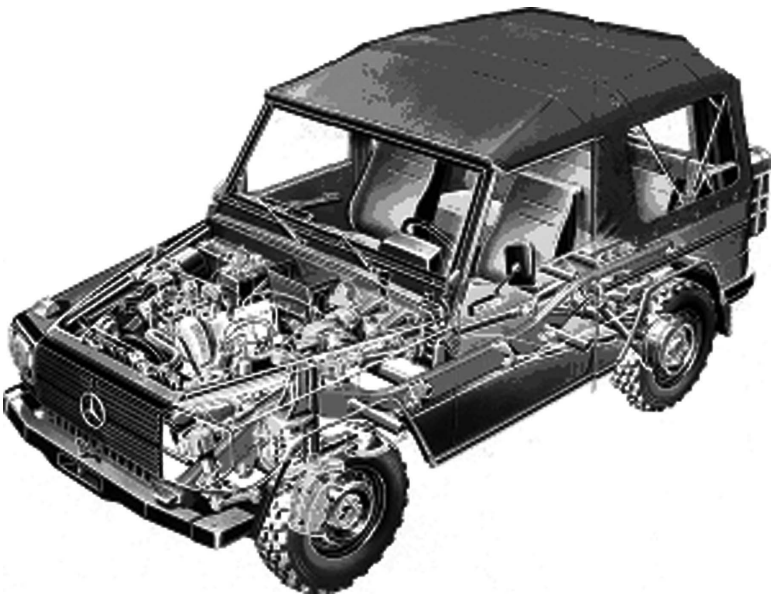

FIGURE 12.4 Puch Mercedes "G." (Reproduced from a leaflet from Steyr Daimler Puch A.G., Steyr, Austria.)

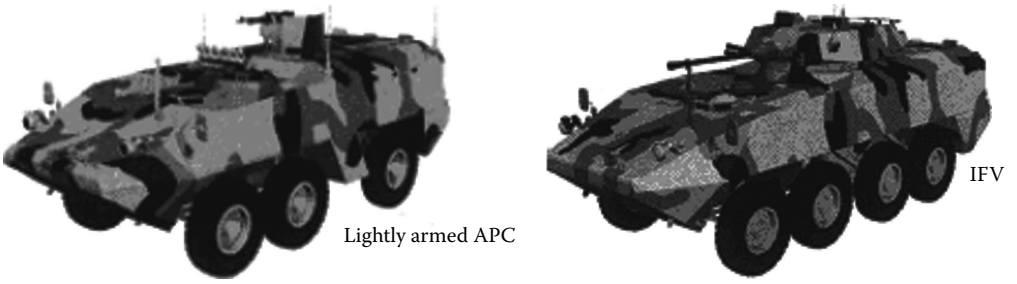

FIGURE 12.5 Family of wheeled armored vehicles. (Reproduced from Hohl, G.H., Geländegängige Fahrzeuge, Script for the lecture at the Technical University Vienna, Vienna, Austria.)

They can be divided into lightly armed APC with three axles, *I*nfantry *F*ighting *V*ehicles (IFV) with four axles, and *A*rmored *C*ombat *V*ehicles (ACV) with a five-axle concept, which can have almost the same tasks as MBTs.

12.2.4 Tracked Non-Armored Vehicles

Tracked non-armored vehicles are a niche. Contrary to armored versions, they have a kind of frame as the vehicle body. The oversnow vehicles in skiing areas belong to this one well-known category (Figure 12.6).

Another famous one and introduced in great number is the Swedish BV 206 with an articulated steering system (see Section 12.5.2.3.2). This vehicle can be used for transport of persons and/or goods, for ambulance purposes, and as a carrier for light weapons, radio, and light fire-fighting equipment (Figure 12.7).

FIGURE 12.6 Oversnow vehicle "Pisten Bully." (Reproduced from a leaflet from Kässborer A.G.)

FIGURE 12.8 Modern MBT; "German *Leopard 2*." (Reproduced from Ford, R., *Panzer von 1916 bis heute*, Karl Müller Verlag, Köln, Germany.)

12.2.5 Tracked Armored Vehicles

Tracked armored vehicles can principally be divided into battle tank versions, with the engine compartment in the rear and in APC concepts with the engine compartment in the front. The main representatives of these species are the MBTs and APC.

Both types look similar: they are armored, have a turret with a weapon, and are tracked, but they have quite different missions and design principles (see Section 12.5.1.2; Figure 12.8).

History and technology of tracked armored vehicles are described in detail in Ref. [4].

Modern MBTs have suspensions with a high degree of energy absorption and high travel of the road wheels and a revolving turret. The engine is a diesel and in one block with the transmission–steering unit. (For more details about this concept, see Section 12.5.)

12.3 VEHICLE–TERRAIN INTERACTIONS

As mentioned in Section12.1, the off-road vehicle and the terrain influence each other.

This chapter describes the interactions in the contact area between the "running gear," which is the umbrella term for wheels and tracks, and the contacts between the terrain and parts of the vehicle.

12.3.1 Running Gear–Terrain Interaction

The first step in investigating the interaction is to define the properties of the soil.

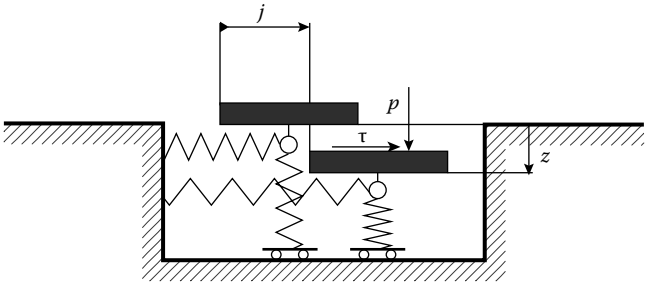
Many theories and models are available for the estimation of the interaction, and each of these theories has advantages and disadvantages that are suitable for certain applications but unfortunately they are not related to each other.

12.3.1.1 Terrain Specifications

For the prediction of traction of an off-road vehicle, it is necessary to define the ground. There are three methods in use:

- Bekker values
- Cone pentrometer values
- Basic soil parameters

12.3.1.1.1 Bekker Values



When observing movements of an off-road vehicle on soft ground, two things can be recognized:

- Sinkage
- Shear displacement

These two motions can be described by the plate model. A small piece has two movements in vertical (sinkage) and horizontal (shear) direction. The movements work against two symbolic springs. Contrary to springs in mechanical engineering, they have a plastic and a nonlinear characteristic. The stresses versus displacements in both directions can be regarded as one of the specifications of the soil properties (Figure 12.9).

The pressure–sinkage relationship can be characterized by the equation proposed by Bekker [2,5,6] and Wong [7,8]:

$$p = \left(\frac{k_c}{b} + k_\phi \right) z^n \tag{12.1}$$

j.....Shear displacement
z.....Sinkage
p.....Nominal normal pressure
τ.....Shear stress

FIGURE 12.9 Plate model. (Based on an idea in Krick, G., Wechselbeziehung zwischen starrem Rad, Luftreifen und nachgiebigem Boden, thesis, Munich, Germany, 1971; reproduced and modified from Hohl, G.H., Geländegängige Fahrzeuge, Script for the lecture at the Technical University Vienna, Vienna, Austria.)

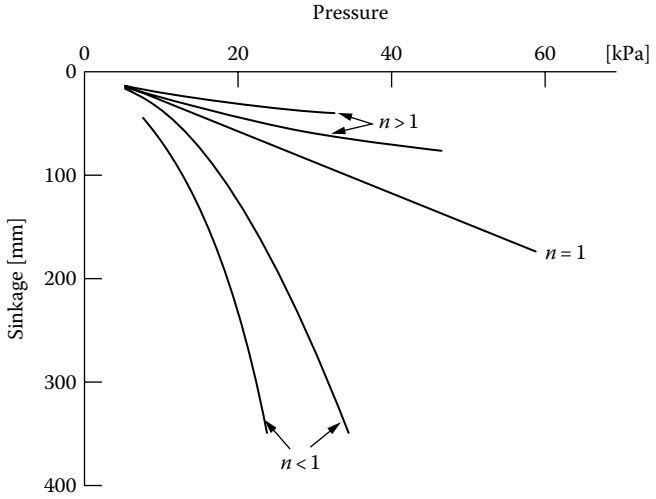


FIGURE 12.10 Nominal pressure–sinkage curves (parameter *n*). (Reproduced and modified from Wong, J.Y.: *Theory of Ground Vehicles*. 2001. Copyright Wiley-VCH Verlag GmbH & Co. KGaA.)

where

p is the nominal pressure [kN/m^2]
b is the smaller width of a rectangular plate or radius of a circular plate [m]
z is the sinkage [m]
k_c is the cohesive modulus
k_ϕ is the frictional modulus
n is the pressure–sinkage parameter

Using the dimensions mentioned earlier, k_c has the dimension (kN/m^{n+1}) and k_ϕ has the dimension (kN/m^{n+2}), n is dimensionless. The soil parameters k_c, k_ϕ, n can be derived by a minimum of two tests with plates of different widths (Figure 12.10).

The pressure–sinkage relationship is strongly influenced by size and shape of the plate as well as by the velocity of the penetration [9].

The state of failure, which is the maximum shear stress (τ_{max}) in soils, is a function of the nominal pressure p and is expressed by the Mohr–Coulomb failure criterion:

$$\tau_{max} = c + p \tan \phi \tag{12.2}$$

where

p is the nominal pressure
c is the cohesion
ϕ is the angle of internal friction

The shear stress (τ)–shear displacement (j) relationship is a function of τ_{max}, which depends on the normal pressure. The τ–j relationship is described by an exponential function proposed by Janosi and Hanamoto:

$$\tau = \tau_{max}(1 - e^{-j/K}) = (c + p \tan \phi)(1 - e^{-j/K}) \tag{12.3}$$

The value K can be determined from the slope of the shear curve at the origin (Figure 12.11).

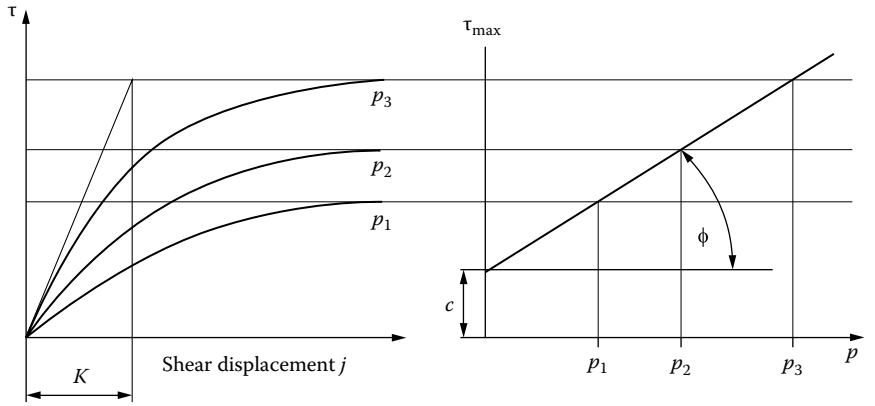

FIGURE 12.11 Shear stress–shear displacement relationship (Coulomb equation). (Reproduced and modified from Hohl, G.H., Geländegängige Fahrzeuge, Script for the lecture at the Technical University Vienna, Vienna, Austria; Wong, J.Y.: *Theory of Ground Vehicles*. 2001. Copyright Wiley-VCH Verlag GmbH & Co. KGaA.)

According to the Bekker theory, soil can be determined by the five values:

- Cohesive modulus, k_c
- Modulus of internal friction, $k_ø$
- Exponent, n
- Cohesion, c
- Angle of internal friction, ø

This method is also described in more detail in *Wong Mechanics*, Chapter 5.1, "Bevameter Techniques," as well as in Refs. [2,5–7]. A list of the Bekker values can be found in Ref. [7], Table 2.3.

The Bekker values can be used for predicting traction force–slip relationship and motion resistance of wheels and tracks (see *Wong Mechanics*, Chapters 5.2, 5.3, 6.1, and 6.2).

12.3.1.1.2 Cone Pentrometer

Cone pentrometers were developed for military purposes by the U.S. Army for the investigation of trafficability of soil toward the end of World War II. The cone pentrometer consists of a 30° circular cone with a base area of ½ in.^{2} (3.23 cm^2).

The measured values are expressed in the so-called *C*one *I*ndex (CI), which is the penetration force divided by the cone base area [1,3,7,10].

The necessary force is applied by pushing the cone slowly at a rate of about 30 mm/s through the soil. The force is measured by a deformable steel ring, which acts as a spring. The displacement is measured by dial gauge. With the spring characteristic, the penetration force can be determined (Figure 12.12 and Table 12.1).

Moisture content has a great influence on the CI values [11].

The Cone Pentrometer Method is used for empirical models like the *N*ATO *R*eference *M*obility *M*odel (NRMM), which is useful for the prediction of the mobility of military units. The advantage of the cone pentrometer method is that the terrain values can be easily measured. These values can also be used to investigate a "go or no go" situation and for predicting with an empirical method the drawbar coefficient μ_{20} at 20% slip for several soil types (see Section 12.3.1.2.2.4).

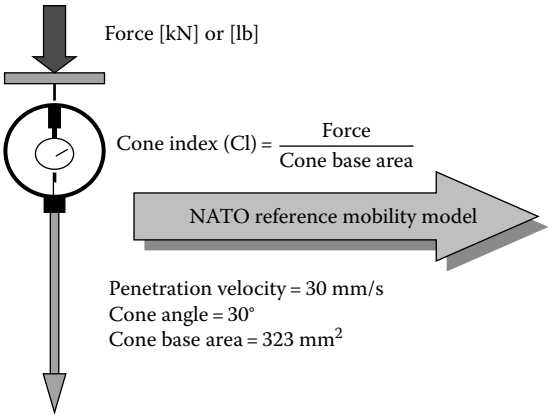

FIGURE 12.12 Cone pentrometer. (Reproduced and modified from Hohl, G.H., Geländegängige Fahrzeuge, Script for the lecture at the Technical University Vienna, Vienna, Austria.)

TABLE 12.1
CI Values versus Soil Types

Soil Types	CI (N/cm²)
Coarse grained sand	200
Dry grassland	150
Sandy loam (medium dry)	120
Sandy loam (wet)	30–50
Ploughed field	20

Source: Reproduced and translated from Hohl, G.H., Geländegängige Fahrzeuge, Script for the lecture at the Technical University Vienna, Vienna, Austria.

12.3.1.1.3 Basic Soil Properties

Soil is a multiphase medium that contains varying degrees and in various states of three distinct phases:

- Solid (inorganic and/or organic particles)
- Liquids (water and/or ice other fluids)
- Gas (air and/or other gases)

In natural soil the three phases are intimately mixed and shown schematically in Figure 12.13. The content of the three components can be expressed in percentage of volume or weight. The ratios between them define the basic physical soil properties.

The mostly used relationships are

- Porosity (n)
- Water content (w)
- Unit weight (γ)

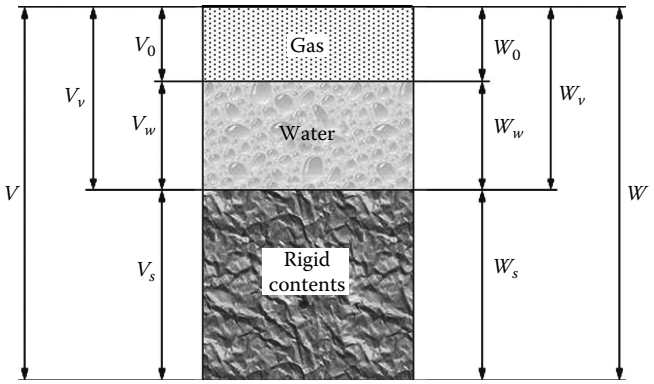

FIGURE 12.13 Idealized three-phase soil system. (Reproduced and modified from Hohl, G.H., Geländegängige Fahrzeuge, Script for the lecture at the Technical University Vienna, Vienna, Austria; *Vehicle Traction Mechanics*, Yong, R.N., Copyright, from Elsevier.; Karafiath, L.L. and Nowatzki, E.A., *Soil Mechanics for Off-Road Vehicle Engineering*, Trans Tech Publications, Aedermannsdorf, Switzerland.)

Porosity (n) in [%] is defined as the ratio of the voids $V_v = V_0 + V_w$ and the total volume:

$$n = \frac{V_0 + V_w}{V} 100 = \frac{V_v}{V} 100 \tag{12.4}$$

An easily measurable parameter that influences many of the soil characteristics is the *water content* (w) expressed as a percentage:

$$w = \frac{W_w}{W_s} 100 \tag{12.5}$$

The *unit weight* (γ) of the saturated soil–water system is defined by the total weight divided by the total volume:

$$\gamma = \frac{W_w + W_s}{V} = \frac{W}{V} \tag{12.6}$$

Unfortunately, it is not possible to define all characteristics of the soil usable for the interaction only by the physical values. There are also no generally valid relationships expressed in equations between the physical values, on the one hand, and the Bekker and CI values, on the other. But trends can be given: k_c, k_ϕ, c, and ϕ decrease with increasing water content w and increasing porosity n.

The CI increases with increasing unit weight γ and decreases with increasing water content w.

There were some attempts to find a relationship between the basic soil properties and Bekker values [1,5]. Hintze found a relationship for seasonal moisture and the CI values [11]. The properties of organic terrain are described in detail in Refs. [1,3,10].

12.3.1.2 Traction Forces

Before presenting calculation models for the prediction and methods for the measurement of traction forces of a terrain vehicle under certain ground conditions, it is necessary to make some definitions [1–3,5–7,12].

12.3.1.2.1 Definitions

The aim of an off-road ride is not only to move cross-country but also to produce traction for acceleration, to overcome obstacles and slopes, and to pull or push various types of trailers as agricultural implements, working and earthmoving machines, as well as military equipment like cannons. The force available at the drawbar is named drawbar pull (mostly abbreviated in literature with DP or F_d). The tractive effort F is the force directly acting at the running gear (wheel or track), which comes from the engine via all gear reductions and minus the internal friction. This force is due to the resisting forces ΣR not being fully available for pulling actions.

$$F_d = F - \sum R \tag{12.7}$$

ΣR includes all resistances like internal resistance of the running gear, the losses due to the interaction with the terrain, and the gradient and obstacle resistance. The tractive effort F is easy to determine when the torque–speed curve of the engine and the transmission characteristics are known.

DP is not constant, and it is a function of slip (i), which is defined as

$$i = \frac{v_{th} - v_a}{v_{th}} = 1 - \frac{v_a}{v_{th}} = 1 - \frac{v_a}{r\omega} \tag{12.8}$$

where

v_{th} is the theoretical speed ($r\omega$)
r is the radius
ω the angular velocity of the tire or of the sprocket
v_a is the actual speed
r is the radius of a wheel or sprocket

Slip i, which in some publications is also abbreviated with (s), can be expressed in decimal values between 0 and 1 or in percent values between 0% and 100%. Slip value 1, respectively, 100%, describes a rotating but immobile wheel or track.

The coefficient of traction μ_{tr}, which is a widely used parameter, is defined as the ratio of the DP F_d and the load on the driven wheels, respectively, the load on the track W_d:

$$\mu_{tr} = \frac{F_d}{W_d} = \frac{F - \sum R}{W_d} \tag{12.9}$$

The coefficient of rolling resistance μ_r is a parameter that is defined as the ratio of the sum of the rolling resistances and the load of the driven wheels, respectively, the load on the track W_d:

$$\mu_r = \frac{\sum R}{W_d} \tag{12.10}$$

Especially for working machines and tractors, the efficiency of the off-road vehicle in transforming the power produced by the engine and the power available at the drawbar is of economic interest. The tractive efficiency η_d is defined as the ratio of drawbar power P_d ($P_d = F_d v_{th}$) to the delivered power P by the engine:

$$\eta_d = \frac{P_d}{P} = \frac{F_d v_a}{P} = \frac{\left(F - \sum R\right) v_{th}(1-i)}{P} \tag{12.11}$$

This equation shows that the tractive efficiency η_d is high in cases of low slip values but in the case of 1, respectively, 100% slip, 0. Therefore, for a high tractive efficiency, the maximum of DP should be at low slip values.

12.3.1.2.2 Drawbar Pull–Slip Curves

12.3.1.2.2.1 Shape of the Curves The F_d (dB), respectively, the μ_{tr}–slip curves, have two principal shapes. In loose soils, progressive continuous characteristics up to 100% slip can be observed. Dense soils have a maximum in the range between 15% and 30% slip.

The magnitude and shape of a traction or traction force or coefficient of traction curve versus slip is the result of complex interactions between the running gear system and the terrain.

It is difficult to compare curves with completely different shapes as shown in Figure 12.14. In Ref. [13], four methods are described to evaluate the different curves (see Figure 12.15):

1. *Maximum* μ_{tr}—the maximum value or an average of a small amount of data (3% of the total data) surrounding the maximum.
2. *Average peak* μ—the optimum tractive performance, calculated by averaging the top 20% of the μ values.
3. μ *at 12% slip*—the value occurring when slip is 12%.
4. *SAE* μ—an average of the μ between a slip of 28% and 75%.

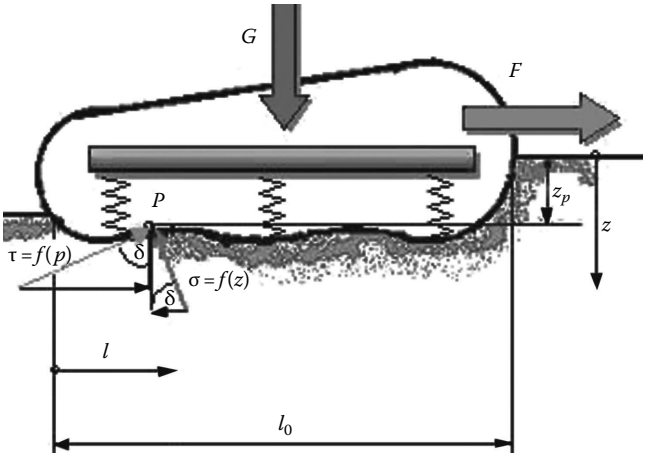

FIGURE 12.16 Principle of the SIM. (Reproduced from Hohl, G.H., Geländegängige Fahrzeuge, Script for the lecture at the Technical University Vienna, Vienna, Austria.)

12.3.1.2.2.2 Stress Integrating Method The classical *S*tress *I*ntegrating *M*ethod (SIM) initiated by Bekker [2,5,6] and developed by Wong [7,8], who approaches the phenomena of the running gear—soil interaction in more detail—is based on the Bekker terrain measurements.

To evaluate the relationship between the DP and the slip of a running gear system (wheel or track), the normal and shear stress distributions, depending on slip along the interface, have to be determined first. The vertical components of both stress types represent the load (*G*) and the horizontal components are equal to the tractive force (Figure 12.16).

This method can also be used for rigid wheels [1,7,8] as well as for tracked vehicles [7,8] and is described in detail in Refs. [7,8].

The flexibility of a pneumatic tire can be described with different contact shapes [14–18].

Some other scientists also developed models for the prediction of tractive force in soft soil and organic surface based on other considerations [14,19].

12.3.1.2.2.3 Finite Element Method The Finite Element Method (FEM) is widely used for stress determination in complex elements in mechanical engineering. In recent years, many attempts have been made to apply this successful method to the analysis for the running gear–terrain interaction. Professor Schmid and his assistants were very successful in this method [16,20–23].

The FEM investigates the phenomena of wheel–soil interaction in detail by defining a rolling contact between an elastic tire and soft soil (Figure 12.17).

The terrain is represented by a system of elements in triangular or rectangular form with specific constitutive relationships and interconnections at nodes to form a mesh. In the soil model, the soil has elastoplastic properties and the strength limits in a three-dimensional state are defined according to the Drucker–Prager theory. Based on this consideration, the soil FEM can be applied for frictional and cohesive soil. The tire is considered as piecewise linear elastic material for tread carcass and rim in the form of three concentric rings.

Similar to the FEM is the Distinct (Discrete) Element Method. The term discrete element method (DEM) is a family of numerical methods for computing the motion of a large number of particles like molecules or grains of sand. This method used for terramechanics is described in more detail in Refs. [24,25].

12.3.1.2.2.4 Empirical Method With this method, the tractive performance of a running gear is based on an empirical model. The dimensionless terms, the so-called numerics are related to the drawbar coefficient and the drawbar efficiency both at 20% slip. The maximum of DP is usually in this range. Therefore, these two dimensionless values lead to the index 20 (μ_{20} and η_{20}) [1,3,7,26,27].

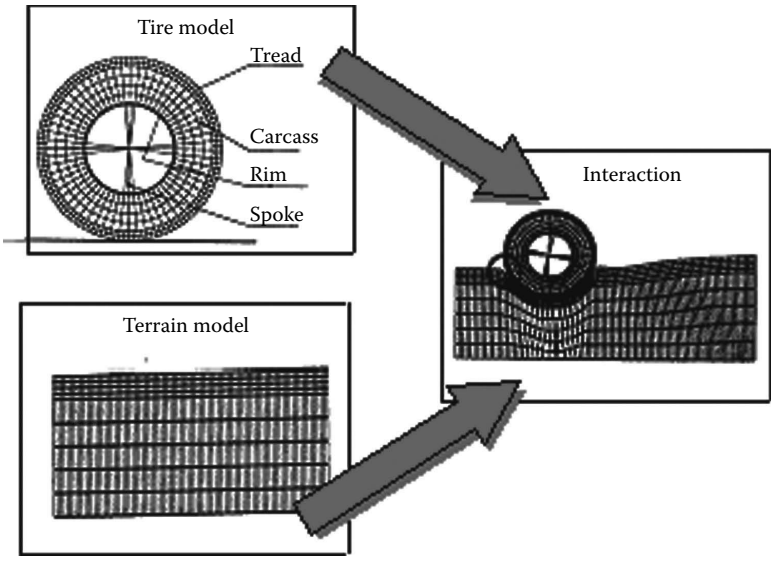

FIGURE 12.17 Principle of the FEM. (Reproduced and modified from Schmid, I., Interaction of vehicle and terrain, *6th European ISTVS Conference*, Vienna, Austria, 1994.)

The "numerics" include the terrain data with the CI (in this model, the CI is abbreviated with C) and the tire data (diameter d, width b, section height h, deflection δ, and wheel load W). Depending on the soil type, three "numerics" are defined (Figures 12.18 and 12.19):

Clay–tire numeric N_c

$$N_c = \frac{C(bd)(d/h)^{1/2}}{W} \cdot \frac{1}{1+(b/2d)} \tag{12.12}$$

Sand–tire numeric N_s

$$N_s = \frac{G(bd)^{3/2}}{W} \cdot \frac{\delta}{h} \tag{12.13}$$

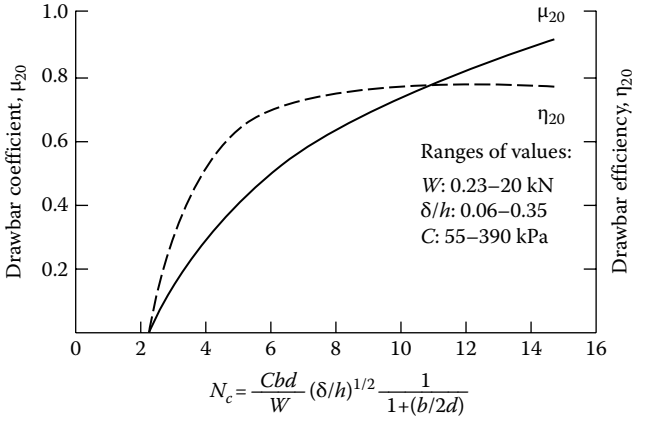

FIGURE 12.18 Empirical relationship between drawbar coefficient and drawbar efficiency at 20% slip for the clay–tire numeric N_c (left). (Reproduced from from *Vehicle Traction Mechanics*, Yong, R.N., Copyright, from Elsevier.)

Cohesive and frictional sand–tire numeric N_{cs} (Figure 12.20)

$$N_{cs} = \frac{C(bd)}{W} \tag{12.14}$$

12.3.1.2.2.5 Practical Method To obtain realistic DP–slip curves, it is necessary to test the running gear under in situ situations. There are several ways available:

Test of a single wheel in a soil bin under laboratory conditions

- Single wheel tester on a natural surface
- Test rig pulling a braking (parent) vehicle
- Test rig pushing a braking vehicle
- Test of an overall vehicle

The tasks of a single wheel test are to measure only the interaction of a tire with the soil, without influences from the other components of the vehicle. In soil bins, the soil has laboratory conditions with constant and defined soil properties (CI, water content, porosity etc.) (Figure 12.21).

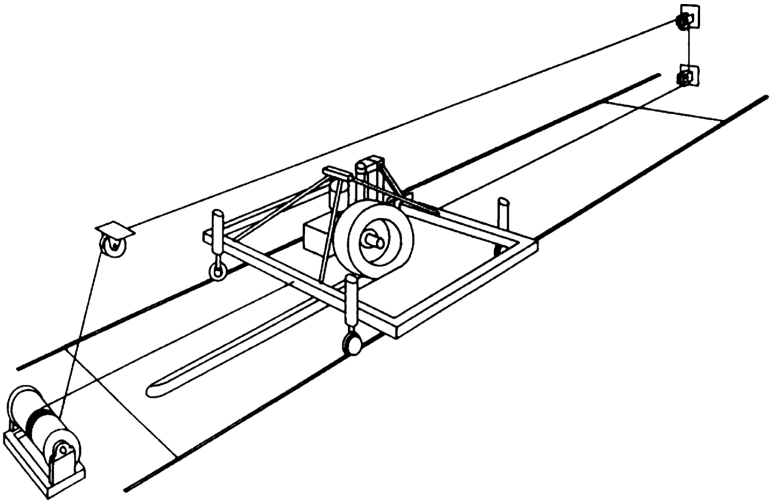

FIGURE 12.21 Principle of a soil bin. (Reproduced from Schwanghart, H. and Zweier, A., Influence of tread on drawbar pull of tires for small off-road vehicles, *11th International ISTVS Conference*, Lake Tahoe, NV.)

Soil Bin Tests

The test tire is mounted on a single wheel test rig running on rails and towed by a cable winch. The test wheel is driven by a hydraulic or an electric motor. The wheel load is applied by a constant ballast weight. The wheel rotates with a constant speed. By varying the forward speed of the test rig, any slip between 0% and 100% can be set. Measuring wheel torque, DP, load, sinkage, wheel speed (v_{th}) and wagon speed (v_a), and tractive force, respectively, DP–slip curves can be determined (Figure 12.22).

Outdoor Single Wheel Tester

Contrary to the soil bin tests, the single wheel testers described in the following work on a horizontal terrain under natural soil conditions, which are prepared to a certain degree.

There are two types of single wheel testers:

- Test device with a towed braking (parent) vehicle
- Test device in a frame with a pushed braking vehicle

In both cases, the tester consists of two vehicle bodies. The driving part is the test tire and the driven part is pushed or pulled and has a braking function. The force in between is the DP. The motion of the braking vehicle is without slip and thus represents the actual speed.

The single wheel tester designed by Royal Armaments Research & Development Establishment (RARDE) is shown in Figure 12.23. The force P between the two vehicle bodies is the DP and due to the measurement of torque, the tractive force can be determined.

The theoretical speed v_{th} is measured at the hub of the test wheel and the actual speed v_a at the hub of the parent vehicle.

The parent vehicle is pushed by the hydraulically driven test wheel. With this test equipment, not only the tractive force but also the lateral force can be measured (Figures 12.24 and 12.25).

Overall Vehicle Tests

The advantage of an overall vehicle test is that the soil conditions are realistic and the procedures for testing and measuring are easier. On the other hand, however, the soil conditions are not as equal in property as in a soil bin, the speed is not steady, and, therefore, the acceleration forces are included.

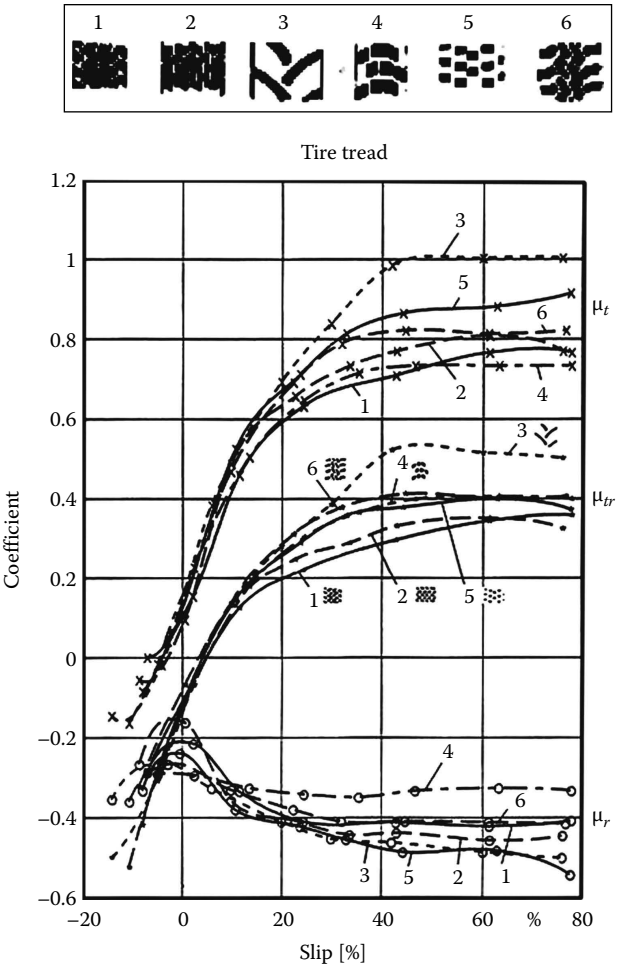

FIGURE 12.22 Test results of a soil bin test with six test tires; the numbers represent different tires. (Reproduced and modified from Schwanghart, H. and Zweier, A., Influence of tread on drawbar pull of tires for small off-road vehicles, *11th International ISTVS Conference*, Lake Tahoe, NV.)

FIGURE 12.24 University of Stuttgart–Hohenheim single wheel tester; test arrangement. (Reproduced from a picture from University of Stuttgart–Hohenheim, Stuttgart, Germany.)

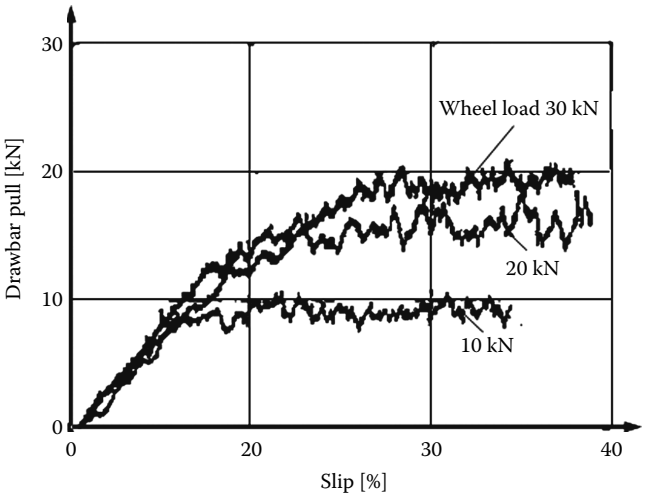

FIGURE 12.25 University of Stuttgart–Hohenheim; single wheel tester; test results. (Reproduced and modified from Kutzbach, H.D., Investigation on tractor tyres test stand and results, *6th European ISTVS Conference*, Vienna, Austria, 1994.)

The test vehicles are equipped with test tires towing a braking (parent) vehicle. The DP is measured by a force transducer attached to the rope between the two vehicles.

The principal way of measuring DP, theoretical and actual speed, load, and in some cases torque is similar for the test methods mentioned earlier.

Load is applied by weights. For all types of single wheel testers, it is not a problem to measure the theoretical speed as it is proportional to the revolutions of the wheels or the sprocket. It is more difficult to measure the actual speed in field tests with a complete vehicle. One widespread method is to use a towed wheel also named "Peiseler" or "fifth wheel." The disadvantage is that such a wheel can temporarily lose ground contact and that the wheel itself can be subject to slip.

Another method, which was used by the author, is a noncontact sensor system. The contactless operation of the measuring device fully preserves the maneuverability of the vehicle in all directions. DP is measured by a dynamometer hook fixed to a rigid point. In the case of single wheel testers and tests with a complete vehicle, the dynamometer hook is attached between the test vehicle and the braking vehicle.

In the tests mentioned in Figure 12.26, the actual speed was measured by a contactless measuring device and for the determination of the DP, the towing forces and the accelerations of the vehicle mass were taken into consideration. Knowing the DP according to the soil properties and the

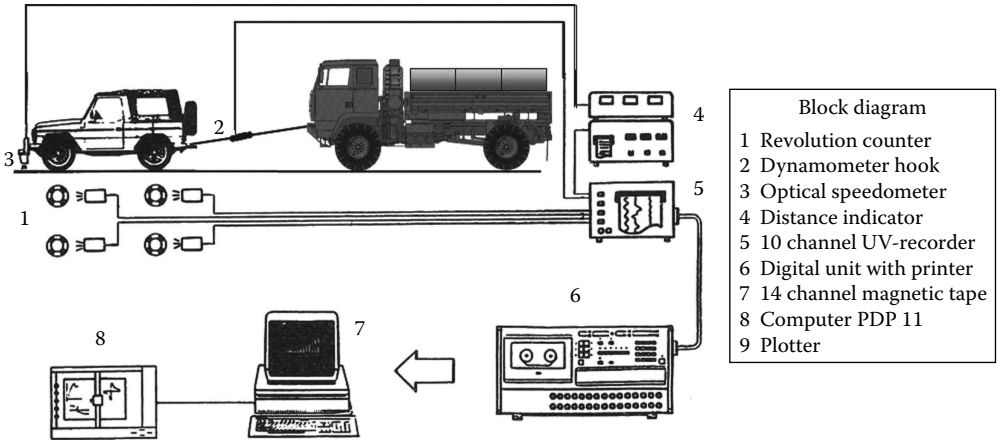

FIGURE 12.26 Austrian Agency of Military Technology; test arrangement. (Reproduced and modified from Hohl, G., A method to determine coefficient of traction-slip relationship of tyres in "in-situ" tests, *9th International ISTVS Conference*, Barcelona, Spain.)

different contact shapes [7,8,16–18], the maximum speed and the acceleration can be determined. For the prediction of acceleration, the translatory and rotatory masses have to be taken into consideration. There are two ways to combine these two masses:

- To put the translatory masses to the rotatory ones [28,29]
- To put the rotatory masses to the translatory ones [7,30] (Figure 12.27)

12.3.2 Vehicle Geometry—Terrain Interaction

The "waviness" of the ground obviously may degenerate into small irregularities, which cause vibrations (see Section 12.4) and deep cut forms that may stop the vehicle motion entirely. These geometrical obstacles are described in Section 12.3.2.1.

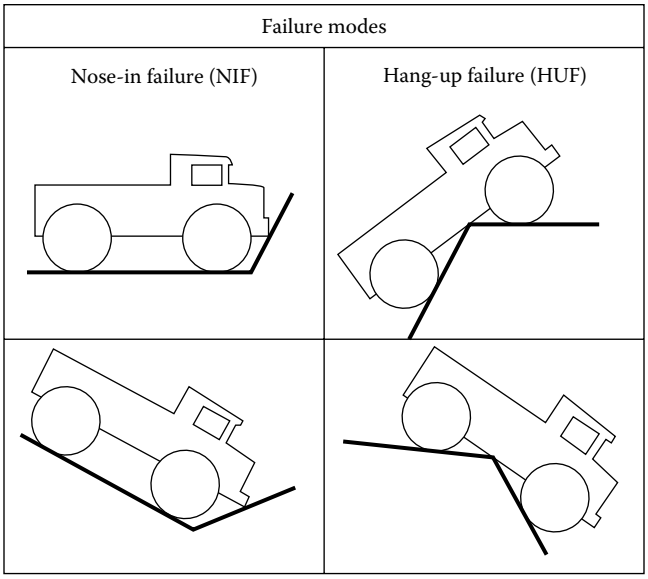

FIGURE 12.28 Vehicle–terrain failure modes. (Reproduced from Bekker, M.G., *Introduction to Terrain-Vehicle Systems*, University of Michigan Press, Ann Arbor, MI, 1969.)

12.3.2.1 Failure Modes

Due to the unevenness of the terrain, parts of the vehicle can come into contact with the ground and can be immobilized independently from the physical conditions of the surface. There is a great variety in the form and sizes of natural terrain obstacles that may immobilize a terrain vehicle. According to Bekker [2], the mechanics of interaction of these two geometries must be defined in any characterization of terrain roughness from the viewpoint of

- Obstacle crossing
- Vehicle controllability
- Ride comfort (see Section 12.4; Figure 12.28)

With the two principal failure modes defined by Bekker [2], nearly all geometrical vehicle terrain conflicts can be described:

- Nose-in failure (NIF)
- Hang-up failure (HUF)

An NIF happens when the front or the rear end interferes with the obstacle.

In case of an HUF, the bottom of a vehicle comes into contact with an obstacle. Both types occur on convex or concave obstacle forms.

12.3.2.2 Vehicle Geometry

To avoid an NIF, it is important that the terrain vehicle has high angles of approach and of departure.

The *angle of approach* is defined as the maximum angle that an obstacle can overcome without striking the obstacle and damaging the vehicle.

The *angle of departure* is the maximum angle at which the vehicle can exit an obstacle without striking the obstacle and damaging the vehicle.

For a vehicle with good off-road abilities, both values should be in the range of 30°–40° or more (Figure 12.29).

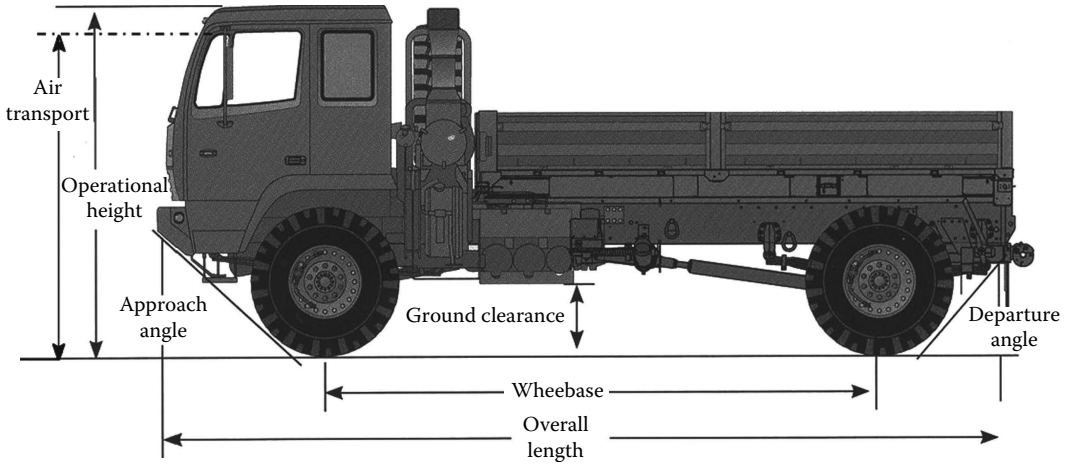

FIGURE 12.29 Definition of departure angle and approach angle. (Reproduced and modified from Hohl, G.H., Geländegängige Fahrzeuge, Script for the lecture at the Technical University Vienna, Vienna, Austria.)

An HUF situation occurs when a vehicle moves over a wedge-formed obstacle. The shape of the ridge is defined by the breakover angle, which is the maximum angle a vehicle can traverse an obstacle without striking or hanging up between the axles. To find a geometrical relationship between the hung-up diameter D_r and the breakover angle β and the wheel diameter D, the axle distance l, and the ground clearance h_g, it is easier to move the wedge underneath the vehicle bottom.

The geometry of the wedge can be defined as ground clearance diameter D_r or as breakover angle β. There is a complicated relationship between both and the vehicle dimensions, axle distance l, and wheel diameter D. The breakover angle should be more than 20°:

$$D_r = \frac{2l^2 D(\cos\beta - \cos^2\beta)}{4l^2 \sin\beta - D^2(\cos^2\beta - 2\cos\beta + 1)} + \sqrt{\left[\frac{2l^2(\cos\beta - \cos^2\beta)}{4l^2 \sin^2\beta - D^2(\cos^2\beta - 2\cos\beta + 1)}\right]^2} + \frac{4l^4}{4l^2 \sin^2\beta - D^2(\cos^2\beta - 2\cos\beta + 1)} - D \tag{12.15}$$

In accordance with Figure 12.30 the vehicle will fail if

$$h_g \le 0.5\left[(D + D_r) - \sqrt{(D + D_r)^2 - l^2}\right] \tag{12.16}$$

The relationships in the equations earlier show that a high clearance diameter D_r, respectively, a low wedge angle β and high wheel diameter D and a short axle distance l are positive for overcoming a wedge-formed obstacle.

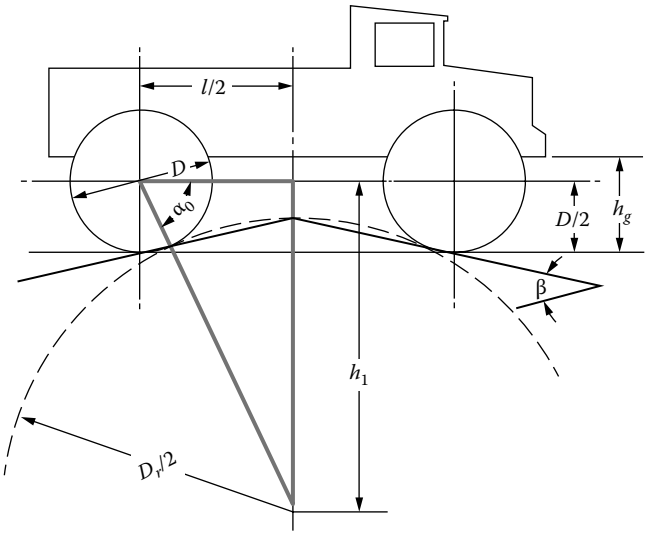

FIGURE 12.30 Longitudinal clearance diameter D_r and breakover angle β. (Reproduced from Bekker, M.G., *Introduction to Terrain-Vehicle Systems*, University of Michigan Press, Ann Arbor, MI, 1969.)

Transverse ground clearance is measured between the wheels on one axle. It can be defined by the diameter D_{rt} of the circle that touches the inner side of the tires and the lowest hanging point under a vehicle (usually a differential or the exhaust system).

Another definition is the zenith of the segment of the circle, which touches the wheels and the lowest point of the vehicle under the body (Figure 12.31).

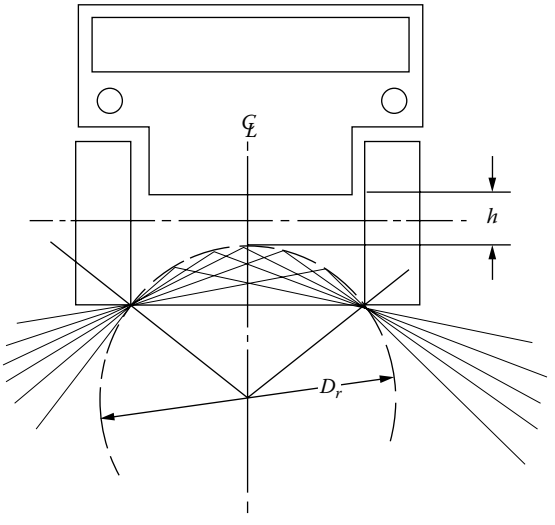

FIGURE 12.31 Transverse clearance diameter D_r. (Reproduced from Bekker, M.G., *Introduction to Terrain-Vehicle Systems*, University of Michigan Press, Ann Arbor, MI, 1969.)

- Vertical walls (A) and (B)
- Horizontal cavities (C)

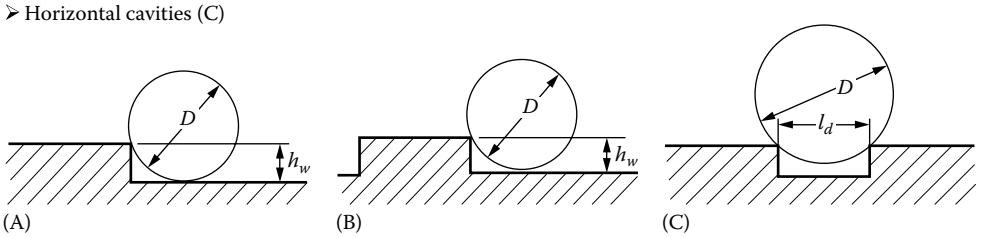

FIGURE 12.32 Vertical walls (A) Plateau type wall, (B) Bump type wall, and (C) Horizontal cavity. (Reproduced from N.N., *Engineering Design Handbook*, Automotive Series, Automotive Suspensions, AMCP 706–356, Headquarters, U.S. Army Materiel Command, Huntsville, AL.)

12.3.2.3 Overcoming Step-Formed Obstacles

Bekker [6] defined two elementary types of obstacles related to the geometry of terrain surface (Figure 12.32):

The described model with rigid wheels and no spring reactions is two-dimensional and the terrain and the vehicle are described by the following data:

Terrain	*Vehicle*
• Height of the step (h_w)	• Tire diameter (D)
• Coefficient of traction (μ_a)	• Wheel base (s)
• Coefficient of rolling resistance (μ_r)	• Position of C.G. (s_1, h_0)

The geometric situation when the front wheel encounters the wall is different from that when the rear wheel overcomes the wall.

12.3.2.3.1 Two-Axle All-Wheel Drive

The main principle of investigating climbing ability over a step is similar for all situations and is demonstrated in Figure 12.33 for a plateau-type wall by means of a two-axle all-wheel drive vehicle just entering the step.

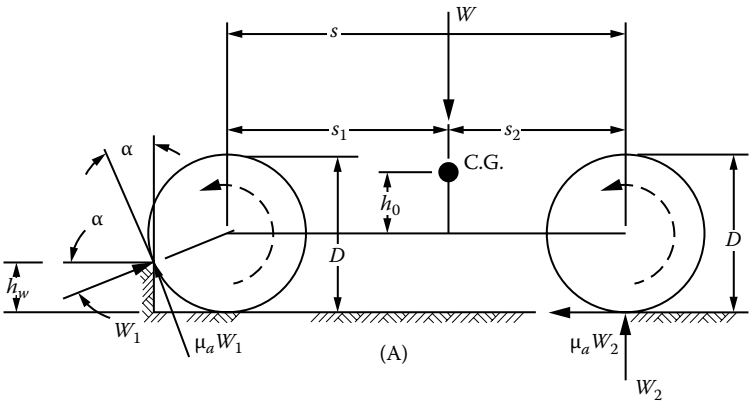

FIGURE 12.33 Two-axle vehicle 4 × 4 encountering a step in situation A. (Reproduced from Hohl, G.H., Geländegängige Fahrzeuge, Script for the lecture at the Technical University Vienna, Vienna, Austria; Bekker, M.G., *Theory of Land Locomotion*, University of Michigan Press, Ann Arbor, MI, 1956; N.N., *Engineering Design Handbook*, Automotive Series, Automotive Suspensions, AMCP 706–356, Headquarters, U.S. Army Materiel Command, Huntsville, AL; Hohl, G.H. and Peschak, B., A model to predict the overcoming of geometrically defined obstacles by a two-axle wheeled vehicle, *13th International ISTVS Conference*, TU München, Munich, Germany, 1999.)

The sum of all horizontal and vertical forces and the sum of the momentum around the axis of the front wheel *I* are zero. This way of solving the equations is hereby described in Figure 12.33 and shows situation A when the front wheel hits edge A of the step. The equilibrium of forces and momentums yield the following equations:

$$\begin{aligned} W_1 \cos\alpha - \mu_a W_1 \sin\alpha - \mu_a W_2 &= 0 \\ W_1 \sin\alpha + W_2 + \mu_a W_1 \cos\alpha - W &= 0 \\ -\mu_a W_1 \frac{D}{2} + W_2 s - W s_1 - \mu_a W_2 \frac{D}{2} &= 0 \end{aligned} \tag{12.17}$$

Solving the three equations (Equations 12.17) with three unknown values yields to the following implicit relationship:

$$\left[\frac{1}{\mu_a} - \frac{1+\mu_a^2}{\mu_a}\left(\frac{s_1}{s}\right) - \frac{D}{2s}\right]\cos\alpha - \left[1 - \frac{\mu_a D}{2s}\right]\sin\alpha - \frac{\mu_a D}{2s} = 0 \tag{12.18}$$

$$\sin\alpha = 1 - \frac{2h_w}{D} \tag{12.19}$$

$$\cos\alpha = \frac{2\sqrt{Dh_w - h_w^2}}{D} \tag{12.20}$$

$$T_1 = \left[\frac{1}{\mu_a} - \frac{1+\mu_a^2}{\mu_a}\left(\frac{s_1}{s}\right) - \frac{D}{2s}\right] \tag{12.21}$$

$$T_2 = \left(1 - \frac{\mu_a D}{2s}\right) \tag{12.22}$$

Using the auxiliary terms T_1 and T_2 (Equations 12.21 and 12.22) and the geometrical relationships (Equations 12.19 and 12.20) leads to Equation 12.23, where the vehicle data D, s, s_1, as well as the terrain data h_w and μ_a are linked together:

$$h_w = \frac{D}{2} \times \frac{T_1^2 + T_2 - \sqrt{\left(T_1^2 + T_2\right)^2 - \left(T_1^2 + T_2^2\right)}}{T_1^2 + T_2^2} \tag{12.23}$$

12.3.2.3.2 Rear-Wheel Drive

For rear-wheel drive, the traction coefficient μ_a for the front wheel has to be replaced by the coefficient of rolling resistance—μ_r in Equation 12.18.

This yields to the implicit relationship:

$$\frac{\mu_r D}{2s} = \left[\frac{S_1}{S}\left(\frac{\mu_a + \mu_r}{\mu_a}\right) - \frac{\mu_r}{\mu_a} + \frac{\mu_r D}{2s}\right]\sin\alpha - \left[\frac{1}{\mu_a} - \frac{1 - \mu_a\mu_r}{\mu_a}\left(\frac{S_1}{S}\right) - \frac{D}{2s}\right]\cos\alpha \tag{12.24}$$

h_w, respectively, h_w/D, can be solved in an iterative way by using the geometrical relationships in Equations 12.21 and 12.22. Assuming that μ_r is very small and thus can be set to zero, an explicit solution of this equation can be obtained between h_w/D and the vehicle and terrain parameters. This would be correct for hard ground.

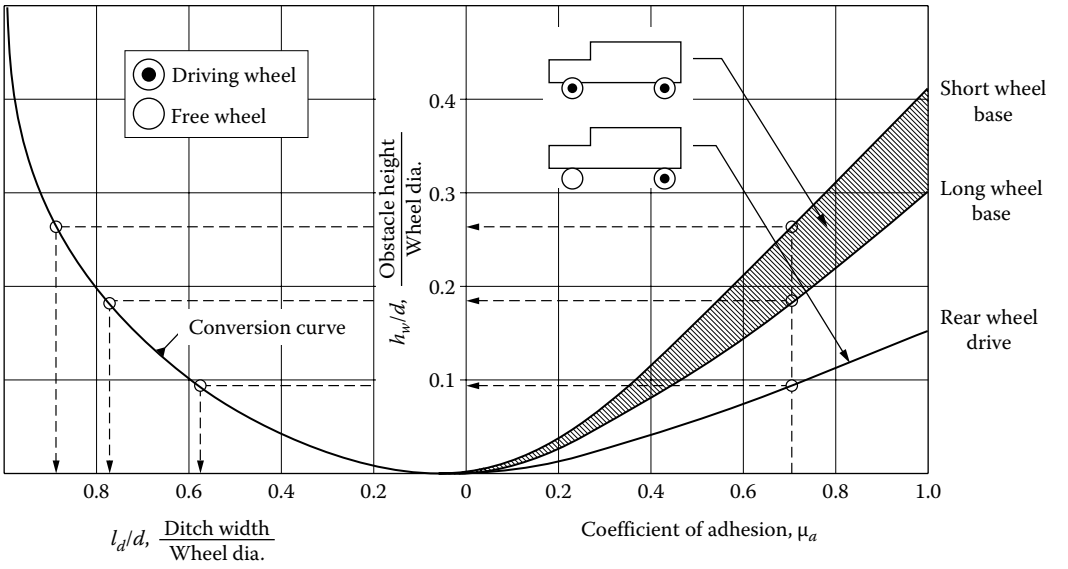

FIGURE 12.34 Step overcoming with parameters μ_a in situation A and ditch overcoming with l_d/d. (Reproduced and modified from Bekker, M.G., *Theory of Land Locomotion*, University of Michigan Press, Ann Arbor, MI, 1956.)

It is very useful to compare the various vehicle parameters by using the h_w/D relationship.

$$\left(\frac{h_w}{D}\right) = \frac{1}{2}\left\{1 - \frac{1}{\sqrt{1+\mu_a^2\left[(s_1/s)/1-(s_1/s)-(\mu_a D/2s)\right]}}\right\} \tag{12.25}$$

Crossing a ditch with the width l_d and a wheel diameter D leads to a similar situation as described in Figure 12.34 and Equation 12.26. The geometrical relationships between l_d/D and h_w/D are

$$\frac{l_d}{D} = 2\sqrt{\frac{h_w}{D} - \left(\frac{h_w}{D}\right)^2} \tag{12.26}$$

This leads to a relationship between μ_a, respectively, l_d/D to h_w/D.

The situation B in Figure 12.35 shows the rear wheel of an all-wheel drive vehicle overcoming a step. The geometrical situation in combination with equilibrium of forces and momentums yields to the following equations:

$$\begin{gathered} W_1 + W_2\sin\alpha + \mu_a W_2\cos\alpha - W = 0 \\ -\mu_a W_1 + W_2\cos\alpha - \mu_a W_2\sin\alpha = 0 \\ -W_1 s\cos\beta - \mu_a W_1\left(\frac{D}{2} - h_w\right) - \mu_a W_2\left(\frac{D}{2}\right) + W[(s-s_2)\cos\beta - h_0\sin\beta)] = 0 \end{gathered} \tag{12.27}$$

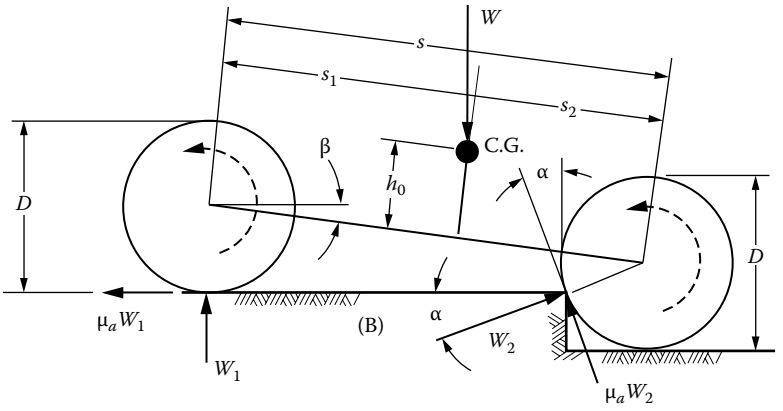

FIGURE 12.35 Two-axle vehicle 4 × 4 encountering a step in situation B. (Reproduced from Bekker, M.G., *Theory of Land Locomotion*, University of Michigan Press, Ann Arbor, MI, 1956; N.N., *Engineering Design Handbook*, Automotive Series, Automotive Suspensions, AMCP 706–356, Headquarters, U.S. Army Materiel Command, Huntsville, AL; Hohl, G.H. and Peschak, B., A model to predict the overcoming of geometrically defined obstacles by a two-axle wheeled vehicle, *13th International ISTVS Conference*, TU München, Munich, Germany, 1999.)

Solving the Equations 12.27 yields to the following implicit relationship:

$$\left[\left(\cos\beta-\mu_a\sin\beta\right)+\frac{\mu_a D}{2s}\right]\sin\alpha-\left\{\left(\frac{1+\mu_a^2}{\mu_a}\left(\frac{s_1}{s}\right)-\mu_a\right)\cos\beta\right\}-$$

$$-\left\{\left[\frac{1+\mu_a^2}{\mu_a}\left(\frac{h_0}{s}\right)+1\right]\sin\beta-\frac{D}{2s}\right\}\cos\alpha=\frac{1}{2}\mu_a\frac{D}{s}\left[(s-s_1)\cos\beta+h_0\sin\beta\right] \tag{12.28}$$

$\sin\alpha$ and $\cos\alpha$ are as before in Equations 12.19 and 12.20.

With the following relationships of Equations 12.29 and 12.30, the maximum obstacle height h_w can be determined in an iterative way:

$$\sin\beta=\frac{h_w}{s} \tag{12.29}$$

$$\cos\beta=\sqrt{1-\left(\frac{h_w}{s}\right)^2} \tag{12.30}$$

The analysis of Equations 12.28 in combination Equations 12.19, 12.29, and 12.30, shows that the effect of s_1/s is opposite when the front wheels or the rear wheels of the four-wheel-driven vehicle negotiates an obstacle. A nose-heavy vehicle with a long wheel basis will perform it better with the rear wheels than when crossing it with the front wheels. Large s/D values improve the performance of the rear, regardless of the weight distribution.

Figure 12.36 indicates the effect of weight distribution s_1/s and the height of the C.G. on an obstacle climbing ability of the front wheels (situation A) and the rear wheels (situation B). For situation A, the C.G. near to the rear wheels is better; in situation B, a nose-heavy vehicle is better.

As the location of the C.G. cannot be changed while overcoming a step, the best performance is when the C.G. is in the middle of the two axles.

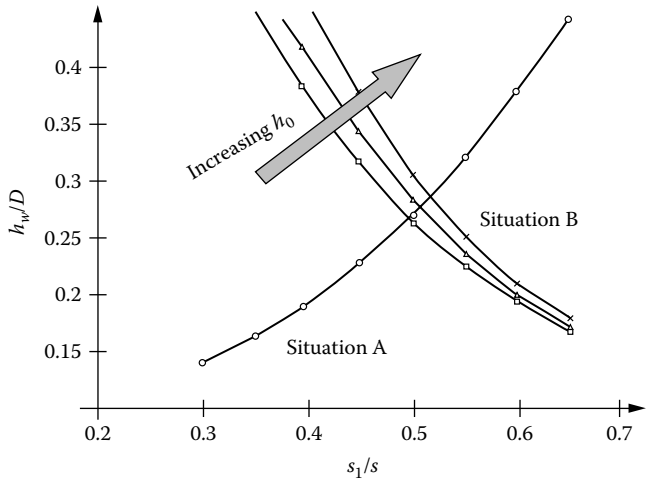

FIGURE 12.36 h_w/D in relation to s_1/s in comparison between front wheels (situation A) and rear wheels (situation B) encountering a step with a constant μ_a in situation A. (Reproduced from Hohl, G.H. and Peschak, B., A model to predict the overcoming of geometrically defined obstacles by a two-axle wheeled vehicle, *13th International ISTVS Conference*, TU München, Munich, Germany, 1999.)

12.3.2.3.3 Single and Rigid Wheel Model

Another way to approach the problem of overcoming a step is to consider only the front wheels and to summarize the traction forces F_R acting in the hub of the front wheel and coming from the rear wheels as in the case of a multi-axle vehicle [15,17].

Figure 12.37 shows the forces acting on a rectangular step at the very beginning of the overcoming. The wheel is driven by torque T_F. Force F_R is the sum of the traction forces of the rear wheels. Front axle load is W_F.

The equilibrium of forces and the torque in point A, respectively, in the center of the wheel are

$$T_F + F_R\left(\frac{D}{2} - h_w\right) - W_F l = 0 \tag{12.31}$$

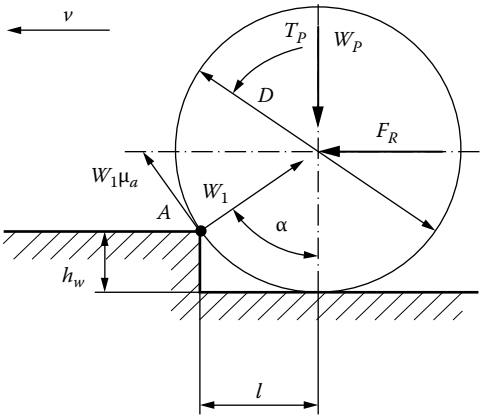

FIGURE 12.37 Single and rigid wheel model. (Reproduced from Antonov, A.S., Militärfahrzeuge Band 2, Militärverlag der Deutschen Demokratischen Republik, Berlin, Germany.)

$$T_F = W_1 \mu_a \times \frac{D}{2} \tag{12.32}$$

The sum of the forces in direction W_1 are

$$W_1 = F_R \sin\alpha + W_F \cos\alpha \tag{12.33}$$

The geometrical relationships are

$$l = \sqrt{Dh_w - h_w^2} \tag{12.34}$$

$$\sin\alpha = \frac{2l}{D} \tag{12.35}$$

$$\cos\alpha = 1 - \frac{2h_w}{D} \tag{12.36}$$

Equations 12.31 through 12.36 lead to the implicit equation:

$$W_F \sqrt{Dh_w - h_w^2} - \mu_a \left(F_R \sqrt{Dh_w - h_w^2} + W_F \frac{D - 2h_w}{2} \right) - F_R \left(\frac{D}{2} - h_w \right) = 0 \tag{12.37}$$

This rather complicated-looking equation can be solved and results in a relationship between h_w/D and the front wheel load W_F, the coefficient of traction μ_a in point A, the tractive forces coming from the rear wheels F_R, and the diameter of the front wheel D.

Equation 12.38 allows varying the different possibilities of the rear axle (e.g., multi-axle systems, different wheel loads, and different coefficient of traction on the front and rear wheels).

$$\frac{h_w}{D} = \frac{1}{2} \times \left(1 - \frac{1 - \mu_a \left(F_R / W_F \right)}{\sqrt{\left(1 + \mu_a^2 \right) \left(1 + \left(F_R^2 / W_F^2 \right) \right)}} \right) \tag{12.38}$$

The rules for a rigid wheel, described earlier, are the basis for the investigation of a flexible tire crossing a rectangular step. Taking the deformation of the tire into consideration, the forces do not act on the circumference of the ideal rigid wheel; they act as seen in Figure 12.38.

In this model, only the movements and the action and reactions of forces and momentums of the front wheel are considered. The tractive forces of the rear wheels are summarized in force F_R.

The process of crossing a step ($h_w < D/2$) by a wheel with a pneumatic tire can be divided into two stages. The movements from stage 1 to stage 2 are to be considered step by step:

$$N \sin\alpha + N\mu_a^* \cos\alpha - F_R - W_x = 0 \tag{12.39}$$

$$N \cos\alpha + N\mu_a^* \sin\alpha - W_F + W_Z = 0 \tag{12.40}$$

$$N\mu_a^* \left(\frac{D}{2} - \delta^* \right) + W_z \mu_a \left(\frac{D}{2} - \delta \right) - T_F = 0 \tag{12.41}$$

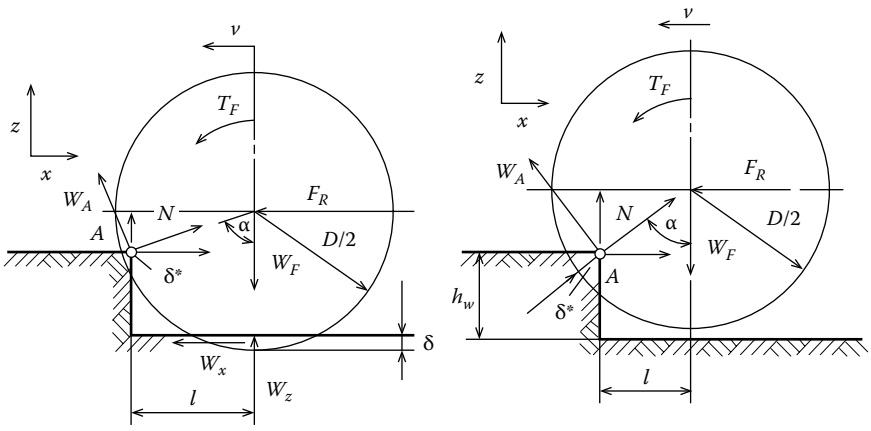

FIGURE 12.38 Single and flexible tire model. (Reproduced and modified from Ageikin, Ia.S., *Off-the Road Mobility of Automobiles*, Oxonion Press PVT. Ltd., New Delhi, India.)

where

μ_a is the coefficient of traction and the rolling plane

μ_a^* is the coefficient of traction between the tire and the edge of the step at point A

$\mu_a^* = 1,2\mu_a \ldots . - \ldots 1,3\mu_a$

$$h_w = \frac{D}{2}\left\{1 - \left[\frac{(1-(2\delta^*/D))}{\sqrt{1+((n-1)\mu_a - \mu_a^*/1-(n-1)\mu_a\mu_a^*)^2}}\right]\right\} \tag{12.42}$$

In the case of a front-wheel drive, the coefficient of traction force for the rear wheels μ_a has to be substituted by the coefficient of rolling resistance of the rear wheels μ_{aR}.

In the case of a rear-wheel drive, the coefficient of traction of the front wheels μ_a^* has to be substituted by the coefficient rolling resistance of the front wheels μ_{aF}^*.

12.4 SHOCKS AND VIBRATIONS

12.4.1 General

The surfaces over which off-road vehicles move are generally uneven because of the roughness and also because of single obstacles of the terrain. The crew and the vehicle experience more shocks and vibrations than ordinary road vehicles. Restrictions on speed can be imposed by small *irregularities* and a *wavy surface*, on the one hand, and larger obstacles, such as *bumps* and *ditches*, on the other.

Thus off-road speed is usually limited by the ability of the driver to withstand these vibrations in order to negotiate and retain adequate control of the vehicle motion (Figure 12.39).

The impact of vibrations to the crew depends on the following factors:

- Irregularities of the terrain
- Speed
- Suspension system of the vehicle
- Design of the seat

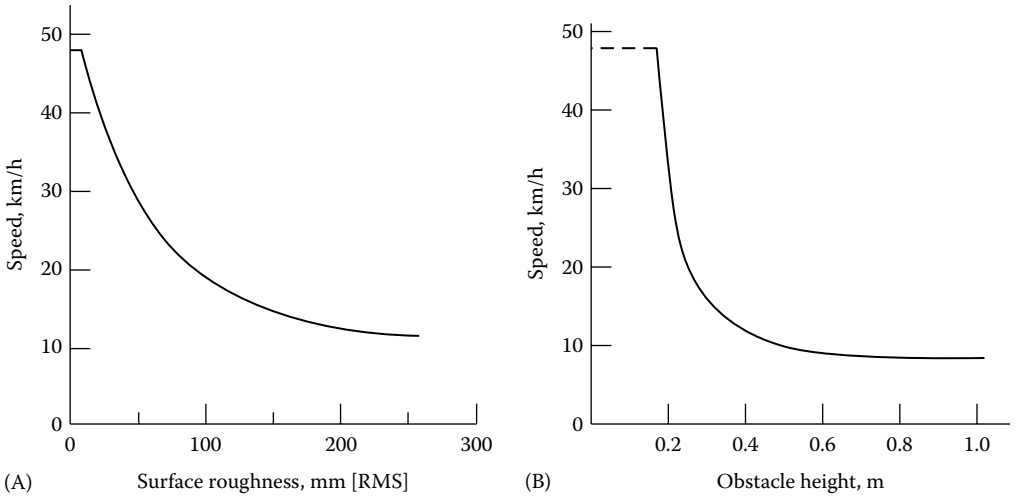

FIGURE 12.39 Speed of an MBT (A) versus surface roughness (B) versus obstacle height. (Reproduced and modified from Ogorkiewcz, R.M., *Tank Technology*, Jane's Information Group, London, U.K.)

Such developments to improve the driver seat, however, should not be at the expense of the driver's ability to "feel" the terrain. Therefore, a new definition of the term "speed" should be made:

S_{techn}: the technical speed is defined as the maximum speed that is possible from the technical performance of the vehicle and the available traction excluding the human factors.
S_{tol}: the tolerable speed is the speed that is tolerable for the crew. This speed will not be the same for all crew members.
S_{miss}: the mission speed or tactical speed of terrain vehicles should not be higher than the lowest tolerable speed for any crew member.
S_{fire}: the fire speed is the speed where a combat vehicle can successfully use the fire weapons and other equipment of the vehicle (Figure 12.40).

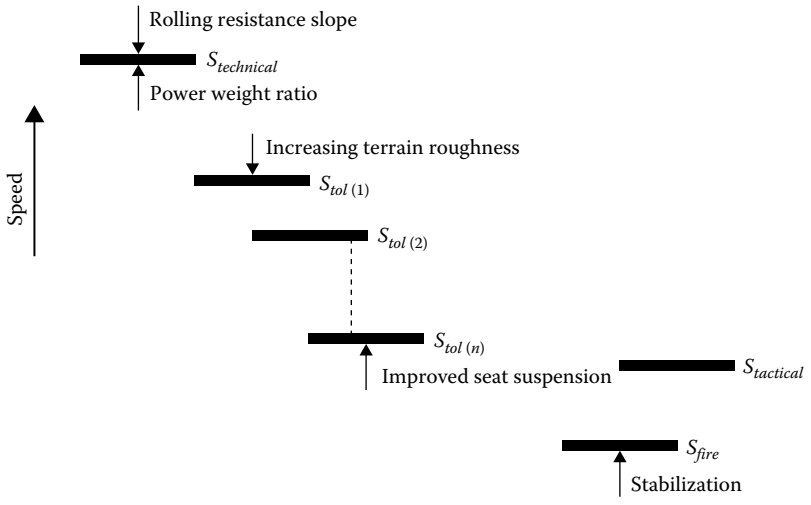

FIGURE 12.40 Speed definitions. (Reproduced from Hohl, G., Ride comfort of off-road vehicles, *8th International ISTVS Conference*, Cambridge, U.K., 1984.)

12.4.2 Human Response to Vibrations

12.4.2.1 General

The human body itself has no special sense organ to register mechanical vibrations nor does it have any specific defense mechanism to counter those vibrations. Prolonged exposure to whole body vibrations (WBV) can cause harmful physiological responses.

Both methods of investigation result in the conclusion that a human being exposed to mechanical vibrations can be affected by *reduction in comfort*, in *working efficiency*, and, in some circumstances, *health and safety.*

The reasons for human reactions to mechanical vibrations experienced by cross-country travel can be categorized into three groups. These are

- Physical effects
- Physiological effects
- Psychological effects

12.4.2.2 Mechanical Models of the Human Body (Physical Effects)

For the purpose of investigating the effects of mechanical vibrations, the human body should not be regarded as a rigid mass. Theoretical models of varying degree of complexity have been developed by several researchers to represent the human body as a mechanical system of masses, springs, and dampers (Figure 12.41).

Vibrations with frequencies below 1 Hz can also result in a general feeling of discomfort. These vibrations can cause kinetosis, or motion sickness, and the characteristics of these symptoms are quite different from those described earlier. Human reactions to vibrations below 1 Hz depend on a large number of external factors, for example, age, sex, vision, activity, and unpleasant odors (Table 12.2).

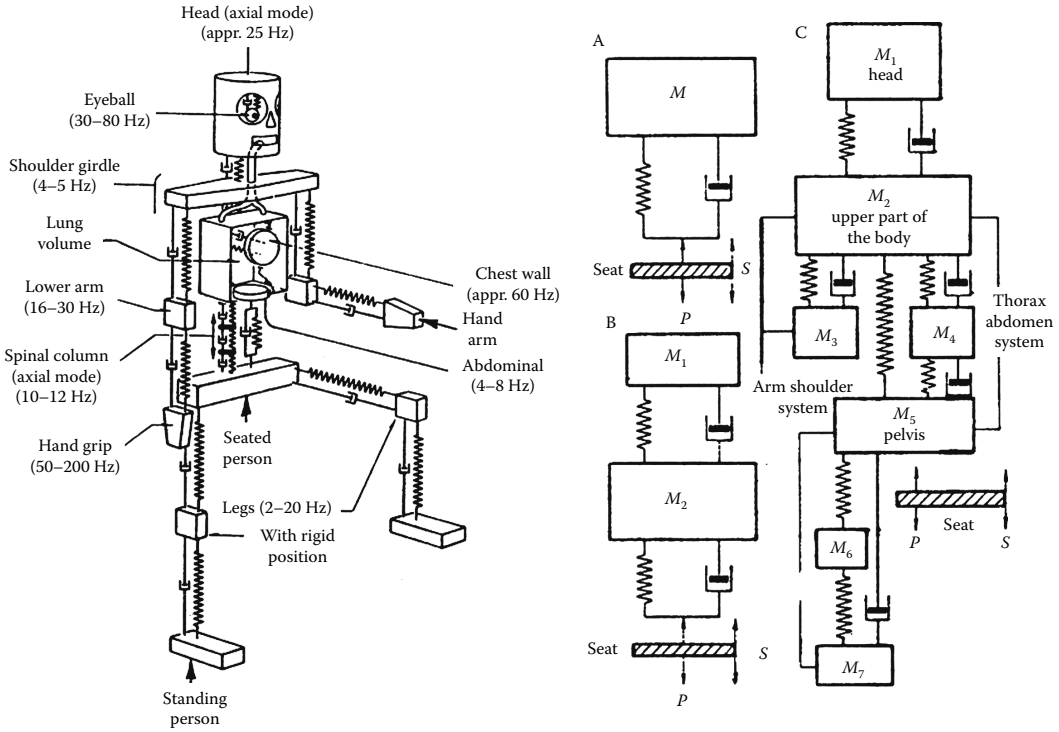

FIGURE 12.41 Mechanical substitute systems for the human body. (Reproduced from Hohl, G., Ride comfort of off-road vehicles, *8th International ISTVS Conference*, Cambridge, U.K., 1984.)

TABLE 12.2
Physiological Symptoms Dominate in the Range of 1–20 Hz

Symptoms	Frequency
General feeling of discomfort	4–7
Difficulties in breathing	2–4
Headache symptoms	13–20
Abdominal pains	4,5–10
Speech disorders	13–20
Urge to urinate	10–18
Lump in the throat	12–16
Chest pains	5–7
Increased muscle tension	4–9
Lower yaw symptoms	6–8

12.4.3 Test Methods, Recommendations, and Standards

Many investigations have attempted to measure the subjective reactions to objective measurable vibrations and to develop methods for quantitatively describing short- and long-term effects of vehicle vibrations on occupants of terrain vehicles.

None of the methods is really satisfactory for off-road rides, as the criteria were developed for "boulevard" rides. The crew of off-road vehicles expects a harsh ride. Though the results vary in some cases, they still coincide with the fact that the subjective perception is a function of frequency. One problem is that the human reactions to WBV differ from person to person and that human beings cannot remember the intensity of vibrations very well.

Over the years, numerous ride comfort criteria have been proposed.

Two of these criteria are mentioned:

- "rms" acceleration criteria
- "Absorbed power" criterion

The test persons were subjected to a pair of sinusoidal vibration stimuli of the same frequency. All following stimuli are more intensive than the previous ones. The test person can select the acceleration in order to have the same subjective perception. All tests came to the result that the highest perception of discomfort was in the range of 4–8 Hz. This fact was the basis for the ISO 2631-1978 [31] and VDI 2057-1957 [32] standards.

In both standards, only the frequencies between 1 and 80 Hz are taken into consideration. Higher frequencies come near to the audio range and do not affect the discomfort described earlier.

Both standards put the equal sensation curves in three straight lines in a double logarithmic coordinate system and the same three criteria for the limits of human exposure to WBV (Figure 12.42):

- Preservation of comfort "reduced comfort boundary"
- Preservation of working efficiency "fatigue-decreased proficiency boundary"
- Preservation of health or safety "exposure limit"

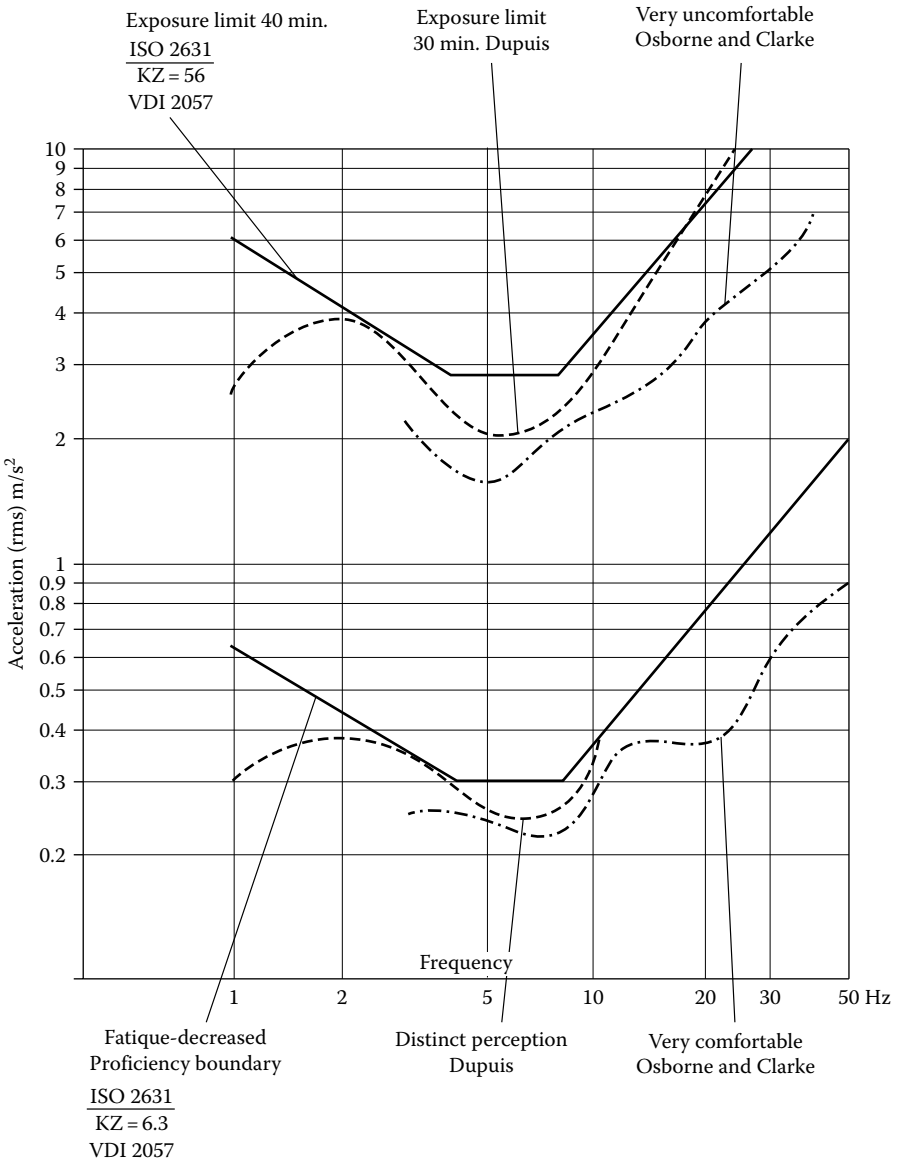

FIGURE 12.42 Equal sensation curves; comparison between standards and different research results. (Reproduced from Hohl, G., Ride comfort of off-road vehicles, *8th International ISTVS Conference*, Cambridge, U.K., 1984.)

Figure 12.43 shows clearly that the main influences on ride comfort are the speed and the surface. In all cases, the person on the rear seat of the loading platform was in the worst position.

The concept in the VDI 2057-1957 [31] and ISO 2631-1978 [32] standards was not supported by research results in laboratory tests. The modified and new standards ISO 2631-1:1997 (E) [33] and ÖNORM ISO 2631-1: 2005-11-01 [34] extend the frequency range below 1 Hz and delete the concept of "fatigue-decreased proficiency boundary" due to vibration exposure.

In the earlier-mentioned standards, methods for the measurement of periodical, random, and transient WBV are defined.

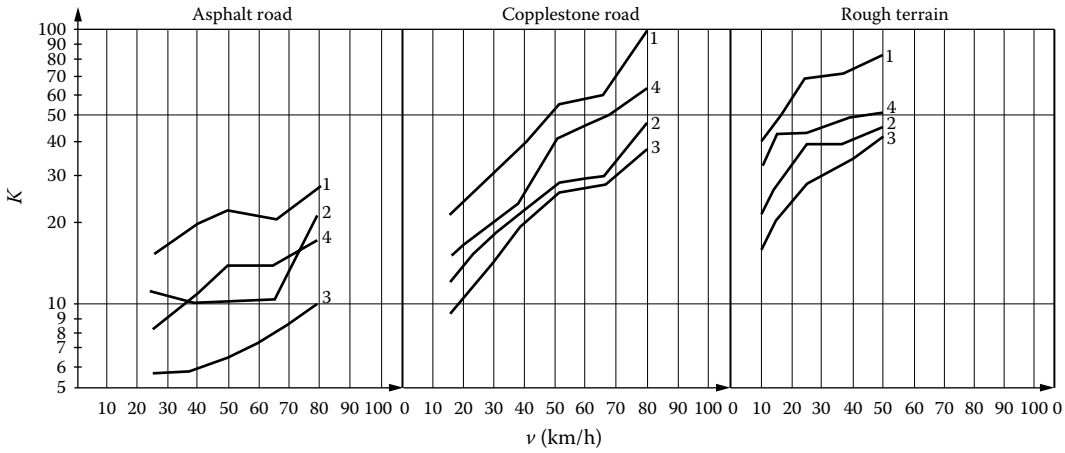

FIGURE 12.43 *K*-values depending on surface, seat position, and speed. (Reproduced from Hohl, G., Ride comfort of off-road vehicles, *8th International ISTVS Conference*, Cambridge, U.K., 1984.) Position 1: rear seat; position 2: front seat of the loading platform/commander seat; position 3: seat mount of the driver's seat; position 4: driver seat.

The frequency range considered is

- 0.1–0.5 Hz for motion sickness
- 0.5–80 Hz for health, comfort, and perception (Figure 12.44)

W_k is the frequency weightings for a sitting person in z-direction; W_d in x, y direction for a laying person; and W_f for kinetosis.

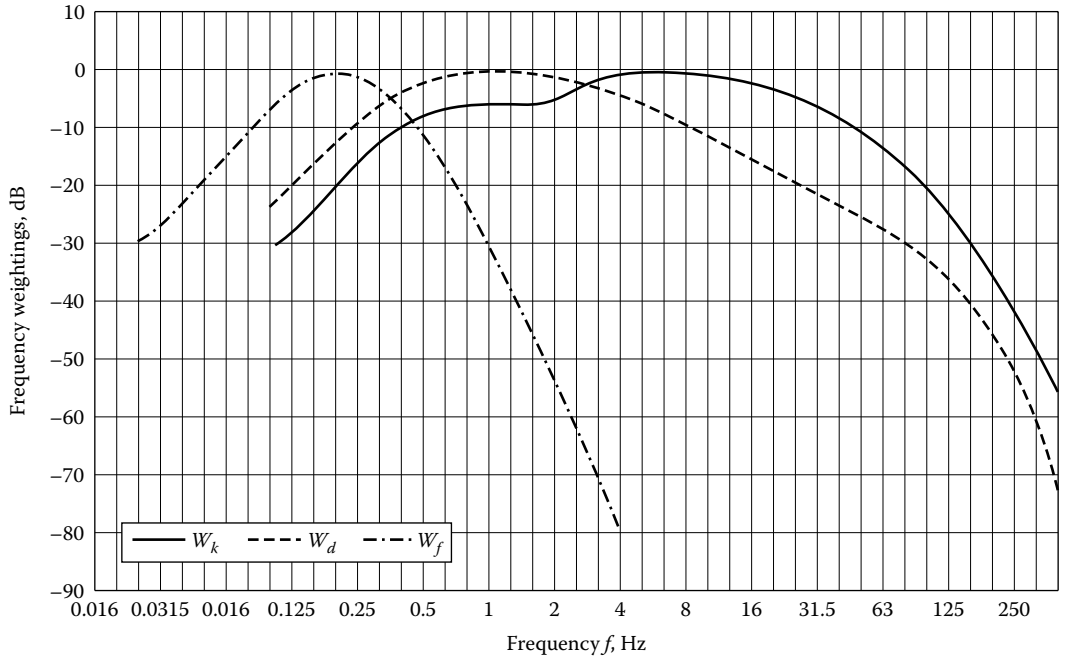

FIGURE 12.44 *K*-values depending on surface, seat position, and speed. (Reproduced and modified from Hohl, G., Ride comfort of off-road vehicles, *8th International ISTVS Conference*, Cambridge, U.K., 1984.)

12.4.3.1 Absorbed Power

The U.S. Army uses "absorbed power" to measure the level of discomfort of an occupant riding in a vehicle. Average absorbed power can be calculated if the time history of acceleration at a selected point, for example, the driver's seat, is known. The smaller the absorbed power is for a given vehicle, running over a specific profile at a certain speed, the better the vehicle ride [35,36].

The absorbed power concept offers certain advantages over pure acceleration for terrain vehicle ride quality evaluation. Firstly, it takes into account multifrequency and multiaxial vibration across a broad frequency range. Secondly, it provides proper weighting functions for all frequencies and axes according to body response.

12.5 TECHNICAL CONCEPTS

This section describes technical solutions and concepts of wheeled and tracked off-road vehicles in armored and non-armored versions.

12.5.1 Vehicle Bodies

The vehicle bodies for off-road vehicles in tracked and wheeled versions are

- Frame
- Hull

12.5.1.1 Frame

Frames used for non-armored vehicles are

- Ladder frame (Figure 12.45)
- Central tube frame (Figure 12.46)

Vehicles transporting closed van bodies and containers across terrain conditions with high obstacles have to incorporate a frame-to-body connection that could never be reached with a non-torsion-resistant frame [37,38] (Figures 12.47 and 12.48).

The cross section on the right shows an overall view of a torsionally resilient frame of an 8 × 8 terrain truck. The frame consists of two side members and several tubular cross-members that are mounted in holes in the side members and welded to their inner and outer side.

Calculations and tests have demonstrated that when lifting one wheel of a torsion-friendly frame of 1 m, the frame handles no more than 57% of total torsion contrary to the stiff frame, which

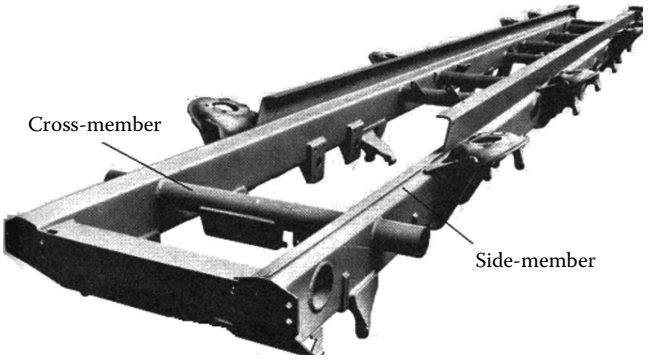

FIGURE 12.45 Conventional ladder frame. (Reproduced and modified from Klanner, R., Cross-country trucks for fast off-highway operation, *6th International ISTVS Conference*, Vienna, Austria, 1978.)

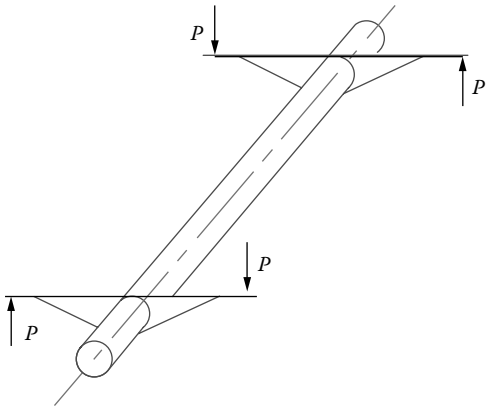

FIGURE 12.46 Central tube frame. (Reproduced from Hohl, G.H., Geländegängige Fahrzeuge, Script for the lecture at the Technical University Vienna, Vienna, Austria.)

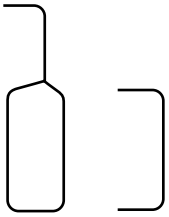

FIGURE 12.47 Closed and open side member sections of a ladder frame (left). (Reproduced from Klanner, R., Cross-country trucks for fast off-highway operation, *6th International ISTVS Conference*, Vienna, Austria, 1978.)

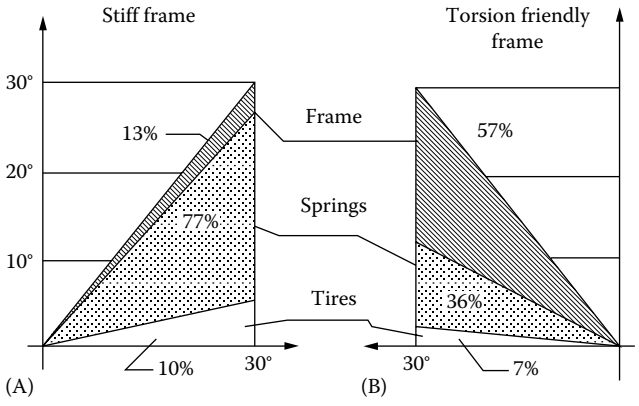

FIGURE 12.48 Deflections of a stiff (A) and a torsion-friendly frame (B). (Reproduced and modified from Hoepke, E. et al., *Nutzfahrzeugtechnik ATZMTZ-Fachbuch*, Vieweg Verlag, Berlin, Germany.)

covers 13% of the deflection. In a stiff frame concept, the springs do the main work in twisting situations. Central tube frames and *X*-frames are extremely stiff, but only the first concept is realized in practice.

12.5.1.2 Hull

The arrangement of the driveline and the design of the hull are dependent on the function of the armored vehicles. The main representatives of this type are MBTs, APC, and AWV.

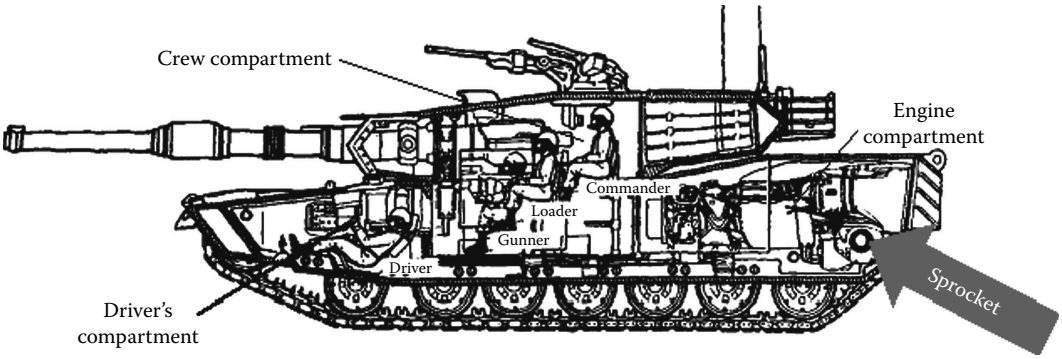

FIGURE 12.49 Space partition of an MBT (sprocket in the rear). (Reproduced and modified from Hohl, G.H., Geländegängige Fahrzeuge, Script for the lecture at the Technical University Vienna, Vienna, Austria.)

In an MBT, the engine compartment and the final drive are located in the rear. The crew compartment for the commander, the gunner, and, in some cases, the loader is in the middle and the driver is in the front part.

The task of an APC is mostly to cooperate with MBTs and to transport an armor-protected group of six to nine infantrymen. The infantrymen are located in the rear of the hull. The commander and the gunner are in the middle, and the driver and the engine–transmission block are in the front and thus the final drive is also located there.

Most of the other armored tracked and wheeled vehicles with other tasks belong to one of the two principal concepts described earlier (Figure 12.49).

The Israeli MBT "Merkava" is an exception; it can accommodate a small group of infantrymen in the rear of the tank, which means that the engine is in the front of the vehicle.

This configuration offers the advantage that there is no need for an additional APC to perform the infantry functions. Moreover, the front of the vehicle is well protected by the engine block. This MBT is a front-droop vehicle and its sight instruments are negatively influenced by the flickering hot air from the cooling system of the engine (Figure 12.50).

The most frequently used material for the hull, in order to increase its resistance to penetration by projectiles, is heat-treated and hardened steel. Aluminum armor began to develop in the United States in 1959 with the production of an aluminum-hulled personnel carrier, which became the M113, the most used APC in the world, but the latter material remained a niche product.

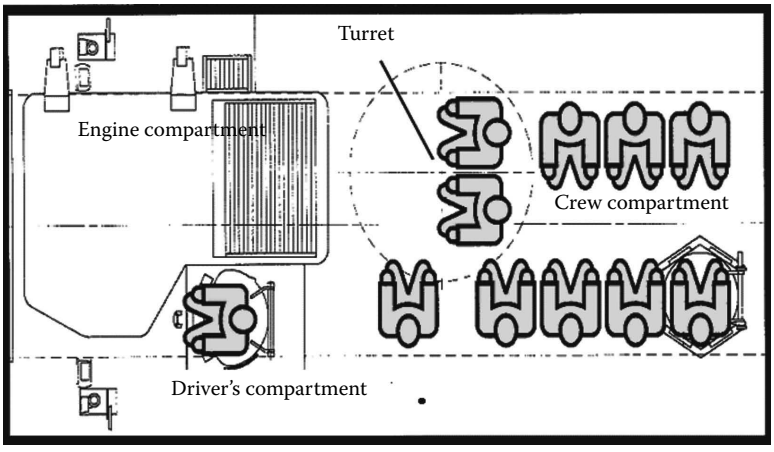

FIGURE 12.50 Space partition of an APC (sprocket in the front). (Reproduced and modified from Hohl, G.H., Geländegängige Fahrzeuge, Script for the lecture at the Technical University Vienna, Vienna, Austria.)

The advantage of a hull compared to a frame is its more rigid structure as the moment of resistance increases by the square of the distance to the neutral axis.

12.5.2 Power Train

12.5.2.1 General

The arrangement and the components of the power train differ for wheeled and for tracked off-road vehicles (Figures 12.51 and 12.52).

Wheeled Vehicles	Tracked Vehicles
Engine	Engine
Gearbox	Transmission–steering unit
Transfer case	Final drive unit
Axle differentials	Tracks
Final drive unit	
Wheels	

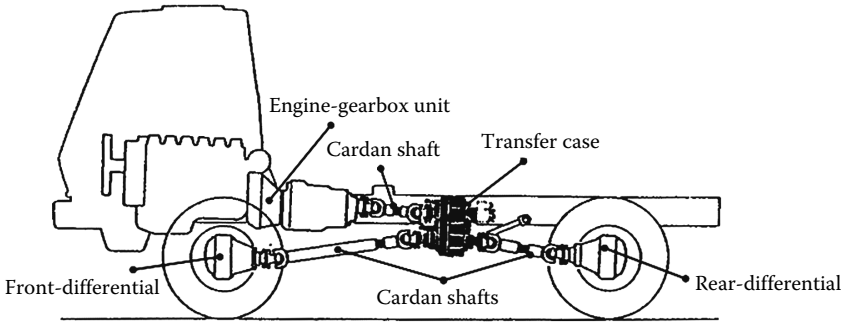

FIGURE 12.51 Conventional power train of a wheeled non-armored vehicle. (Reproduced and modified from Hohl, G.H., Geländegängige Fahrzeuge, Script for the lecture at the Technical University Vienna, Vienna, Austria.)

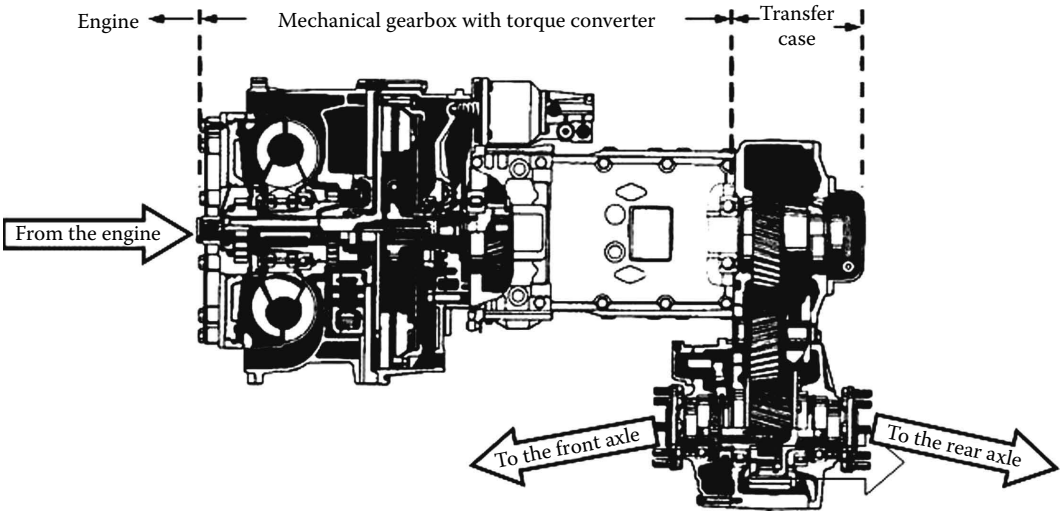

FIGURE 12.52 Engine–gearbox transfer case unit concept. (Reproduced and modified from Hohl, G.H., Geländegängige Fahrzeuge, Script for the lecture at the Technical University Vienna, Vienna, Austria.)

There are also exceptions regarding these two concepts mentioned earlier. The light military vehicle "Iltis" has no transfer case. The front-wheel drive comes directly from the gearbox. For off-road operations, there is a very low first gear speed installed. This concept requires only one cardan shaft between the engine–gearbox unit and the rear-wheel drive.

Due to the dependent connection between the engine–gearbox block, the long distance between the front axle and the front engine hood contour, the vehicle has a poor angle of approach [39].

12.5.2.2 Engine

It should be evident that acceleration increases with power-to-weight ratio, in spite of the fact that the maximum possible tractive effort is limited in all cases to the same value by the coefficient of traction. Thus, the higher the power-to-weight ratio, the lower is the required overall gear ratio, which has the threefold effect of reducing the number of gears that are necessary, of increasing the average value of the tractive effort over the speed range, and of reducing the value of the inertia mass factor, which clearly increases the acceleration.

12.5.2.2.1 Diesel Engine

The reason for the general adoption of diesels in preference to spark-ignition engines is that they increase the operating range for a given fuel tank capacity because of their greater thermal efficiency and, therefore, lower fuel consumption. For diesel engines, the injection system and enhanced exhaust gas aftertreatment are the subject of intensive research.

The actual acceleration of two typical tanks with different power-to-weight ratios is shown in Figure 12.53 in terms of curves of velocity and distance covered against time. The tank with the higher power-to-weight ratio can obviously attain a given velocity or reach a particular distance more quickly than the other.

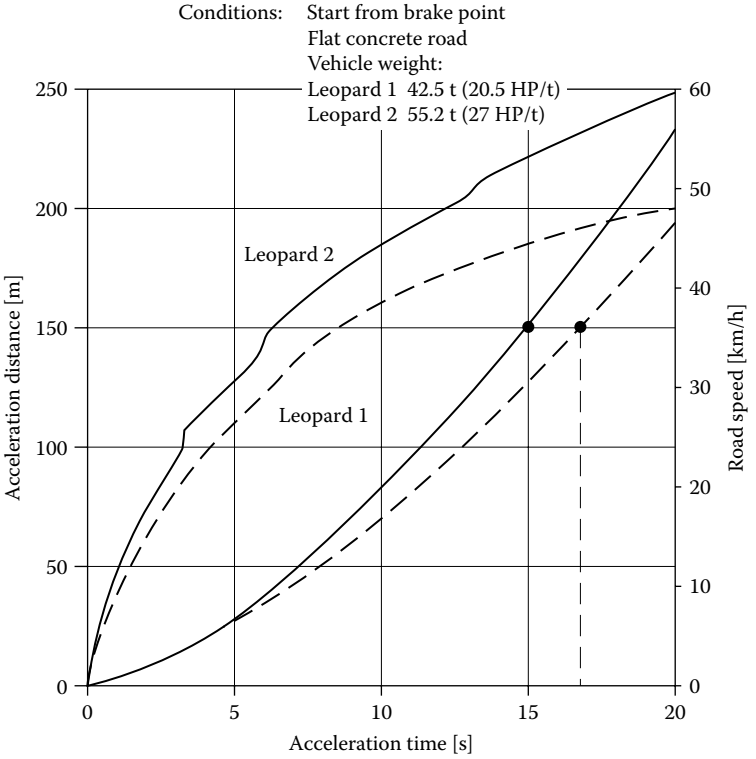

FIGURE 12.53 Tank acceleration "Leopard 1" versus "Leopard 2." (Reproduced from Ogorkiewcz, R.M., *Tank Technology*, Jane's Information Group, London, U.K.)

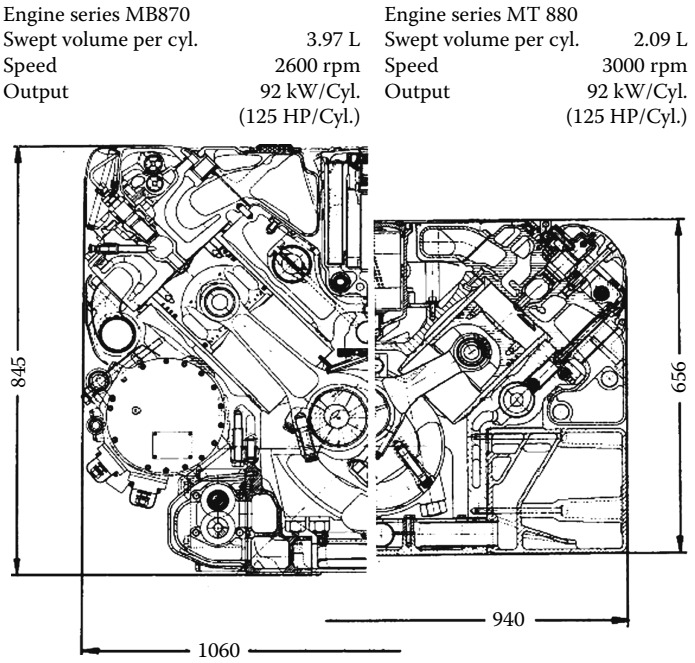

FIGURE 12.54 Comparison of the size of the MB 870 engine and MB 880 engine. (Reproduced from Ogorkiewcz, R.M., *Tank Technology*, Jane's Information Group, London, U.K.)

The situation for tracked armored vehicles is quite different, as these vehicles have limited space in their engine compartments [40–42]. Such engines are mostly based on commercial models but have to be adapted for a small volume. For these tracked armored vehicles, the engines with accessories, air-cooling and filter systems, as well as a transmission–steering system are integrated into a power pack. This power pack must be tailored to the specific requirements. Producers of engines for these types of vehicles are trying to reduce the dimensions. A good example for this trend of the downsized engine is the MTU 870 modified to the MTU 880 with the same power (Figure 12.54).

In recent years, the power-to-volume ratio kW/m^3 has improved rapidly and will presumably increase further.

Only for heavy tracked vehicles, the question arises: Diesel Engine or Gas Turbine?

Soon after "diesels" had become generally accepted as tank engines, an alternative to them began to emerge in the form of gas turbines. The advantages of gas turbines are the high specific output and the favorable torque–speed characteristics. Another advantage of the gas turbine over a conventional combustion engine with translation motion of the pistons is that the rotating motion of the turbine is transferred into another rotating motion.

The main reason that gas turbines are not more frequently used in terrain and also in other vehicles is the fact that the fuel consumption of a gas turbine in a part-load situation is very disappointing. Even under full load, the fuel consumption exceeds that of a diesel engine. The thermal process of a gas turbine needs an enormous surplus of air. This needs a bigger filter system and grill inlets, which is problematic for armored vehicles.

The low emissions of carbon monoxide and unburned hydrocarbons make the exhaust gas quality of turbines better than for diesel engines. Service intervals and maintenance requirements are positive features.

The AGT-1500 used in the U.S. MBT "Abrams" (Figure 12.55) is one of the few examples of gas turbines in vehicles (Figure 12.56).

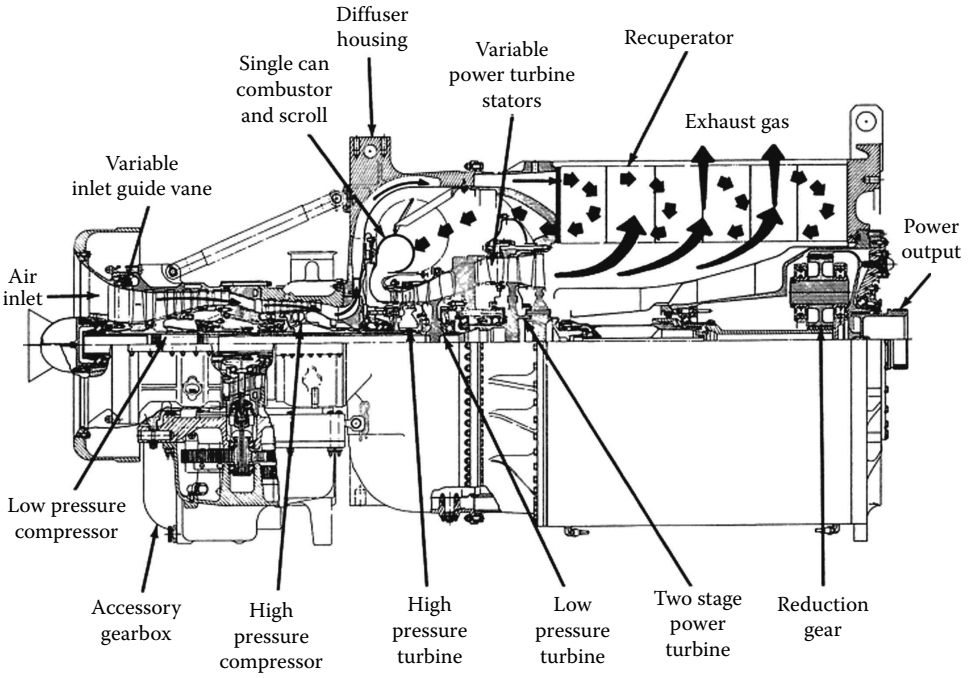

FIGURE 12.55 AGT-1500 for the U.S. MBT "Abrams." (Reproduced from Ogorkiewcz, R.M., *Tank Technology*, Jane's Information Group, London, U.K.)

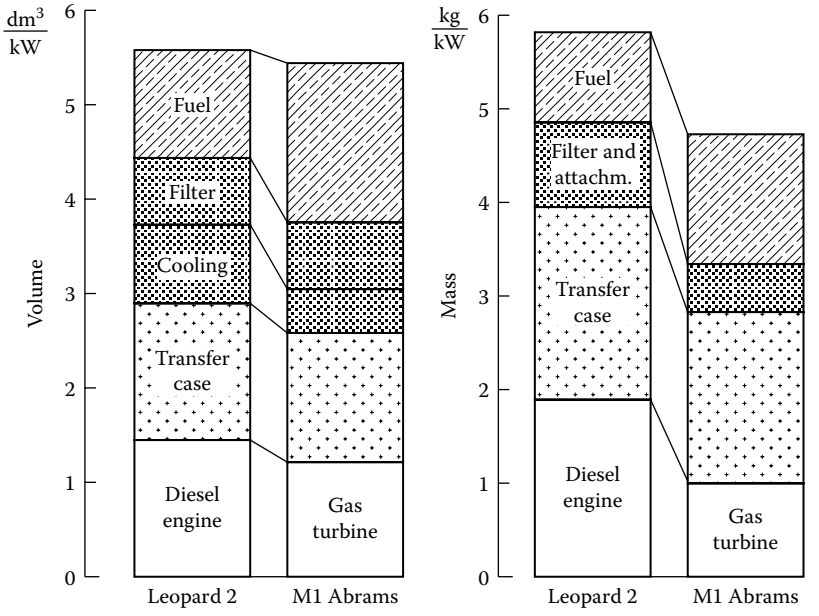

FIGURE 12.56 Differences of masses and volumes between diesel engine and gas turbine. (Reproduced and modified from Schmid, I., Grundlagen der Geländegängigkeit—Wechselwirkung zwischen Rad und nachgiebigen Boden, Vorlesung des Institutes für Kraftfahrwesen und Kolbenmaschinen der Universität der Bundeswehr Hamburg, Hamburg, Germany, 1990.)

12.5.2.3 Transmission

12.5.2.3.1 Wheeled Vehicles

For wheeled off-road vehicles of all concepts, the standard question arises whether to use a manual or an automatic transmission. Both systems are in use. However, in order to release the driver from routine functions, the number of automatic transmissions for off-road vehicles increases.

The idea of an increased number of gear steps leads to a *C*ontinuously *V*ariable *T*ransmission (CVT) [43,44]. This system, based on a metallic band used for passenger cars, is not suitable for the high torques needed for terrain vehicles. CVTs for this purpose are based on the splitting of power from the drive unit into a mechanical and a hydraulic part. Until now, this system has only been used in tractors (Figure 12.57).

The benefits of a CVT system are

- Fully automated power train from the engine to the wheel
- Smooth vehicle acceleration
- Very good efficiency of the engine as the engine speed can be adjusted independent of the vehicle speed
- No perceptible gear steps and no interruption of the power flow

12.5.2.3.2 Tracked Vehicles

Steering principles of tracked vehicles have certain unique features and are quite different from those of wheeled vehicles. Separate treatment of the steering of tracked vehicles is, therefore, required. Nowadays, there are two possible methods that can accomplish the steering of tracked vehicles. These are *skid steering* and *articulated steering*.

Skid steering is the most used method. Speed of one track is increased and that of the other is reduced, in order to create a turning movement (Figure 12.58).

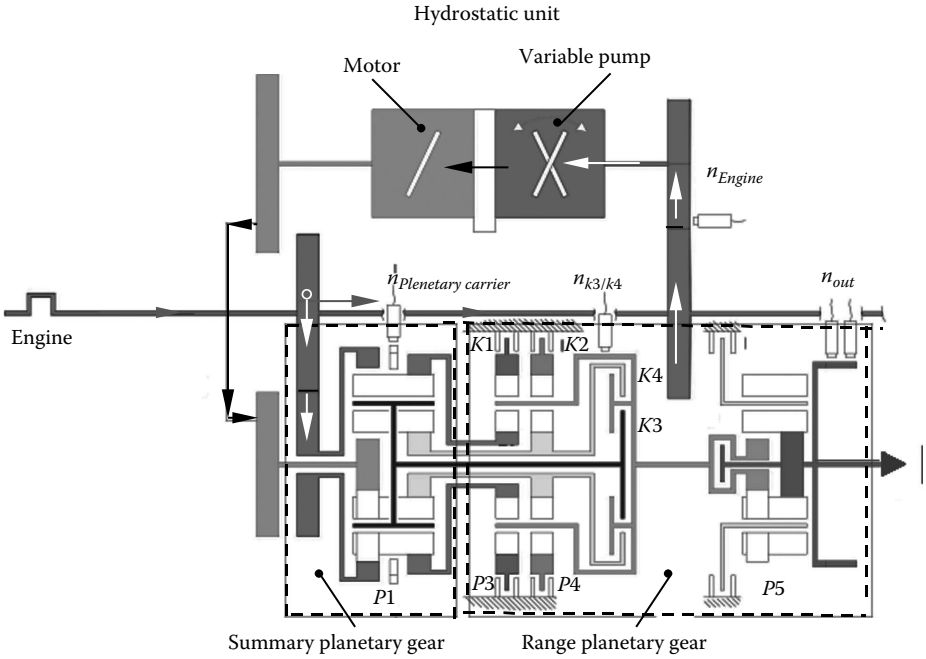

FIGURE 12.57 Mechanical–hydrostatic CVT; principle. (Reproduced from Aitzetmüller, H., Steyr S-matic—The future continuously variable transmission for all terrain vehicles, *13th International ISTVS Conference*, Munich, Germany, 1999.)

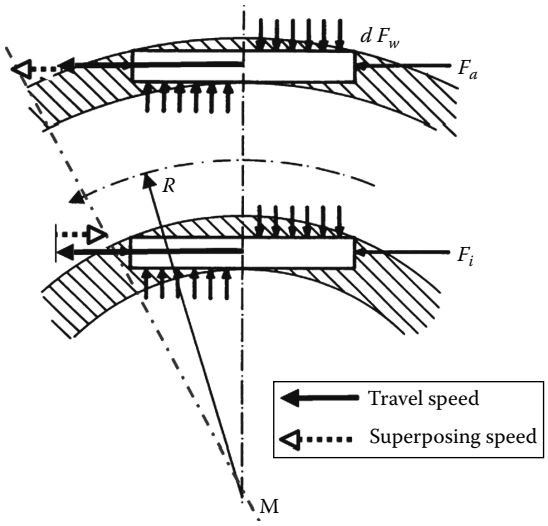

FIGURE 12.58 Principle of skid steering. (Reproduced and modified from Merhof, W. and Hackbart, E.M., *Fahrmechanik der Kettenfahrzeuge,* Leuchtturm, Germany.)

Modern steering units for tracked vehicles add an additional velocity to one track and subtract the same amount of velocity from the other. These additional velocities are done either mechanically (U.S. MBTs M47, M48, M60 [45] or by a hydraulic pump–motor unit, Figure 12.59). The final drive consists of a planetary gear assembly. The additional velocities are usually inserted via the sun wheel. An additional gear wheel on one side causes movement in the opposite directions of the left and the right track.

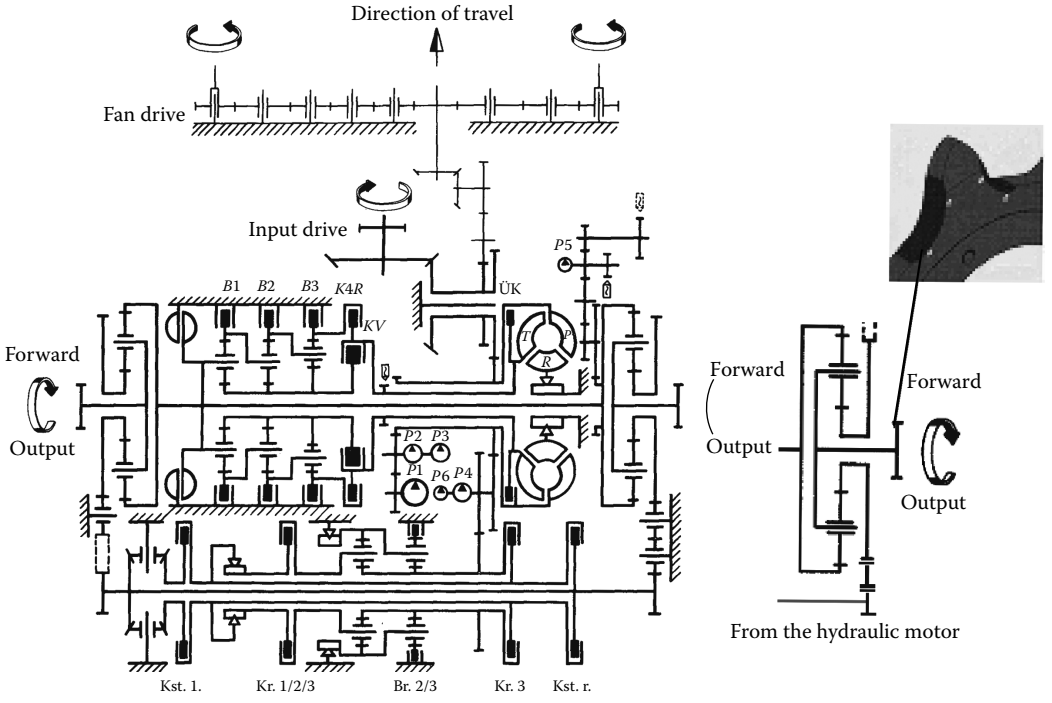

FIGURE 12.59 Transmission–steering unit. (Reproduced and modified from Hohl, G.H., Geländegängige Fahrzeuge, Script for the lecture at the Technical University Vienna, Vienna, Austria; NN, Brochure of ZF Company, Friedrichshafen, Germany.)

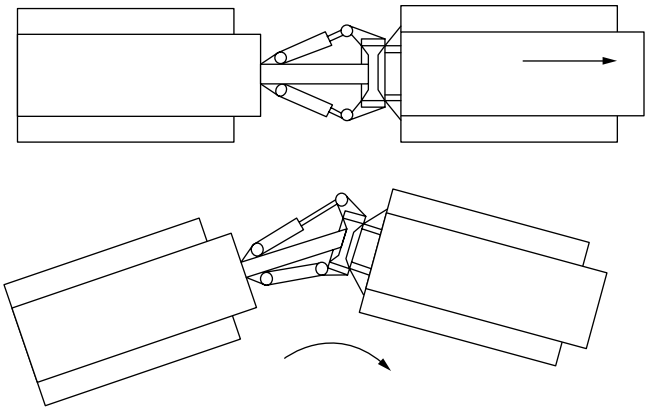

FIGURE 12.60 Principle of an articulated steering. (Reproduced from Wong, J.Y.: *Theory of Ground Vehicles*. 2001. Copyright Wiley-VCH Verlag GmbH & Co. KGaA.)

In articulated steering, turning is initiated by activating the steering joint between the two units, and no adjustment of the thrusts of the outside and inside tracks is required. Thus, the resultant forward thrust of the vehicle can be maintained during a turn. Articulated steering can, therefore, provide tracked vehicles with better mobility during turning maneuvers than skid steering, particularly over soft ground. But on the other hand, a pivot turning is not possible. The most prominent soft-skinned vehicle is the Swedish "BV 206" (see Figure 12.60).

The kinetic of skid steering is described in detail in Ref. [7].

12.5.2.4 All-Wheel Drive and Differential Locks

Both all-wheel drive and differential locks are essential elements of wheeled off-road vehicles [46]. All-wheel drive technology has established itself for the following reasons:

- To increase climbing performance
- To increase traction through full utilization of static friction
- To improve moving of traction
- To increase payload and trailer load

Two principal all-wheel drive systems are in use:

- Selectable
- Permanent

Selectable all-wheel drives can be actuated mechanically by a disc clutch for light vehicles or a dog clutch for heavy vehicles [46] with high torque. The actuation can be done either *manually* intentionally by the driver or *automatically* in the case of an electronic *A*utomatic *D*rivetrain *M*anagement (ADM) [47–50] or by a *viscous coupling.*

The transfer case has two functions:

- To distribute torque to all wheels
- To increase torque for terrain missions by a two-stage gearbox

To compensate the speed differences of the axle drives, permanent all-wheel drive systems have differentials between the axles. These can be bevel gears or planetary gear differentials.

In the case of bevel gears central differentials, the torque distribution is fixed at 50:50. With planetary gear differentials, the drive torque can be split to the two drive axles, as required, by selecting the ratio. Typical torque distribution ratios between front and rear axle are 33:66.

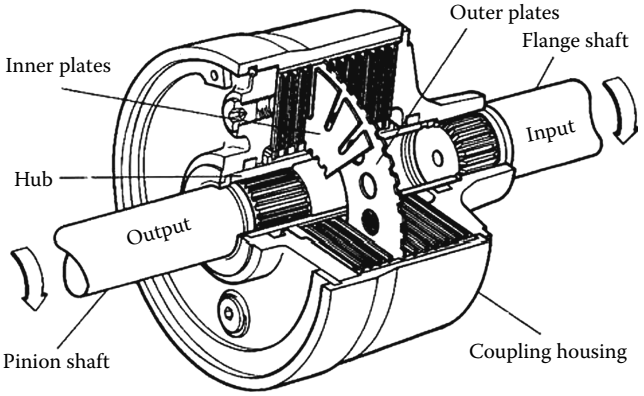

FIGURE 12.61 Viscous coupling; view. (Reproduced and modified from Braess, H.-H., *Handbuch Kraftfahrzeugtechnik*, Vieweg Verlag, Berlin, Germany.)

The use of a *viscous coupling* [51] provides another way of linking two axles, building up the coupling torque between the front and rear axles through viscous friction (slip controlled) depending on the speed differential between the front and rear axles. The viscous coupling is an encapsulated multi-plate system with high-viscosity silicon fluid and automatically distributes the torque between the front and rear axles as a function of the traction conditions at the wheels. If the speed difference is very small, only the rear wheels are driven. Should there be an increasing difference between RMS of the front and the rear wheel drive, the silicon increasingly stiffens with the result that the locking torque between the plates increases and an infinite drive is connected to the front wheels, extending as far as a rigid connection.

The level of coupling torque depends on the clutch characteristic selected. It can be influenced by the level, viscosity, and temperature of the oil (using silicon oil with low viscosity change with temperature) (Figures 12.61 and 12.62).

12.5.2.4.1 Differential Locks

The longitudinal (in the case of all-wheel drive) and transverse differentials have the function to adjust independently of each other according to the different speed of the wheels of the different axles and the difference of the speed by the left and right wheels according to the different distances travelled.

Differential mechanisms can be installed into transfer boxes (longitudinal splitting of speed and torque), as described earlier, and differentials (transverse splitting) between the wheels of one axle.

During many driving maneuvers, windup torques occur in power trains with rigid all-wheel drive, positive differential locks, or nonpositive differential locks with high lock up ratio. These self-generated torques are mainly caused by differing dynamic tire diameters, kinematic slip between front and rear

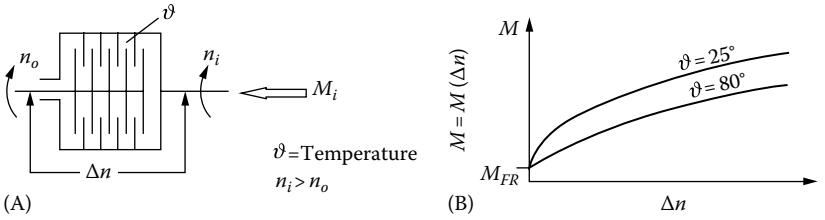

FIGURE 12.62 Viscous coupling; principle (A); torque M versus speed difference Δn (B). (Reproduced and modified from Hohl, G.H., Geländegängige Fahrzeuge, Script for the lecture at the Technical University Vienna, Vienna, Austria.)

axle during cornering, and cinematic slip between the wheels of one axle. The phenomena of self-generated torques are described in detail in Ref. [52].

In extreme off-road situations, there is a need for locking the longitudinal and transverse differentials. This can be done in different ways:

- By activating manually or automatically and by mechanical, magnetic, pneumatic, or hydraulic means and blocking any compensating action by locking the differential unit with a dog clutch. This makes the axle up to a certain degree rigid, with all the resulting advantages and disadvantages.

  The use of such a traction control system is thus appropriate where there is inadequate traction for one wheel or one axle and should only be temporary. This system needs a dog clutch.
- By using mechanical self-locking differentials, which are also known as limited-slip or locking differentials. These are differentials with a compensating action that is deliberately tight and restricted by means of their mechanical abilities. This enables them to transmit torque to one wheel or axle even when the other wheel or axle is spinning because of poor grip. Locking differentials are divided into load or torque controlled and speed or slip controlled.
- By a viscous coupling parallel to the differential. (The principle of a viscous coupling is described earlier.)

The mostly used mechanical differential locks are

- Multi-disc clutch self-differential lock
- TORSEN self-locking differential
- Dog clutch (Figure 12.63)

Multi-disc clutch self-differential lock: The locking effect of a self-locking differential with multi-disc clutch relies on the torque-dependent internal friction generated in two multi-disc clutches mounted symmetrically in the differential cage. The self-locking action results from a combination of the load dependency and spring loading of the multi-disc clutches.

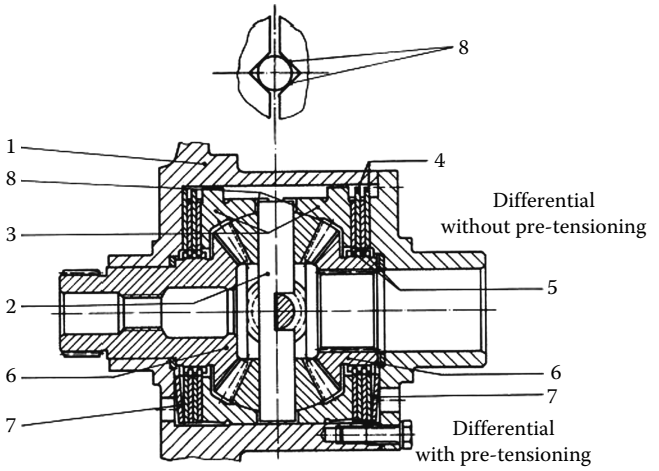

FIGURE 12.63 Limited-slip differential with prestressed multi-disc clutches. (Reproduced from Lechner, G. and Naunheimer, H., *Automotive Transmissions*, Springer Verlag, Berlin, Germany, *Anti-Wheel-Spin Systems for Road Vehicles*, London U.K., 1988.)

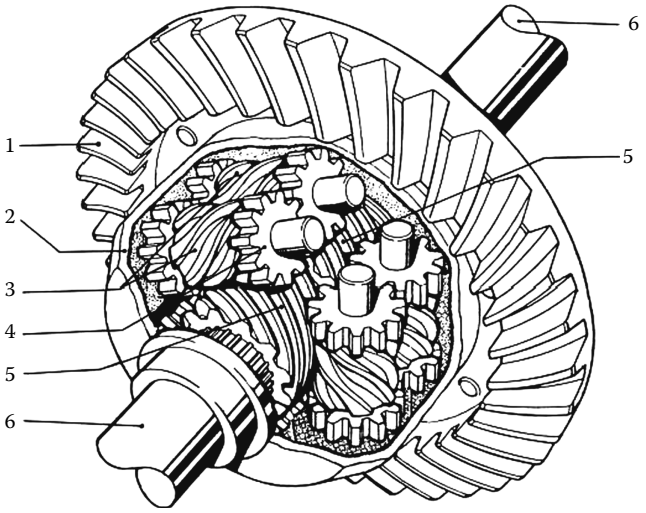

FIGURE 12.64 TORSEN self-locking differential with a worm wheel. (Reproduced from Schlechter, H.P., Design and performance of central tire inflation systems, *6th European ISTVS Conference*, Vienna, Austria, 1994.)

TORSEN self-locking differential: This kind of differential with self-locking abilities can be used for longitudinal and transverse differentials. TORSEN stands for "*tor*que *sen*sing" and is based on the mechanical properties of a worm and bevel gear interaction. The principle is described in detail in Ref. [53] (Figure 12.64).

12.5.2.5 Final Drive

High torque needs high volume and thus weight for gear reductions and shafts. Therefore, the intention of a designer of an off-road vehicle is to go through the vehicle with as low torques as possible but at the end of the power train, high torque is needed to overcome all the resistances of a terrain travel. Therefore, many off-road vehicles have an additional gear reduction in the final drive unit. There are two solutions available:

- Spur gear hub drive
- Planetary set

For soft-skinned wheeled vehicles, spur gear drive reduction can also be used for portal axles (e.g., "Pinzgauer" and "Unimog"). Portal axles have the advantage of an increase in ground clearance but also the disadvantage of a higher C.G. The spur gear concept is also used for tracked vehicles as the Austrian light tank destroyer "Kürassier" shows.

In the case of a planetary unit, it can be located in the hub for wheeled vehicles and for tracked vehicles in the sprocket assembly (Figure 12.65).

12.5.2.6 Tires

In off-road operations, various types of wheeled vehicles are expected to operate over a great variety of surfaces in cross-country transport [54].

During the last years, more military tasks have been transferred from tracked armored vehicles to wheeled armored vehicles, as studies show that in many cases off-road mobility can be obtained by wheeled vehicles. However, one cannot deny that a certain amount of hesitation regarding the suitability of vehicles with pneumatic tires lies in the vulnerability of the tires, as they are very often exposed to the effects of enemy attack. Therefore, military wheeled off-road vehicles are often provided with such an *emergency running* or *run-flat* system.

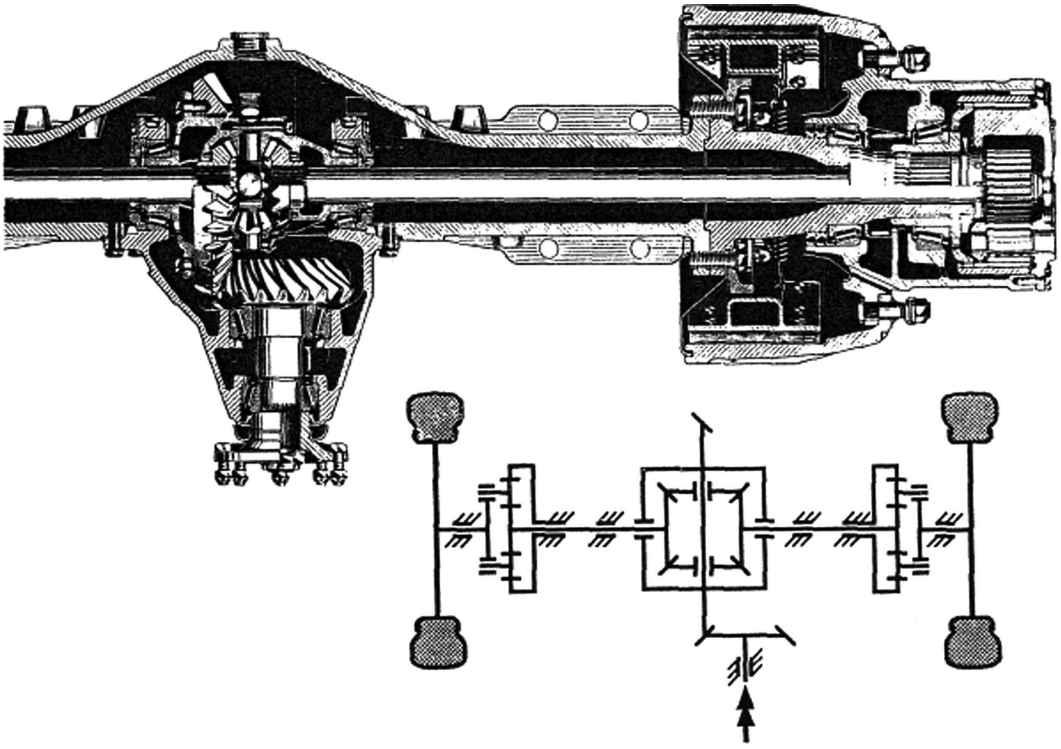

FIGURE 12.65 Final drive planetary gear for a wheeled vehicle. (Reproduced from Schlechter, H.P., Design and performance of central tire inflation systems, *6th European ISTVS Conference*, Vienna, Austria, 1994.)

12.5.2.6.1 Tire Structure

The principal tire structure of off-road tires can be divided into two main groups [7,54]:

- Bias-ply (Diagonal) tires
- Radial-ply tires (Figure 12.66)

12.5.2.6.1.1 Bias-Ply (Diagonal) Tires These tires have two or more body plies that cross at a crown angle of 40° to the center line of the tread and strengthen both the sidewall and

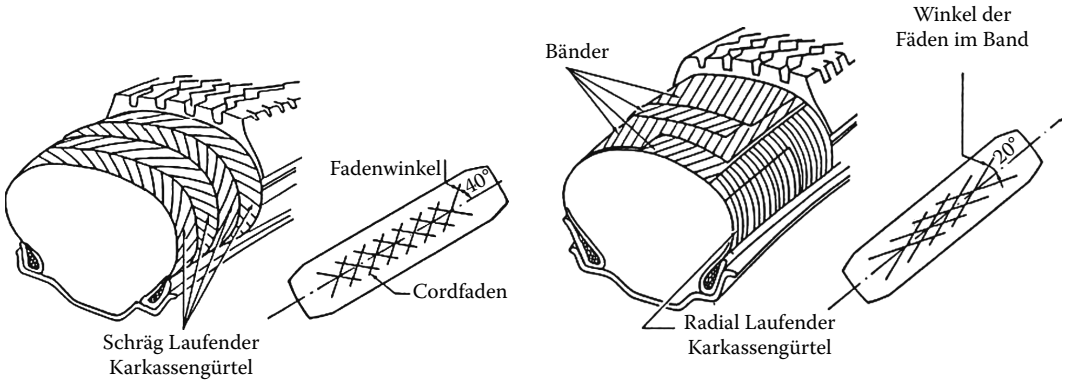

FIGURE 12.66 Tire constructions. (Reproduced from Wong, J.Y.: *Theory of Ground Vehicles*. 2001. Copyright Wiley-VCH Verlag GmbH & Co. KGaA.)

the tread area. Bias-ply tires will always have an even number of body plies because of this. A bias-ply tire usually has a rounded tread face and even at low pressures will not have any sidewall bulge [7].

12.5.2.6.1.2 Radial-Ply Tires The construction of a radial differs from a bias-ply tire: The body cords run across the tire perpendicular to the beads. Radial tires have belt plies that run almost circumferentially around the tire, under the tread, to stabilize the tread, to strengthen the tread area, and to add flexibility to the sidewall. By restricting tread movement during contact with the ground, the belt plies improve tread life.

A radial tire usually has a squared-off tread face and a distinctive sidewall bulge at the tire contact point, even with proper inflation.

While some radial tires may have "tread" on the sidewall, this tread usually has a break at the sidewall transition and the sidewall tread is very thin to minimize heat buildup from radial sidewall flexing.

12.5.2.6.2 Special Tire Systems

*T*ire *I*nflation *S*ystems (TIS) [55–57] and tires with emergency capabilities (run-flat systems) [58–60] will be standard in the future.

It is well known that one possibility to enhance the mobility on soils with limited load carrying capacity is to reduce the tire pressure. This measure helps to increase the transferable tractive force. This is due to the enlargement of the tire tread area, an improved adaptation of the tire footprint to the soil, and enlargement of the effective tire diameter and thus a reduction of the rolling resistance coming from soil compaction (Table 12.3).

The great influence of tire pressure on the transferable tractive force can be seen in Figure 12.67. A tire pressure reduction from 3.5 to 2.0 bar results almost in a duplication of the DP.

The purpose of a run-flat tire system is to allow a vehicle to be driven with one or more flat or damaged tires over a certain distance. A run-flat system is not a replacement or a substitute for a tire.

A run-flat tire is a pneumatic vehicle tire that is designed to resist the effects of deflation and to enable the vehicle to continue to be driven, depending on the type of tire, at reduced speeds (i.e., 80 km/h or 50 mph) and for limited distances.

There are two basic run-flat technologies currently available, described in the following [56]:

12.5.2.6.2.1 Self-Supporting The tire is built with stiffer side walls that can bear the weight of the vehicle even when the pressure within the tire is greatly reduced. The side walls are typically constructed using layers of rubber and a heat-resistant cord that prevent the side walls from folding or creasing. The bead around the edge of the tire is also specialized to grip the wheel rim so as to avoid becoming detached from the rim.

TABLE 12.3
Tire Foot Prints of a Tire with 24.1 kN Load

12.5.2.6.2.2 Auxiliary Supported Auxiliary-supported devices provide continued mobility in the event of partial or complete loss of tire air pressure [57–60]. Under combat conditions, these run-flat systems increase crew survivability by allowing them to complete the mission and return safely to base even if the vehicle's tires suffer complete air loss from hostile fire.

In this system, there is an additional support ring attached to the wheel that can support the weight of the vehicle in the event of a loss of pressure.

The inner tube shown in Figure 12.68 is an elastomer support ring in combination with a tubeless radial tire on airtight flat rims. Some other systems have steel rings to support the wheel load after puncture [60].

For tests, the puncture can be simulated either by perforating the tire by firing at it with rifle ammunition (five hits into the side wall and two into the tread) or by opening the valve.

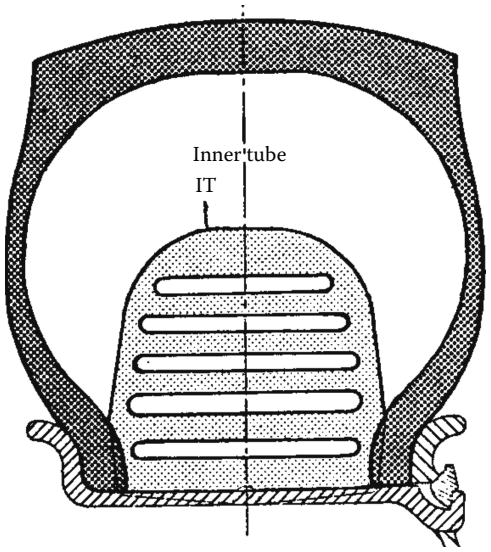

FIGURE 12.68 Auxiliary-supported run-flat system. (Reproduced from Hohl, G. and Pächter, H., Versuche an Reifen mit Notlaufeigenschaften, *FISITA Congress 1986*, Belgrade, Yugoslavia, 1986.)

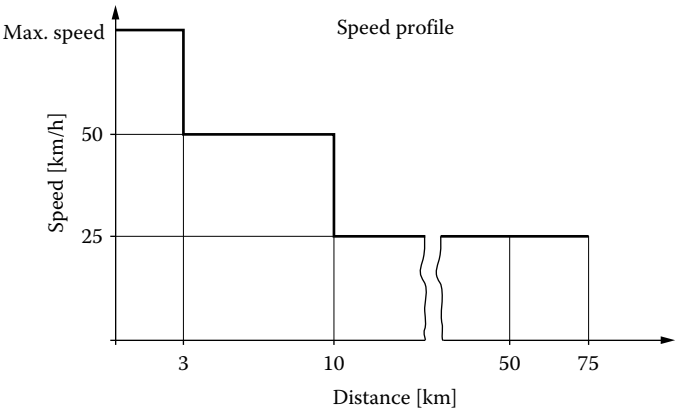

FIGURE 12.69 Speed profile for vehicle with puncture. (Reproduced from Hohl, G. and Pächter, H., Versuche an Reifen mit Notlaufeigenschaften, *FISITA Congress 1986*, Belgrade, Yugoslavia, 1986.)

Outline of the FINABEL Standard [61]

The vehicle with a puncture should be able to

1. Cover an overall distance of 50 km (preferably 75 km) with
   a. A tire still on the rim
   b. Without burning the carcass
2. Handling, steering ability, and speed of the vehicle should not be impaired excessively.
3. Distance should be covered according to the following speed profile (Figure 12.69):

The significant factors influencing the traction of a tire are *soil type* (see Section 12.3.1.1), *tire structure*, *tire diameter*, *tire width*, *wheel load*, *inflation pressure*, and *tread configuration*.

The radial tire is the most used type for passenger cars, trucks, and earthmoving machines. However, on the other hand, bias-ply tires are still in use for motorcycles, agricultural machines, and special military vehicles.

12.5.2.6.2.3 Tire Dimensions and Measurement Definitions The definitions of a tire are rather complicated, confusing, and in some cases not always logical. In this section, only principal definitions can be given. The variety of tire dimensions can be found in handbooks of tire manufacturers:

Nominal wheel diameter: Is the diameter of the rim seat supporting the tire bead. The bead-to-bead diameter is measured at the inside diameter of the tire, once mounted.
Section width: Is the maximum width of the cross section of the tire for an unloaded, mounted, and inflated tire.
Section height: Is the distance from the bead to the tread face.
Aspect ratio: Is the section height in relation to the section width, as percentage.

Tire definition:

The *first* number for a definition is the tire width (usually in inches, for smaller tires sometimes in mm).
The *second* number is the aspect ratio.
The *third* number is the nominal tire diameter (always in inches).
A radial tire is expressed by the letter R, set after the aspect ratio.

For example, a tire with the following dimension:

11/70 R 22.5: It is a radial tire and has a rim diameter of 22.5 in., a tire width of 11 in., and an aspect ratio of 70%.
Deflection δ: Is the difference between section height and loaded carcass section height.
Tread height: Is the inner tread shoulder to the outer tread shoulder.
Loaded section width: Is the section width under loaded conditions.
Tread width: Is the portion of the tread design that comes in contact with the ground.

Other measurements are

Overall diameter: Is the outside diameter of the tire when mounted and inflated but with no vehicle load.
Loaded radius: Is the distance from the wheel axle center line to the ground, drawn vertically. It is the distance from the wheel hub center line to the ground when the tire is inflated and supports vehicle weight (Figures 12.70 and 12.71).
Tire structure of terrain vehicles: An off-road vehicle requires modern radial tires with cross-country profile, which must be able to convert the output torque of the vehicle's engine into tractive effort on the ground. All off-road operations do not need the same degree of traction. As a result, separate tread designs are used for different degrees of tractive effort.

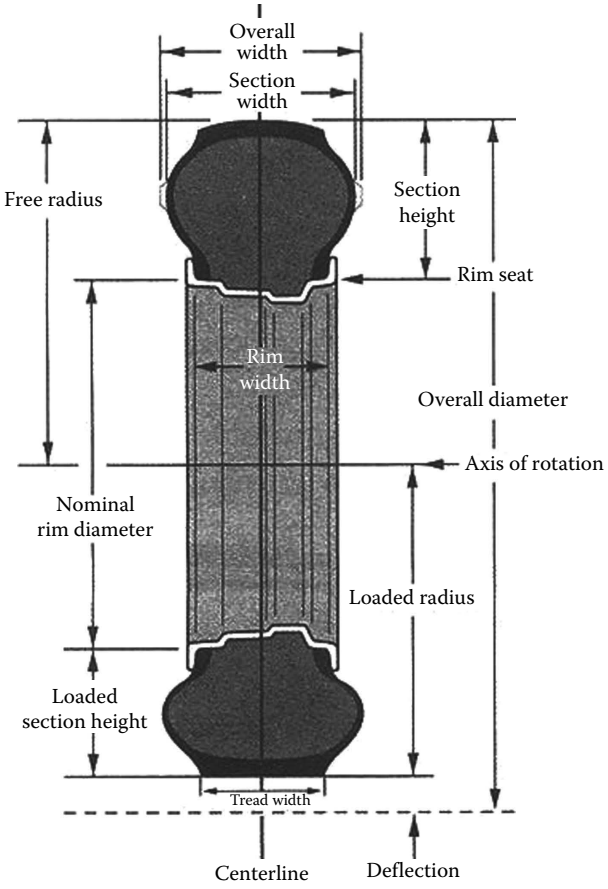

FIGURE 12.70 Tire dimensions. (Reproduced from http://www.actiontireco.com/Scripts/tiredefinitions.asp)

FIGURE 12.71 Conventional terrain tires. (Reproduced from Hohl, G.H., Geländegängige Fahrzeuge, Script for the lecture at the Technical University Vienna, Vienna, Austria.)

Off-road tires can be divided into two principal groups:

- Tires with the dimension of conventional tires but with special terrain treads
- Tires specially designed for off-road operations and with unusual dimensions (Figure 12.72)

Tire load: This influences its traction coefficient and hence its pulling capacity according to the type of soil. The traction coefficient decreases when the load on the tire is increased for loose or soft soils and increases for stiff types of soils. For certain types of soils (stiff frictional), the traction coefficient remains constant, or nearly constant, when the tire load changes for the same inflation pressure.

Tread configurations [62]: The requirements of a tread in terrain situations are to create high adhesive force in longitudinal and lateral directions with a minimum of slippage. Many efforts have been taken to predict a proper profile for wheeled terrain vehicles by computer.

FIGURE 12.72 Unconventional terrain tires. (Reproduced from Hohl, G.H., Geländegängige Fahrzeuge, Script for the lecture at the Technical University Vienna, Vienna, Austria.)

Tire treads with varying degrees of "aggressive" action have been tested to determine their direct influence on traction production. While no real analysis formulations have been derived to specifically quantify the degree of tread "aggressivity" in relation to traction production, much experience with tread design and geometry on tire performance has been gained in recent years through systematic tests.

In the construction field, as typified by dam, waterway, and highway projects that require movement of large quantities of earth and rock, tire types with high flotation characteristics and load carrying capacities are demanded.

The height of the lugs mainly affects the self-cleaning ability of the treads as well as the area of lateral ground shear on cohesive soils, which do not have an adjacent firm layer. With an increase in the height of the lugs, the area of ground shear and, consequently, the tire grip slightly increases.

The shape of the lugs influences the adhesion, self-cleaning ability, and flexibility of a tire. Due to the inclination of the supporting surface of the lugs, there is greater compaction of soils between the lugs, resulting in greater ground resistance to shear.

A *multipurpose tread* for off-road vehicles must provide for a high quality of performance, both on prepared automobile roads as well as on diverse types of soil- and snow-covered surfaces.

The principal requirements of an all-purpose tread are the absence of wheel vibrations while running on a hard surface. They should have low rolling losses on highways, good adhesion under diverse soil surface conditions, good self-cleaning ability, high structural strength, and durability under widely varying operating conditions (Figure 12.73).

The tread patterns of off-road tires are subdivided into "nondirectional" and "directional" types.

Nondirectional tread patterns

1. Combine a "checkerboard" pattern at the center of the tread band with long and sparsely dispersed transverse lugs at the sides. This pattern provides a comparatively high flexibility for the tread, smooth rolling over a hard top road, good adhesion on wet- and snow-covered roads, and a considerably higher adhesion compared to automobile tires. However, it is lower than that for off-road tires insofar as running on soft soils is concerned.
2. The "straight herringbone" tread pattern is less flexible compared to the previous one, but it provides extremely high adhesion on soft soils in a longitudinal direction. Adhesion in the transverse direction, however, is much lower. The tread has poor self-cleaning ability because of reduced flexibility of the lugs.
3. This pattern consists of triangular lugs separated from each other by longitudinal grooves. It provides high flexibility and better adhesion in the transverse direction.

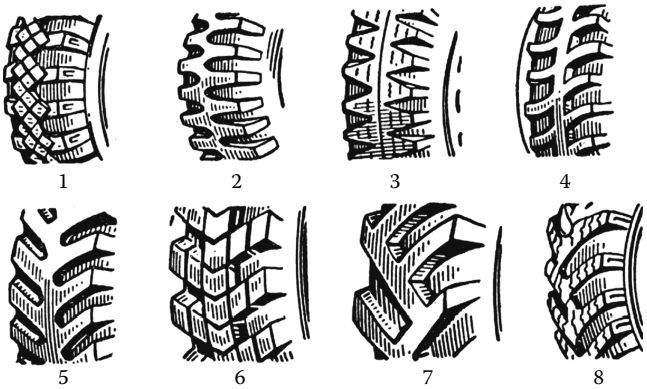

FIGURE 12.73 Tread patterns of "multipurpose" and "off-road" tires. (Reproduced from Ageikin, Ia.S., *Off-the Road Wheeled and Combined Traction Devices*, Oxonion Press PVT. Ltd., New Delhi, India.)

4. The "semi-spiral" pattern also has better adhesion in the transverse direction compared to the straight "herringbone" pattern tread. However, a lateral soil reaction component appears in the case of such a tread, which adversely affects the stability of the machine.

Directional tread patterns

5. The "herringbone with a continuous belt" at the center of the tread band is characterized by satisfactory self-cleaning and adhesive properties on soft soils. It ensures a relatively smooth ride over hard-covered roads. However, the tread is not sufficiently flexible.
6. The "disjointed herringbone" tread enhances the flexibility, reduces the rolling losses, and slightly improves the self-cleaning ability.
7. The "skew herringbone" tread pattern is similar to the tractor tread, except for a considerably larger area for the lugs with a smaller height. Such a tread pattern achieves better adhesion on soft soils compared to the herringbone pattern. However, for running on hard roads, it does not provide a smooth ride and, furthermore, the tread wear is uneven resulting in higher rolling losses.
8. The "disjointed skew herringbone" pattern is one of the most widely used tread patterns for off-road vehicle tires. The separation of the lugs by grooves increases the flexibility of the tread, reduces rolling losses, and improves the self-cleaning ability of the tire. Treads of this pattern may have either sharp or rounded shoulders.

Compared to the nondirectional treads, the directional tread pattern provides better self-cleaning ability and tire–soil adhesion over soft soils both in the longitudinal and transverse directions, when the tires are mounted in such a way that the vertex is pointed in the direction of rotation.

12.5.2.7 Tracks

Tracks have two basic functions:

1. To spread the load acting from the road wheels, to prevent sinking in soft soil
2. To transmit tractive effort generated by the engine

Tracks of armored and soft-skinned vehicles can be divided into

1. Band tracks
2. Segmented tracks
   a. One-pin track
   b. Two-pin track

Both types have a *rubber-coated* pattern or are equipped with *removable pads*. Now a new two-pin track is on the market, in which the sprocket has a toothing connection with the main body, like a one-pin track. This concept makes the track lighter and cheaper (Figure 12.74).

Band tracks are only in use for very small tracked vehicles like snow mobiles. However, there is now a trend to use this type also for heavier tracked vehicles up to 20 t. The limit for these endless one-piece molded tracks could be 30 t vehicles. Band track is a high-performance, low-maintenance alternative to the segmented metal track traditionally used for tracked combat vehicles.

A *segmented track* consists of pin-jointed steel elements.

In the case of a one-pin track, two chain elements are connected by a dry bearing pin. The sprocket drives the track via the steel casting main body. The disadvantage of this type is rattling noise and the short lifespan due to the dry bearing.

Several attempts have been made to improve the dry pin type of tracks like lubricated pins or needle bearings, but all these attempts were not successful.

FIGURE 12.74 Band track for an APC. (Reproduced from Hohl, G.H., Geländegängige Fahrzeuge, Script for the lecture at the Technical University Vienna, Vienna, Austria.)

Nevertheless, one-pin tracks have the advantage of being cheaper and lighter in comparison with the two-pin track (Figures 12.75 through 12.77).

In two-pin tracks, the sprocket drives the track via the end connectors. Now a new two-pin track is on the market whereby the sprocket is in connection with the main body, like a one-pin track. This concept makes the track lighter and cheaper.

12.5.3 Suspension of Wheeled Terrain Vehicles

This section provides an overview of several suspension systems for wheeled off-road vehicles and a comparison between them. Conflicting suspension requirements for off-road purposes are reviewed [63–65].

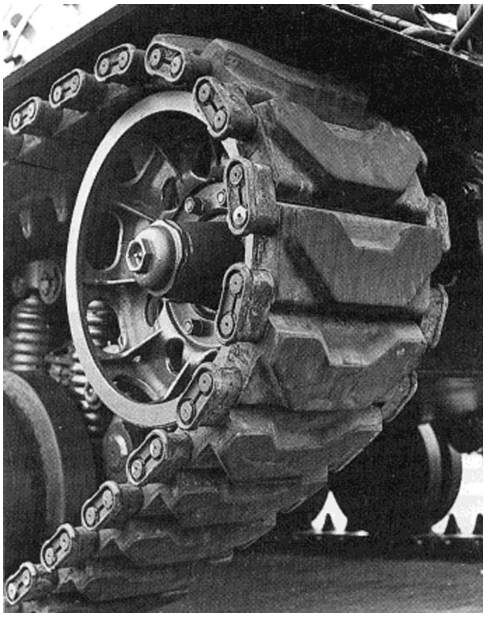

FIGURE 12.76 Rubber-coated track. (Reproduced from Ogorkiewcz, R.M., *Tank Technology*, Jane's Information Group, London, U.K.)

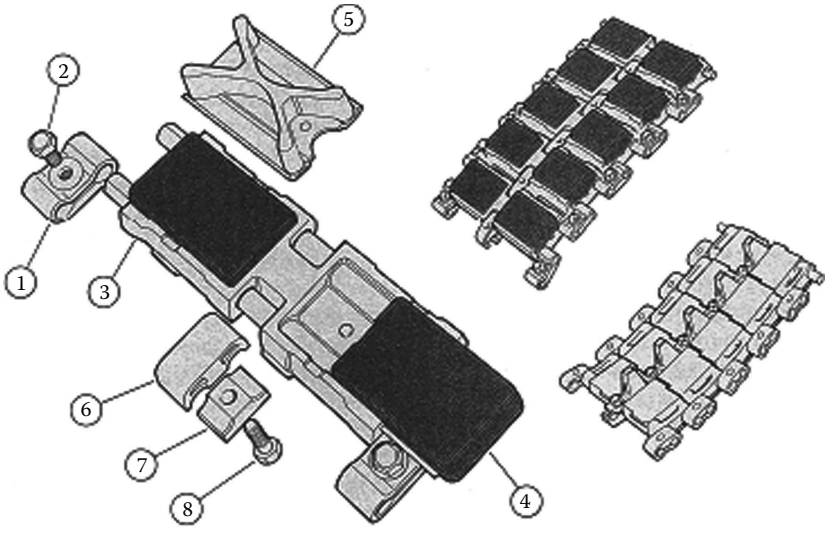

FIGURE 12.77 Diehl "system" track with removable pads. (Reproduced from Ogorkiewcz, R.M., *Tank Technology*, Jane's Information Group, London, U.K.). (1) End connector, (2) end connector bolt, (3) track link body with integral center guide, (4) replaceable rubber track pads, (5) grouser which can replace a track (for ice and snow conditions), (6) center connector, outer part, (7) center connector, inner part, and (8) center connector bolt.

The independent suspension is well established for passenger cars; however, the issue is not clear for trucks and off-road vehicles.

The mathematical models represented are based on the laws of mechanics.

12.5.3.1 General

The main consideration about suspension of wheeled vehicles is in many respects the same for armored and non-armored versions.

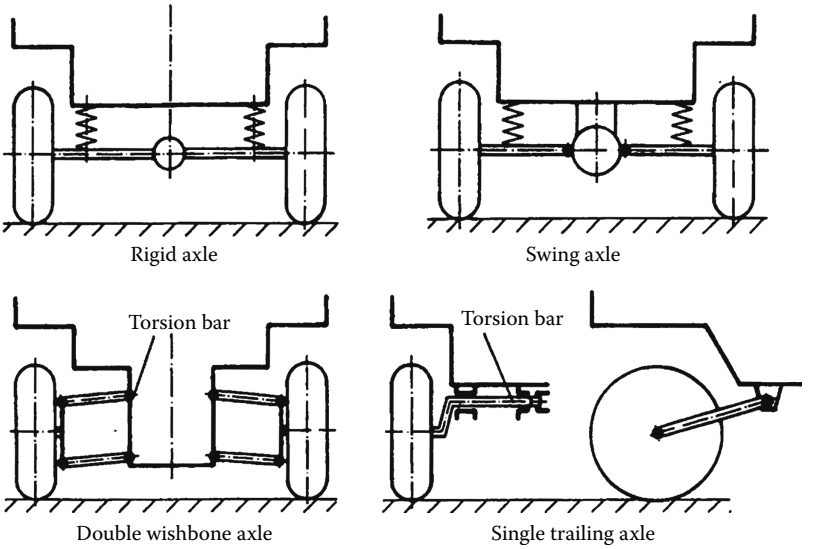

FIGURE 12.78 Main suspension systems for wheeled off-road vehicles. (Based on an idea from Klanner, R., Die Radaufhängung des geländegängigen Kraftfahrzeuges, thesis, Technical University Vienna, Vienna, Austria, 1943; Reproduced from Hohl, G.H., The influence of the suspension system on the mobility of wheeled off-road vehicles, *11th ISTVS Conference*, Lake Tahoe, NV, 1993; Hohl, G.H., An overview of suspension systems of wheeled off-road vehicles, *10th ISTVS Conference*, Vienna, Austria, 1994.)

According to the mechanical relationship between wheels, axles, springs, and the frame (hull), the suspension systems for off-road vehicles can be classified in two major categories, as in Figure 12.78:

- Non-independent types (rigid axle)
- Independent types (swing, double-wishbone, single trailing axles)

As both systems are being used successfully, it is worthwhile investigating their advantages and disadvantages. Suspension systems are examined with respect to

- Their ability to twist
- Body roll in curves and on slopes
- Wheel and steering control
- Economical, practical, and design considerations
- Overall height and configuration of vehicle bottom

The purpose of the suspension system of a wheeled vehicle is to support the weight of the vehicle, to separate the axles from the vehicle chassis, and thus to isolate the structure as far as possible from shock loading and vibrations caused by irregularities of the terrain.

Frames of modern off-road vehicles have a torsion-resistant chassis (see Section 12.5.1.1). Following this trend, the theoretical considerations of this section here are based on a rigid frame for soft-skinned vehicles and a rigid hull for AWV. When taking the flexibility of structures into consideration, methods and complicated computer models as FEM have to be used.

12.5.3.2 Non-Independent Suspension

Non-independent suspensions are characterized by rigid transverse structural members connecting the opposite wheels. With this arrangement, a vertical displacement of one wheel causes a displacement of the other wheel of the same axle.

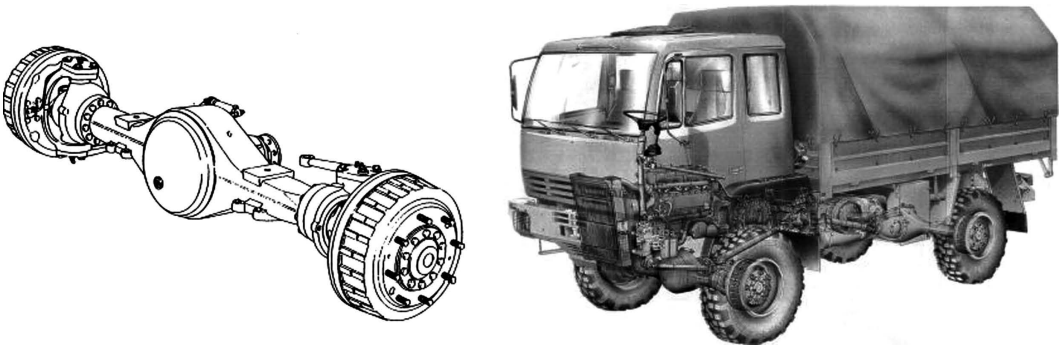

FIGURE 12.79 Medium military truck "Steyr 12M18." (Reproduced from Hohl, G.H., Geländegängige Fahrzeuge, Script for the lecture at the Technical University Vienna, Vienna, Austria.)

The non-independent category consists only of one type, the *rigid axle*, sometimes also known as the *beam axle*, which is the oldest and most widely used system (Figure 12.79).

The rigid axle system with leaf springs is one of the most commonly used suspension systems for heavy commercial and military road and off-road vehicles. The torque reactions, driving thrust, and road-induced forces are transmitted to the springs that must be rigid enough to maintain reasonable wheel and axle alignment under these conditions.

Laminated springs consist of several layers, starting with the main leaf that is supported by shorter ones.

For road vehicles these semielliptic leaf springs are usually slung beneath the axles, but in off-road vehicles they rest on the axle to permit more ground clearance.

In the past years, a special development in the quality of leaf springs has taken place. New designs and new materials have been introduced. A recent design is the so-called taper leaf spring, also known as the parabolic leaf or minimum leaf spring. In this, the number of leaves is reduced and the thickness of the single leaf is increased (Figures 12.80 and 12.81).

Laminated springs consist of several layers, starting with the main leaf that is supported by shorter ones.

For road vehicles these semielliptic leaf springs are usually slung beneath the axles, but in off-road vehicles they rest on the axle to permit more ground clearance.

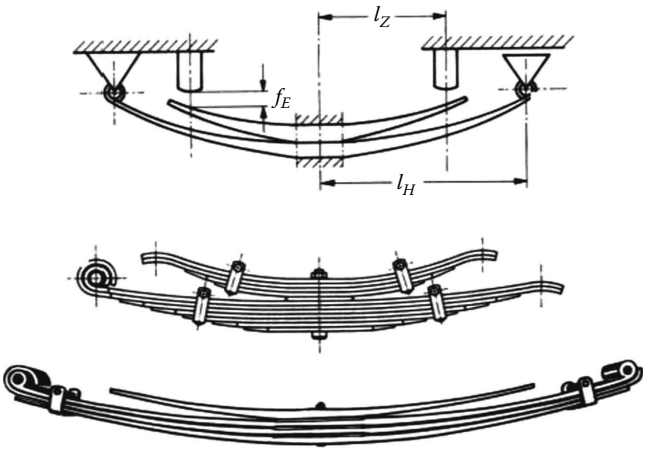

FIGURE 12.80 Leaf springs with a progressive spring characteristics. (Reproduced from Hohl, G. and Heimberg, N., The duro 4 × 4 and 6 × 6—A new concept for a family of soft-skinned and protected off-road vehicles, *EAEC 2001 Congress*, Bratislava, Slovak Republic.)

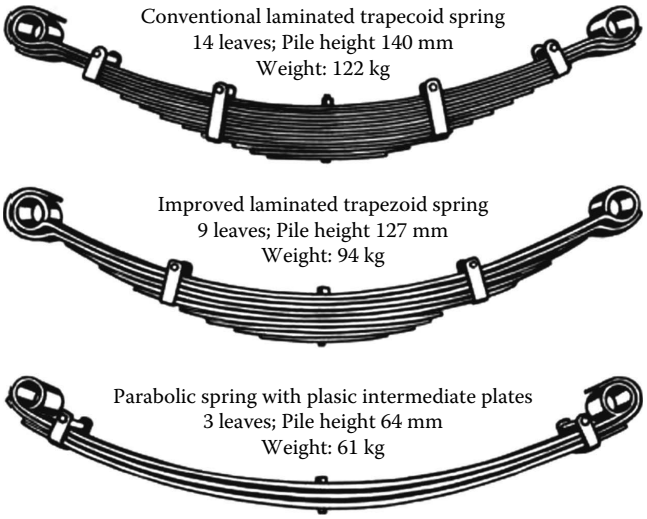

FIGURE 12.81 Leaf spring types with the same spring ability. (Reproduced and modified from Hohl, G. and Heimberg, N., The duro 4 × 4 and 6 × 6—A new concept for a family of soft-skinned and protected off-road vehicles, *EAEC 2001 Congress*, Bratislava, Slovak Republic.)

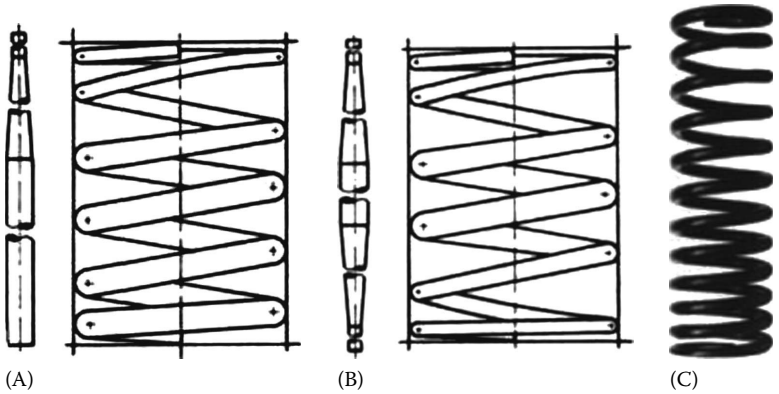

FIGURE 12.82 Coil spring types. (Reproduced and modified from Hohl, G. and Heimberg, N., The duro 4 × 4 and 6 × 6—A new concept for a family of soft-skinned and protected off-road vehicles, *EAEC 2001 Congress*, Bratislava, Slovak Republic.)

In the past years, a special development in the quality of leaf springs has taken place. New designs and new materials have been introduced. A recent design is the so-called taper leaf spring, also known as the parabolic leaf or minimum leaf spring. In this, the number of leaves is reduced and the thickness of the single leaf is increased (Figure 12.82).

The spring travel of leaf springs is limited. For extreme twisting ability and high spring travel, coil springs have to be used. One of the disadvantages with this type is the required volume for assembling. In addition, coil springs have no damping ability and no guiding ability for the axle.

Therefore, rigid axles equipped with coil springs need longitudinal control arms and transverse links (Figure 12.83).

12.5.3.3 Independent Suspension

Independent suspension is characterized by the lack of a rigid structural member to connect the individual wheels. With this arrangement, a vertical displacement of one wheel does not directly affect the other.

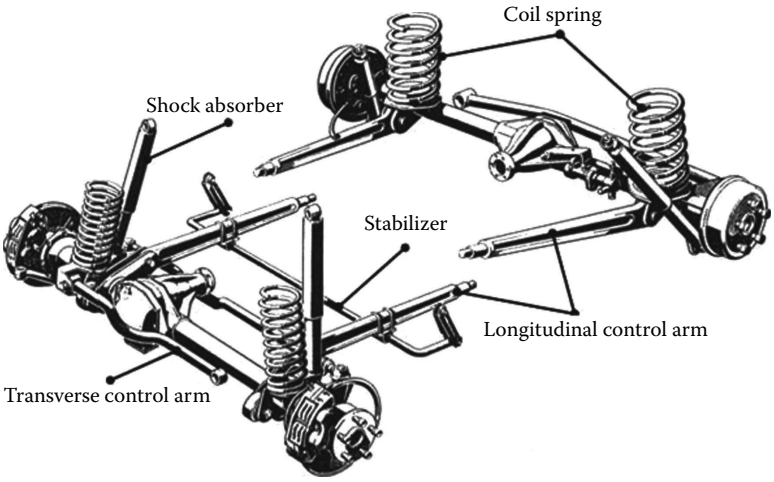

FIGURE 12.83 "Mercedes Puch G"; rigid axle with coil springs and longitudinal and transverse control levers. (Reproduced and modified from Hohl, G.H., Geländegängige Fahrzeuge, Script for the lecture at the Technical University Vienna, Vienna, Austria.)

12.5.3.3.1 Swing Axle

A rarely used but very elegant design for independent suspensions is the swing axle, which is normally used in combination with a central tube frame. Two prominent representatives with a central tube frame and swing axles are the two legendary military off-road vehicles "Haflinger" and "Pinzgauer" and the heavy Czech truck "Tatra" (Figure 12.84).

The central tube reduces additional stresses and torsion of the body caused by wheel travel when riding over rough ground or negotiating an obstacle.

On the other hand, swing axles are a special design. Hardly any commercial components can be used. The connection between axles and differential is complicated and expensive. The ground clearance varies with loading. In the new "Pinzgauer," this problem has been solved by using a pneumatic lifting system to maintain constant ground clearance.

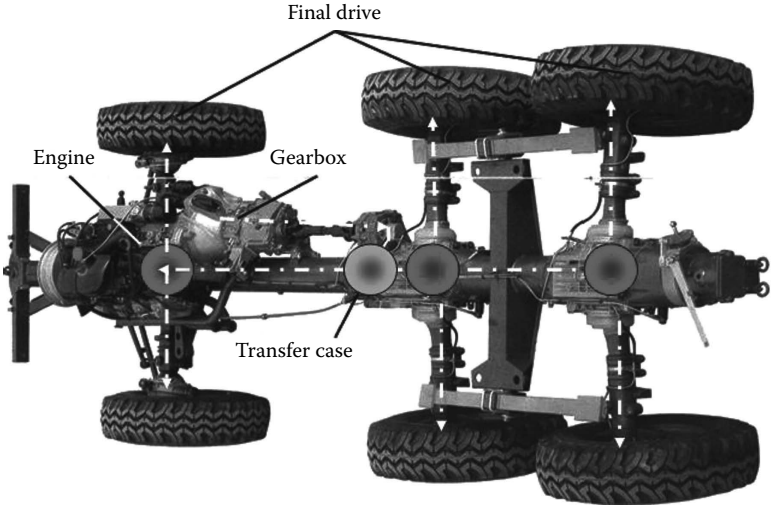

FIGURE 12.84 "Pinzgauer" 3-axle type. (Reproduced and modified from Hohl, G.H., Geländegängige Fahrzeuge, Script for the lecture at the Technical University Vienna, Vienna, Austria.)

In addition to this, contrary to a ladder frame, the body can only be mounted on special points. This fact minimizes the variability of connecting the superstructures.

In the "Tatra" concept, this problem is solved with a subframe mounted on the central tube.

12.5.3.3.2 Double-Wishbone Axle

The double-wishbone axle is a very common concept for SUV and AWV.

The principal design for independent suspensions is the double-wishbone axle with two transverse links. If the two links are of the same length, there is an exact parallel guide of the wheel (Figure 12.85).

The springs can be coil springs or torsion bar springs that are mounted parallel to the longitudinal axis of the vehicle.

In history, there are some examples of independent suspension for off-road trucks but this concept is still a niche in the segment of medium and heavy trucks.

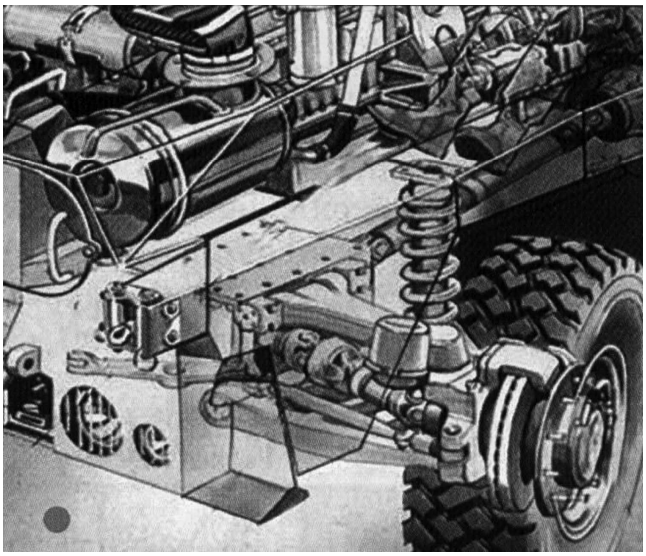

FIGURE 12.85 Double-wishbone axle of a soft-skinned military vehicle. (Reproduced and modified from Hohl, G.H., Geländegängige Fahrzeuge, Script for the lecture at the Technical University Vienna, Vienna, Austria.)

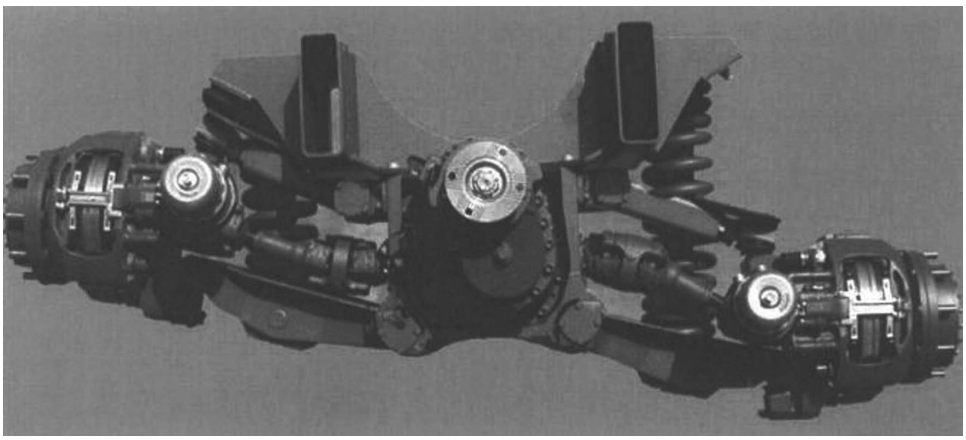

FIGURE 12.86 Double-wishbone axle concept for a heavy off-road truck; (system "Timoney"). (Reproduced from Folder of Timony Company.)

The Timoney Technology Group designs and develops independent suspension systems for a variety of vehicles for commercial and military applications, like APC, combat support vehicles, heavy transporters, and airport crash fire rescue vehicles (Figure 12.86).

12.5.3.3.3 Single Trailing Axle

The single leading or single trailing suspension has its origin in the road wheel design of tracked vehicles. The spring is usually a torsion bar that is mounted crosswise to the longitudinal axis. Therefore, trailer axles are mainly used for non-steered axles or for skid-steering wheeled vehicles.

However, there are also exceptions. The agriculture vehicle series "Reform Muli" has a steerable front axle with trailing axle principle and coil spring system.

An example of this principle is explained in Figure 12.87, the Austrian wheeled AVC "Pandur," which has a combination of a modified double-wishbone axle on the first two axles and a single trailing axle in the rear.

12.5.3.3.4 Unusual Suspension Concepts

Beside the four basic and conventional axle design principles, there are some more interesting solutions on the market (Figures 12.88 and 12.89).

12.5.3.3.5 Active Suspension

The primary function of suspension systems for off-road vehicles is to isolate the crew compartment vibrations caused by terrain irregularities and to maintain running gear contact with the ground. A conventional passive suspension system accomplishes this by using springs and constant damping rates [66–71].

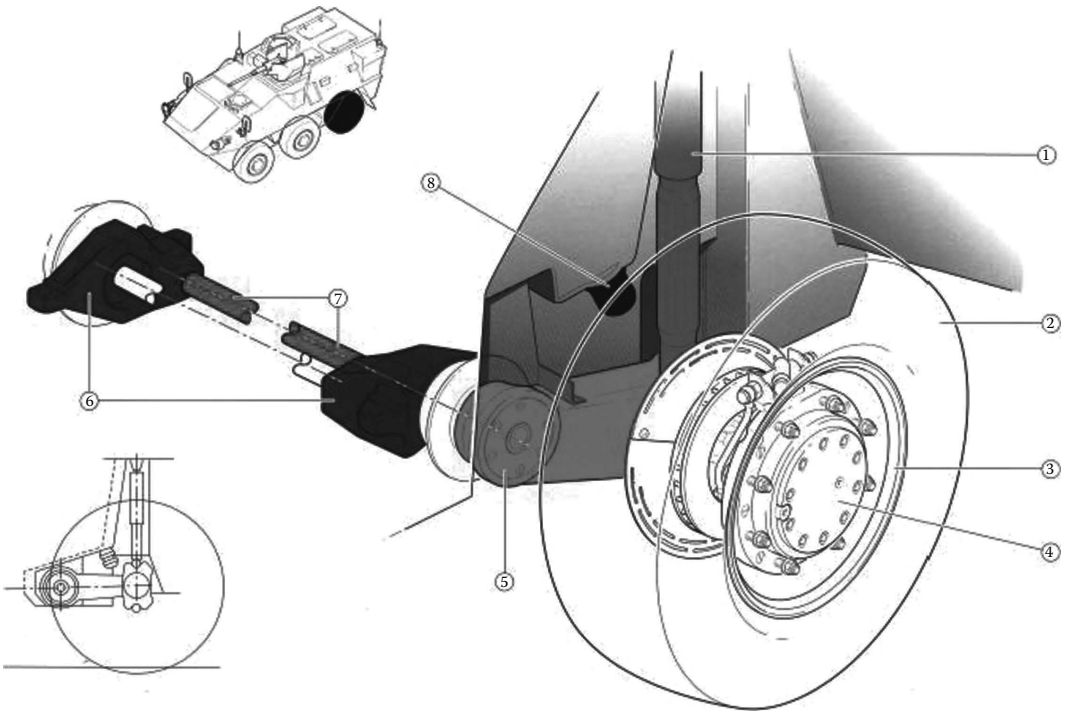

FIGURE 12.87 Single trailing axle (3 axle) of the Austrian AVC "Pandur." (Reproduced from Folder of Steyr Spezialfahrzeuge Company.)

12.5.3.4 Twisting Ability

12.5.3.4.1 General

The differences between the wheel loads ΔW_i of diagonally opposed wheels while negotiating an obstacle can be regarded as one of the indicators of off-road mobility. Equal wheel loads result in more uniform tire adhesion for the production of thrust. In the case of unequal wheel loads, the wheels with the higher load cause increased rolling resistance. The other wheels with decreasing load cause a decrease of traction.

The model used for the mathematical equations is described in Figure 12.90.

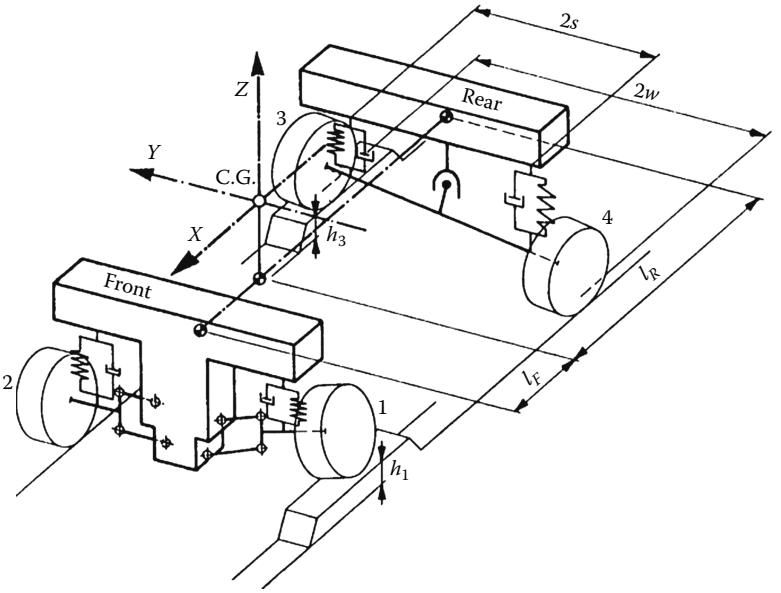

FIGURE 12.90 Basic model for twisting ability. (Reproduced from Hohl, G.H., The influence of the suspension system on the mobility of wheeled off-road vehicles, *11th ISTVS Conference*, Lake Tahoe, NV, 1993; Hohl, G.H., An overview of suspension systems of wheeled off-road vehicles, *10th ISTVS Conference*, Vienna, Austria, 1994.)

Obstacles are put in front of two diagonally opposed wheels—in this figure, the left front wheel and the right rear wheel. Then the heights of the obstacles are increased until an opposite wheel loses ground contact. The purpose of the mathematical investigations is to find a correlation between obstacle heights h_1 and h_3 and wheel load difference ΔW_i for several suspension systems.

Twisting ability h is characterized by the sum of the height (h_1 and h_3) of the obstacles.

$$h = h_1 + h_3 \tag{12.43}$$

The wheel load difference ΔW_i between before and after twisting is defined as follows:

$$\Delta W_i = W_{i0} - W_i \tag{12.44}$$

where

i is the wheel index (1–4)

0 is the situation before twisting that means the vehicle stands on a horizontal plane

The maximum twisting ability is reached when a wheel lifts from the ground.

$$\Delta W_i = W_{i0} \tag{12.45}$$

To make the different axle designs comparable, the spring characteristic is expressed by the travel of the vehicle body (φ_i) under normal load.

For the determination of φ_i for the different axle systems, the geometrical relationships of the axle design and the springs have to been taken into consideration.

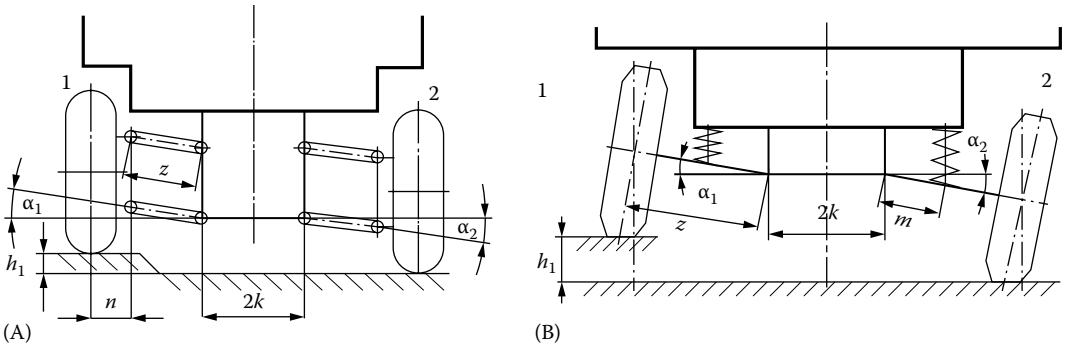

FIGURE 12.91 Double-wishbone axle (A); swing axle (B). (Reproduced from Klanner, R., Die Radaufhängung des geländegängigen Kraftfahrzeuges, thesis, Technical University Vienna, Vienna, Austria, 1943; Hohl, G.H., The influence of the suspension system on the mobility of wheeled off-road vehicles, *11th ISTVS Conference*, Lake Tahoe, NV, 1993; Hohl, G.H., An overview of suspension systems of wheeled off-road vehicles, *10th ISTVS Conference*, Vienna, Austria, 1994.)

The following equations are valid for all types of axles:

- The sum of the wheel loads are equal to the total load.

$$\sum_{i=1}^{4} W_i = W \tag{12.46}$$

- The sum of the momenta through the *X*- and the *Y*-axis is zero.
  (Only the torque through the *Y*-axis can be expressed as one equation for all suspension systems.

$$(W_1 + W_2)l_F = (W_3 + W_4)l_R \tag{12.47}$$

- The equations for the other axle systems depend on the suspension types and can be derived from the geometrical relationships in Figure 12.91.

In order to make the different axle designs comparable, the spring characteristic φ is expressed by the wheel travel under normal load, when the vehicle body is regarded as a rigid basis. A more detailed derivation of the equations can be found in Ref. [63].

12.5.3.4.2 Rigid Axle

In short, only the mathematical derivation of the equations for the rigid axle is given. First, the load of the four wheels ($W_1 \ldots W_4$) and the angles α_F and α_R are unknown.

To determine the six unknown values, six equations are available (Figure 12.92).

Rigid Axle

$$\frac{\Delta W_1}{W} = -\frac{\Delta W_2}{W} = h\frac{l_F l_R s_F^2 s_R^2}{4w_F(l_F + l_R)(l_F s_R^2 w_F \varphi_F + l_R s_F^2 w_R \varphi_R)} \tag{12.48}$$

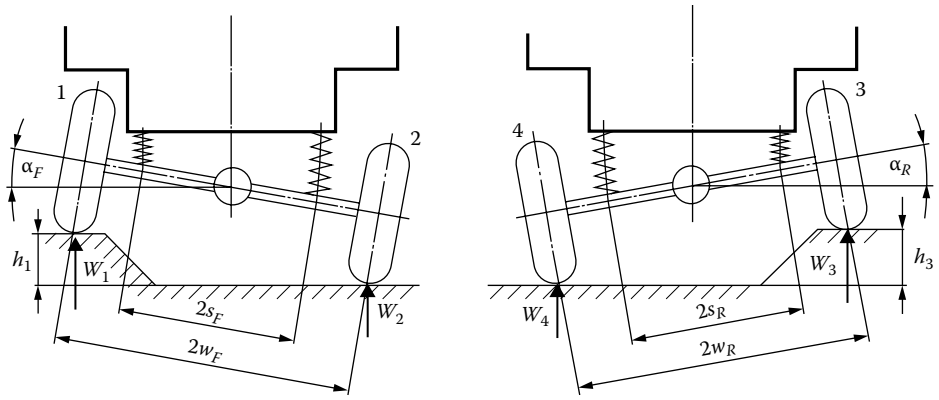

FIGURE 12.92 Rigid axle while negotiating diagonal obstacles. (Reproduced from Hohl, G.H., The influence of the suspension system on the mobility of wheeled off-road vehicles, *11th ISTVS Conference*, Lake Tahoe, NV, 1993; Hohl, G.H., An overview of suspension systems of wheeled off-road vehicles, *10th ISTVS Conference*, Vienna, Austria, 1994.)

$$\frac{\Delta W_3}{W} = -\frac{\Delta W_4}{W} = h\frac{l_F l_R s_R^2 s_F^2}{4w_R(l_R + l_F)(l_R s_F^2 w_R \varphi_R + l_F s_R^2 w_F \varphi_F)} \tag{12.49}$$

When the wheel, respectively, spring tracks w_F, w_R and s_F, s_R as well as φ_F and φ_R are the same for both axles, the equation can be extremely simplified. A further simplification is to put the C.G. in the middle between the axles:

$$\frac{\Delta W_i}{W} = \frac{h}{16\varphi}\left(\frac{s}{w}\right)^2 \tag{12.50}$$

According to Equation 12.45, the maximal obstacle heights for the front and the rear axle can be determined as

$$h_{max(F)} = \frac{2w_F(l_F s_R^2 w_F \varphi_F + l_R s_F^2 w_R \varphi_R)}{l_F s_F^2 s_R^2} \tag{12.51}$$

$$h_{max(R)} = \frac{2w_R(l_F s_R^2 w_F \varphi_F + l_R s_F^2 w_R \varphi_R)}{l_R s_F^2 s_R^2} \tag{12.52}$$

The smaller value of the two equations leads to the maximal twisting ability.

Simplifying these equations, in the same way mentioned earlier, derives to the following relationship:

$$h_{max} = \frac{4\varphi}{(s/w)^2} \tag{12.53}$$

It can be clearly seen that the maximum obstacle height increases with high φ-values (soft spring) and decreases with increasing (*s*/*w*) ratios (the spring is near to the tires).

12.5.3.4.3 Independent Suspensions

The wheel load differences of wishbone and swing axle are independent of the wheel track and spring track relationship. By setting for small values $\sin\alpha = \alpha$ and $\cos\alpha = 1$, the same equation for all three types of independent suspension can be determined:

$$\frac{\Delta W_1}{W} = -\frac{\Delta W_2}{W} = h\frac{l_R l_F z_F w_R}{4(l_F + l_R)(l_F w_R z_F \varphi_F + l_R w_F z_R \varphi_R)} \tag{12.54}$$

$$\frac{\Delta W_3}{W} = -\frac{\Delta W_4}{W} = h\frac{l_F l_R z_R w_F}{4(l_F + l_R)(l_R w_F z_R \varphi_R + l_F w_R z_F \varphi_F)} \tag{12.55}$$

With the simplifications mentioned earlier, the maximal obstacle height can be determined as follows (Figure 12.93):

$$h_{max} = 4\varphi \tag{12.56}$$

The specific wheel-load difference ($\Delta W_i/W$) is less for the rigid axle than for independent suspension systems. The wheel-load difference for the rigid axle depends on the relationship between wheel and spring track. In this diagram, the spring characteristic is equal for both front and rear axle. The maximum height (h) of an obstacle is achieved when the wheel opposite to the wheel on the obstacle loses ground contact, which occurs when the wheel load is zero.

The wheel-load differences for this kind of suspension are independent of the wheel track and spring track relationship. Usually spring track (s) and wheel track (w) are equal for both axles and the equation is easier to understand by looking at the s/w relationship (Figure 12.94).

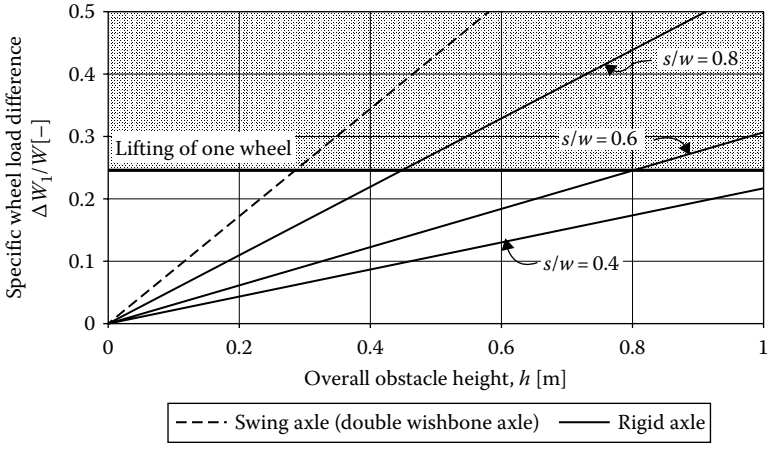

FIGURE 12.93 Specific wheel load difference versus obstacle height. (Reproduced from Klanner, R., Die Radaufhängung des geländegängigen Kraftfahrzeuges, thesis, Technical University Vienna, Vienna, Austria, 1943; Hohl, G.H., The influence of the suspension system on the mobility of wheeled off-road vehicles, *11th ISTVS Conference*, Lake Tahoe, NV, 1993; Hohl, G.H., An overview of suspension systems of wheeled off-road vehicles, *10th ISTVS Conference*, Vienna, Austria, 1994.)

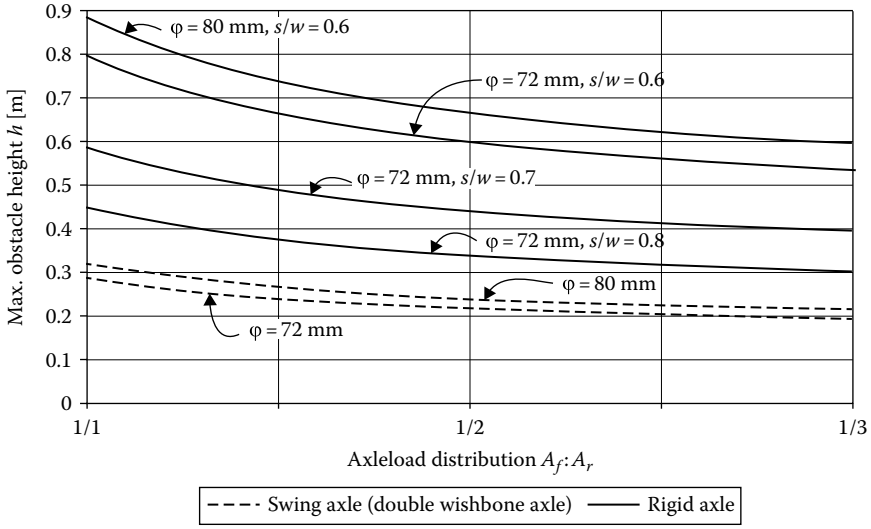

FIGURE 12.94 Max. obstacle height versus axle load distribution, spring stiffness, and axle concept. (Reproduced from Hohl, G.H., The influence of the suspension system on the mobility of wheeled off-road vehicles, *11th ISTVS Conference*, Lake Tahoe, NV, 1993; Hohl, G.H., An overview of suspension systems of wheeled off-road vehicles, *10th ISTVS Conference*, Vienna, Austria, 1994.)

12.5.3.5 Body Roll

12.5.3.5.1 General

Off-road vehicle body roll in curves and on slopes is also an important indicator for cross-country ability. The roll angle should be small. A simple method to achieve this would be to use stiff springs. However, for reasons of ride comfort and to protect both the vehicle itself and the cargo, the use of springs with stiff characteristics is not practical. Curve and slope stability are influenced by the height of the roll center. The roll center is the apparent stationary point around which the body rolls under the influence of centrifugal forces and slope components. The distance between the roll center and the C.G. is regarded as a lever for the torque exerted by roll forces and has a great influence on the roll angle.

The centrifugal force C is defined as follows (R is the radius of the curve, v is the vehicle speed, g is the gravitational acceleration) (Figure 12.95):

$$C = \frac{W}{g} \cdot \frac{v^2}{R} \tag{12.57}$$

12.5.3.5.2 Rigid Axle

The roll center 0 of a rigid axle is easy to determine and it is located in the middle of the axles and the springs. With respect to different axle loads and different wheel and spring distances, it causes a very complicated equation. Making the simplifications mentioned earlier, the following equation can be derived:

$$\alpha_c = \frac{C \cdot (h - h_f)}{(s^2/\varphi) - (h - h_f)} \tag{12.58}$$

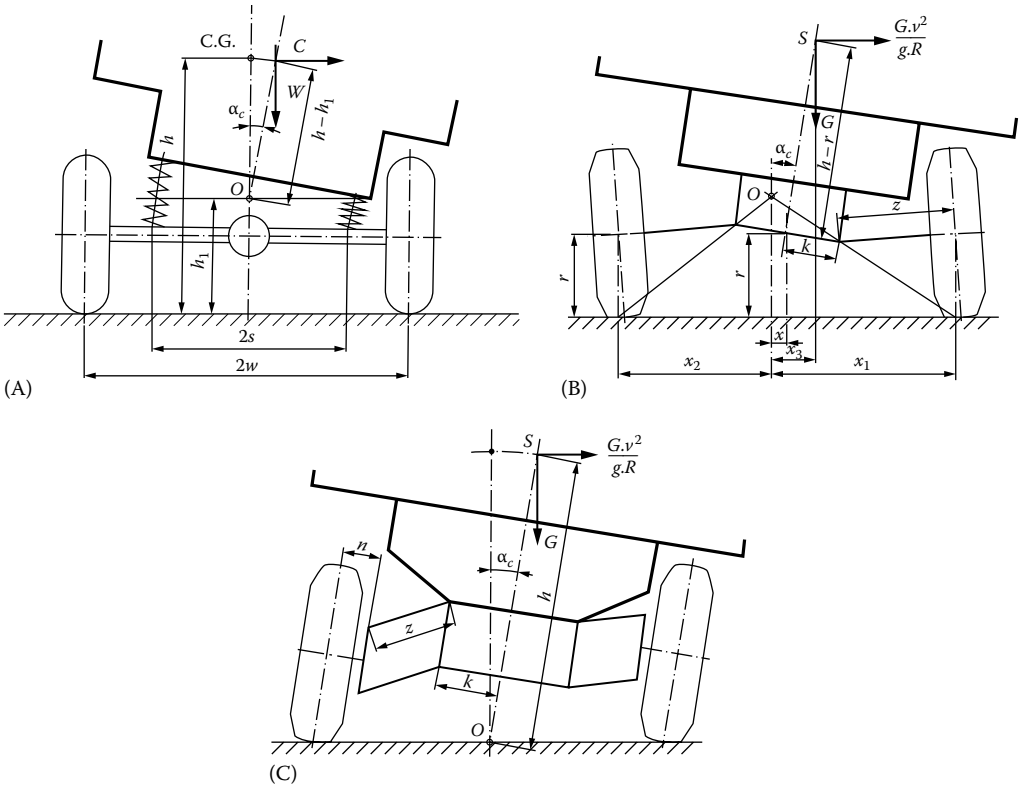

FIGURE 12.95 Centrifugal forces acting on a rigid axle (A) on a swing axle (B) and on a wishbone axle (C). (Reproduced from Klanner, R., Die Radaufhängung des geländegängigen Kraftfahrzeuges, thesis, Technical University Vienna, Vienna, Austria, 1943; Hohl, G.H., The influence of the suspension system on the mobility of wheeled off-road vehicles, *11th ISTVS Conference*, Lake Tahoe, NV, 1993; Hohl, G.H., An overview of suspension systems of wheeled off-road vehicles, *10th ISTVS Conference*, Vienna, Austria, 1994.)

12.5.3.5.3 Independent Suspensions

The roll angle α_c is different for swing and double-wishbone axles:

Swing Axle

$$\alpha_c = C\frac{h-(w/z)\cdot r}{(w^2/\varphi)-(h-r+(w/r)\cdot k)} \tag{12.59}$$

Double-Wishbone and Swing Axle

$$\alpha_c = C\frac{h}{(w^2/\varphi)-h} \tag{12.60}$$

In Figure 12.96, the roll angle versus the several suspension systems is shown. The best system is the one with the lowest roll angle. The rigid axle has lower roll stability. The best situation can be seen in the swing axle. The roll angle for the double-wishbone axle is independent of the geometrical relationship.

Figures 12.91 and 12.92 show the influence of the spring characteristic and the geometry of the axles on the roll angle for several suspension systems.

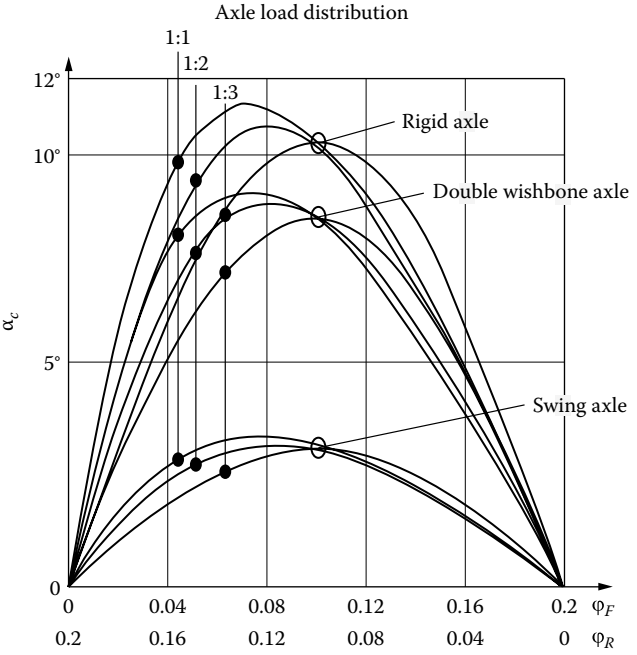

FIGURE 12.96 Roll angle versus suspension system considering different axle load distributions and different spring rates. (Reproduced from Klanner, R., Die Radaufhängung des geländegängigen Kraftfahrzeuges, Thesis, Technical University Vienna, Vienna, Austria, 1943; Hohl, G.H., The influence of the suspension system on the mobility of wheeled off-road vehicles, *11th ISTVS Conference*, Lake Tahoe, NV, 1993; Hohl, G.H., An overview of suspension systems of wheeled off-road vehicles, *10th ISTVS Conference*, Vienna, Austria, 1994.)

12.5.3.6 Steering Ability and Wheel Control

Passing over terrain irregularities and negotiating obstacles is one major task for off-road vehicles. When one wheel of a rigid axle suspension passes over an obstacle, the axle executes angular movement. The wheels are simultaneously displaced by approximately equal and opposite amounts relative to the chassis. Since wheels in movement act as gyroscopes, a forced gyroscopic movement occurs that tends to make the steerable wheels swing about their kingpins. This effect can be seen clearly in Figure 12.97 without any mathematical considerations.

Another problem associated with rigid axle design is that the unsprung masses are higher than for any independent suspension system. This is undesirable when both wheels are crossing an obstacle at the same time because the mass of the whole axle is involved.

12.5.3.7 Further Considerations and Summary

Ground clearance is a very important factor in off-road mobility. The rigid axle design has a constant ground clearance. The lowest point of the suspension system is the differential housing. In contrast to the independent suspension systems, the ground clearance is constant and independent of loading. On the other hand, the differential housing is an obstacle when passing high terrain irregularities. In the case of an independent suspension, the vehicle's belly can be designed to be flat and the clearance is not obstructed by axle beams.

Another disadvantage of a rigid axle system is the overall height. This difference can be seen clearly in an example for a wheeled armored vehicle. The rigid axle requires clearance between the axle and the hull to permit spring action (Figure 12.98).

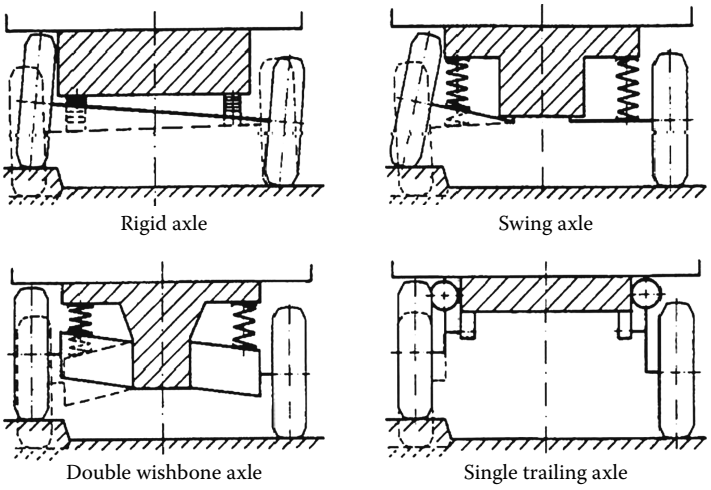

FIGURE 12.97 Wheel control for the main suspension types. (Reproduced from Klanner, R., Die Radaufhängung des geländegängigen Kraftfahrzeuges, Thesis, Technical University Vienna, Vienna, Austria, 1943; Hohl, G.H., The influence of the suspension system on the mobility of wheeled off-road vehicles, *11th ISTVS Conference*, Lake Tahoe, NV, 1993; Hohl, G.H., An overview of suspension systems of wheeled off-road vehicles, *10th ISTVS Conference*, Vienna, Austria, 1994.)

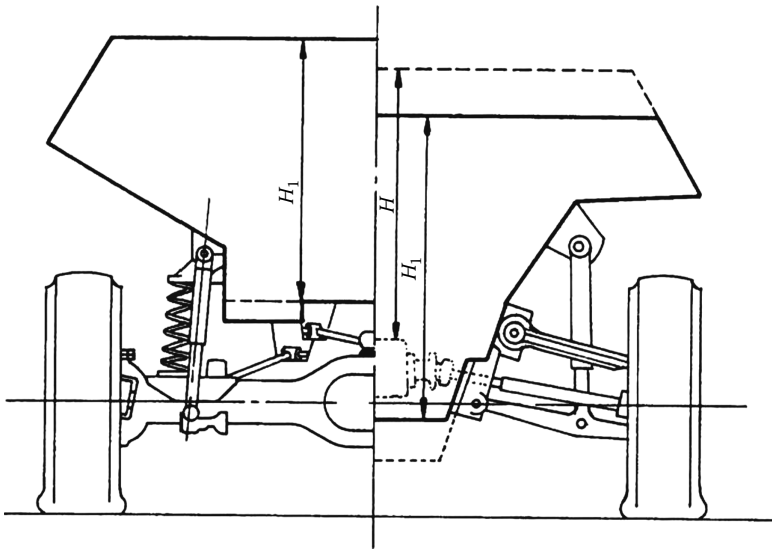

FIGURE 12.98 Wheeled armored vehicle with non-independent and independent suspension designs. 12.5.4 Suspensions of Tracked Vehicles

12.5.4.1 General

The first tanks had nothing between their hull frames and the tracks other than rigidly mounted rollers. This was acceptable only for operations at low speeds for which these vehicles were designed.

In the first decades of the introduction of tracked armored vehicles, all kinds of mechanical spring systems were in use. Leaf, truncate, and disc springs vanished.

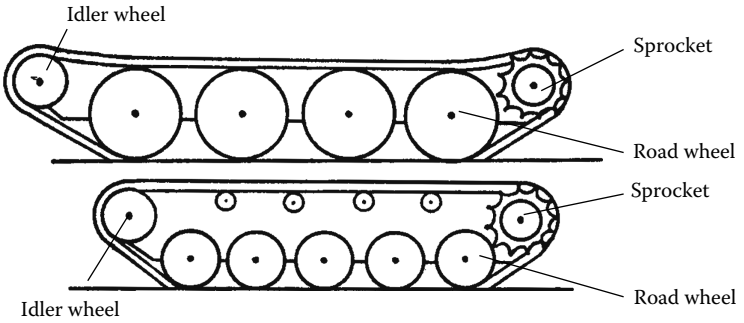

FIGURE 12.99 "Christie" suspension and supporting roller suspension. (Reproduced and modified from Hohl, G.H., Geländegängige Fahrzeuge, Script for the lecture at the Technical University Vienna, Vienna, Austria.)

Coil springs in some niches are still in use. The torsion bar system is the most used spring on tracked armored vehicles but the number of tanks with hydropneumatic suspension is increasing. The most innovative spring system is the hydropneumatic suspension.

For the suspension system of tracked vehicles, two principal systems are in use:

- "Christie" or road wheel suspension
- Supporting roller suspension (Figure 12.99)

The "Christie" suspension supports the upper part of the track by the road wheels. Contrary to this in the supporting roller system, this function is done by the support rollers. Both systems have their advantages and disadvantages.

The rolling resistance decreases with the number diameter, but the diameter is limited to 800 mm. On the other hand, smaller and thus more road wheels spread the weight of the vehicle evenly over the length of the track weight that reduces the peaks of pressure on the ground under the road wheels. The use of support rollers to guide the return run of the track provides larger road wheel travel in vertical direction, causes lower unsprung masses, and avoids either excessive sag of the run of the track, which leads to the track being thrown off, or excessive track tension, which increases rolling resistance. The "Christie" suspension is used for tracked armored vehicles with a lower demand of terrain mobility like self-propelled howitzers.

12.5.4.2 Torsion Bar Suspension

Torsion bar suspension uses the flexibility of a steel bar twisting lengthwise to provide spring actions. One bar of spring steel is used for each road wheel in this type of suspension. One end of the bar is fixed solidly on the opposite side of the hull. The arm rises and falls with the road wheel movement [72] (Figure 12.100).

The main reason for the widespread adoption of a torsion bar suspension has been its light weight and the high levels of performance. The light weight is due to the basic simplicity and it stores more energy in relation to its weight than other spring systems.

The advantages of torsion bar suspensions are, however, accompanied by a number of disadvantages. Thus, while the installation of torsion bars across the bottom of tank hulls is simple and well protected, it also increases the height of the armored vehicle (Figure 12.101).

During WW II, torsion bar suspensions were still being designed to a maximum shear stress of 300 MN/m^2, but the improvements in the manufacturing of spring steels resulted in a maximum shear stress of 800 MN/m^2 in the fifties.

Advances in metallurgical techniques increase the maximum shear stress still further. Thus, modern torsion bar steels are able to operate at up to 1240 MN/m^2 for 68,000 cycles of loading.

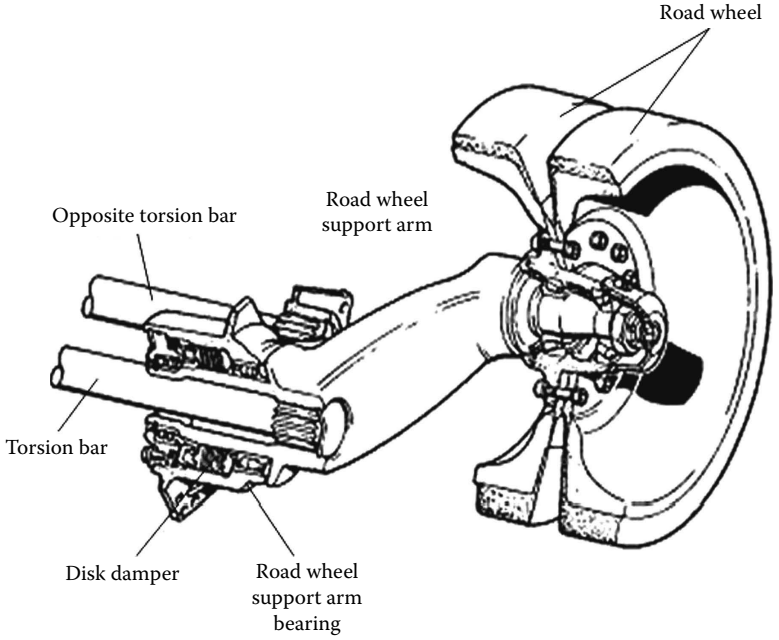

FIGURE 12.101 Torsion bar arrangement. (Reproduced from Spielberger, W.J., *Von der Zugmschine zum Leopard 2*, Bernhard & Graefe Verlag, München, Germany.)

12.5.4.3 Coil Springs

Coil springs have an old tradition. This kind of suspension was commonly used between the two world wars. Examples are the British "Cromwell" tank and the Soviet "T34."

The Israeli MBT "Merkava" has an independent suspension that means each road wheel has an independent spring assembly.

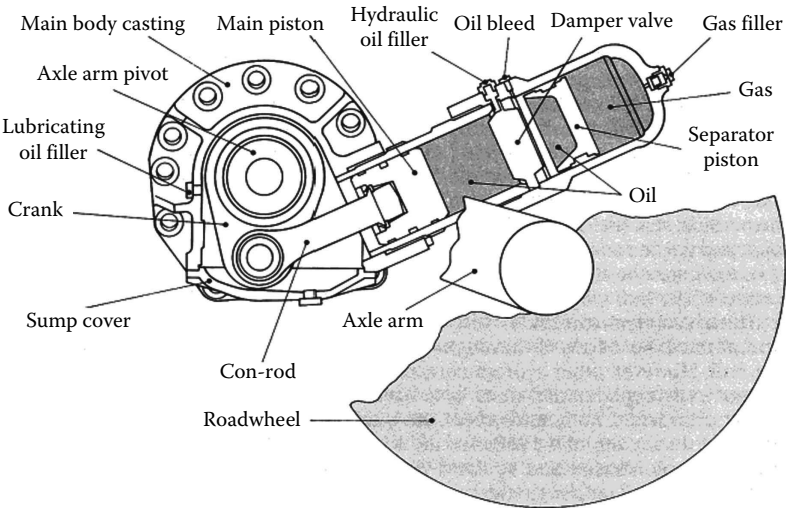

FIGURE 12.102 Hydropneumatic suspension. (Reproduced from Ogorkiewcz, R.M., *Tank Technology*, Jane's Information Group, London, U.K.)

12.5.4.4 Hydropneumatic Suspension

The hydropneumatic suspension contains a volume of gas, separated from a floating piston, or a diaphragm, from hydraulic fluid that transmits pressure between it and a second piston connected to the road wheel arm. Their resilience is based on the compressibility of the gas. Hydropneumatic spring units have progressive load–deflection characteristics.

Each unit is a spring as well as a damper. They provide better damping than suspensions in which dampers are only fitted to some of the road wheels. Moreover, when they are bolted to the hull, they can better dissipate the generated energy by telescopic dampers because the hull constitutes a large heat sink (Figure 12.102).

12.5.4.5 Dampers

There are two principal dampers in use, the *linear* and *rotary* dampers. The linear dampers are well known in private cars and in commercial vehicles. These dampers have the same principle but a greater size. The disadvantage is that mud can cling to the space between the damper and the other parts of the suspension. Rotary dampers have the same principle, but the motion of the piston is a rotary one.

For torsion bar suspensions, these kinds of dampers save space and are not the source of accumulation of mud. Rotary dampers can be fitted in the bearing of the torsion bar or connected with a lever to the rod arm of the road wheel (lever actuated).

As resonance can result in large oscillations, suspensions need to be well damped, as already indicated. On the other hand, damping should be as low as possible to minimize the transmission of impact forces, especially at high speeds or, what amounts to much the same thing, at high forcing frequencies.

In most cases, dampers have been fitted only to the front and rear road wheels. The reason for not fitting them to the center wheels is that they are ineffective there in damping pitching resonance, which sets in at lower frequencies than bounce resonance and is generally more disturbing. In fact, bounce resonance not only sets in later than pitch resonance but does so at frequencies beyond the cross-country speed of many vehicles. However, damping of the vertical oscillations becomes important at high speeds.

Friction dampers have also been used, their principal attraction being greater durability than that of hydraulic dampers. On the other hand, friction damping has been less consistent and has not provided as good a range of characteristics as hydraulic damping. Nevertheless, highly developed, disc-type, rotary friction dampers have been adopted for the "Leopard 2" tank (Figure 12.103).

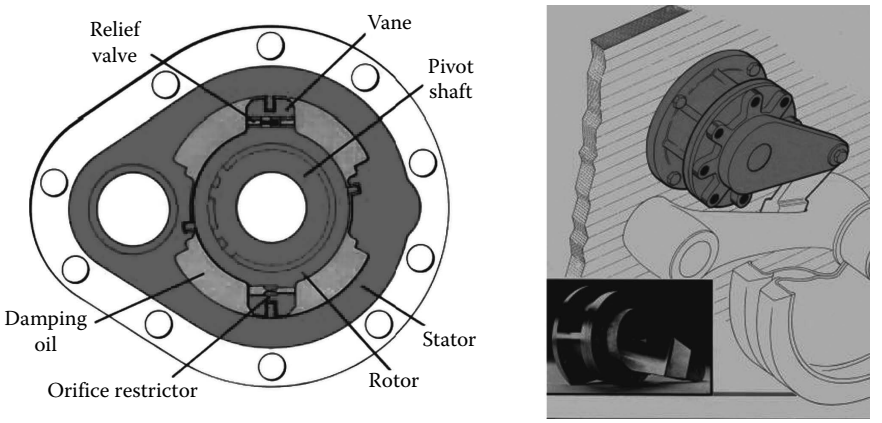

FIGURE 12.103 Rotary dampers. (Reproduced from Holman, T.J., Rotary hydraulic suspension dampers for high mobility off road vehicles, *8th International ISTVS Conference*, Cambridge, U.K., 1984.)

12.6 CONCLUSION

Developments in automotive engineering have always been used for terrain vehicles. It has to be considered that an off-road vehicle is an automobile with some applications for terrain mobility purposes. The engineers of terrain vehicles should apply general developments of present-day automotive engineering for the off-road vehicles of the future.

More recently, an increasing amount of work is now being done by computer simulation. Computer simulation enables engineers to evaluate the performance of equipment under virtual extreme conditions that could be dangerous, damaging, and expensive to perform on the test track. In a computer simulation, it is relatively easy to change the vehicle design parameters.

More than for road vehicles, computer modeling for off-road vehicles is essential.

The term modeling has two meanings for off-road vehicles:

- Modeling of the interaction between running gear and terrain
- Modeling of the vehicle (power train, suspension, running gear, etc.).

In the future, both models might be connected in combination with terrain maps. This model can show an off-road ride in a virtual world. The terrain ride can be seen from the position of an observer outside of the vehicle. Such models have been initiated by and will be improved further.

A next step could be a virtual test of the components and the whole vehicle during an off-road ride.

However, there is also a danger in virtual modeling. It must be considered that a virtual model is very close to reality but is not reality. Therefore, in the validation process, the virtual and the physical models have to be tested identically.

Electronic systems in road and off-road vehicles are becoming more and more common. *X-by-wire systems* are electronic systems without mechanical backup where the X stands for safety related applications, for example, steer by wire and brake by wire.

Hybrid vehicles [72,73] have a great chance as future propulsion systems for future off-road vehicles. Therefore, many attempts have been made to combine electric drives with conventional combustion engines.

The next generation of military ground combat vehicles may be equipped with hybrid electric drives to gain fuel efficiency, generate an abundance of onboard electric power, and reduce noise.

The use of an electric motor/generator in combination with an internal combustion engine offers improved fuel economy and reduced emissions as well as a simpler power train. Hybrid propulsion systems will be a serious alternative to conventional drives, especially for military terrain vehicles in wheeled or tracked concepts.

There is a principal difference between hybrid vehicles for wheeled and racked versions. For wheeled vehicles, two kinds of drive systems are possible:

- Electric motor installed in the hull
- Electric motor installed in the hub of each wheel [74]

The "in-hull installation" is more related to the conventional power train systems. The wheels of a mechanical power train system can be used. Disadvantages are the use of a cardan shaft and limited space for steering.

Conventional tracked armored vehicles have a very complicated mechanic–hydraulic steering system and could be substituted by electric motors. Another solution could be to use two electric motors directly connected for each track whereby very smooth steering is possible [75,76].

Many situations in the terrain cannot be presented in practical training. Therefore, it is necessary to simulate various situations. Nowadays, two-thirds of the driver training is done on a simulator. With this device, unusual and dangerous situations can be simulated. This saves time and cost.

Simulation must be as realistic as possible. Not only the image on the screen must look similar to the real terrain but also the movements of the simulator must follow the same motions as a real vehicle. Of course, also the driver cabin and all handlings devices must be identical with the original vehicle.

In the future, another philosophy, the modular concept for armored off-road vehicles, could take place. The chassis with hull power train and suspension will be produced separately from the body modules. The base vehicle operates independently from the modules. The modules are easily interchangeable and allow maximum flexibility for different mission requirements and multipurpose operations.

Another module system will be to build a low-weight basic tracked vehicle, which has a high maneuverability and can be air transported. For more dangerous situations, additional armor protection can be fitted easily. With this concept, different protection classes for different missions can be realized with one basic vehicle.

Due to the increasing cost constraints also for soft-skinned off-road vehicles, multifunctional equipments for armed forces and civil organizations are required. Different superstructures make the basic vehicle capable for a wide range of functions and missions.

On the other hand, the protection of the environment should not be forgotten. In the future, more emphasis should be put on the environment aspects. This is not only to reduce the exhaust gases but also to save the natural surface where terrain vehicles operate.

Military and civilian off-road vehicles are frequently driven in ecologically sensitive areas. Spilling of fuel and lubricants is sometimes unavoidable. In this respect, biodiesel could have the great advantage of low toxicity and high biodegradability.

Ground pressure exerted by tires or tracks can damage thin and not visible roots. Visible and larger roots suffer from the removal of their bark. The driver should not drive too near to trees and should avoid extreme acceleration and braking in such situations.

13.1 INTRODUCTION

Basic architectural features of motorcycles will be discussed first, followed by considerations of rigid-framed and tilting three-wheelers. Motorcycle architectures derive from those of bicycles, while the rigid-framed three-wheeler is essentially a car in engineering terms. Tilting three-wheelers seem to have more in common with the motorcycle than with the car, but there are elements of both involved. Tilting may be rider controlled or actuator controlled through motion feedback. In the latter case, tilting moments applied by actuators must be reacted on a nontilting part of the vehicle. The influence of these moments on the motions of the nontilting part may be important and should be considered in any design study.

13.2 MOTORCYCLES

Essential to a conventional motorcycle are two wheels nominally in a single plane, with a steering system allowing the front wheel to steer freely around an inclined axis. The longitudinal separation of the wheels defines the wheelbase. The inclined steering axis is structurally convenient, allowing the steering axis to lead, at ground level, the front tire/ground contact center and the handlebars to be conveniently located for the rider. The inclined steering axis is also an important determinant of the stability, control, and response properties of a motorcycle. At low speeds, it is evident that an uncontrolled motorcycle will be unstable in roll, but it transpires that it will typically self-stabilize at a modest speed, as described in Chapter 35. The freedom of the steering system is important to a motorcycle's autostabilization, since this autostabilization depends on the front system steering into a fall, thereby introducing tire forces, through cambering and sideslipping of the front tire, which exert a rolling moment around the machine's mass center necessary to counter the original fall [1]. Those aspects of the design of the motorcycle that influence the self-steering behavior deserve

particular attention. Such aspects include the steering rake, the mechanical trail, and the front wheel gyroscopic torques. Steering the rear wheel appears superficially to be feasible, but dynamic analysis and experimentation [2,3] show it not to be practical. Steering both front and rear wheels has been researched [4], but it does not appear to be advantageous.

The possession of a free steering system leads to the possibility of oscillatory instabilities. When the self-steering is too vigorous, overshoot and oscillations result. Under some running conditions, it may be essential to restrain the steering freedom, to some extent, by means of a damper or other device. Compromise between what is best for one set of conditions and what is best for another may well be necessary. The main oscillatory modes are weave and wobble modes, both of which can be observed near to straight running at constant speed (see Chapter 35). Variants of these modes occur in cornering and in braking or driving, especially under extreme circumstances typical of racing. Oscillatory modes with higher frequencies and of less certain character are often called by the names patter, chatter, or judder [4,5]. An example demonstrated in simulation can be found in Ref. [6], but it is not known how close to real events these results come.

A main structure to connect the wheels together, an engine and transmission system, suspensions, brakes, fuelling, lights, etc., and controls are needed. The main mass of the motorcycle is the power train, an assembly of engine, clutch, and gearbox, which is substantially rigid and which invariably is placed between the wheels, with the rider on, as opposed to in, the motorcycle. The wheelbase is normally about as short as is convenient from a packaging point of view, which implies that the mass center is quite high and front-to-rear load transfers in accelerating or braking are severe. With high-performance machines, in fact, it is not uncommon for longitudinal maneuvering to be limited by wheelie or stoppie, as can be easily observed at the race track. Longer wheelbases, lower riders, and more than usual weather protection have been tried. The Quasar, for example, had a 1.96 m wheelbase, compared with norms for tourers of 1.47–1.52 m and for racing machines of 1.27–1.4 m. Many details can be found in Ref. [4].

The compliance of the structure, the steering geometry, any steering restraints, gyroscopic influences of spinning wheels and power train parts, suspension design details, speed range, performance priorities, tire characteristics, aerodynamic properties, and rider dynamics all interact with each other to determine the performance of a motorcycle/rider combination. The extent to which the parts can be separated from each other and discussed individually is limited by this strong interdependence. Such discussion must be directed mainly at understanding the rather general influences of design features on behavior.

13.2.1 Frame

The main necessary property of the frame, in terms of performance of the motorcycle, is torsional stiffness. If the frame is too compliant, the weave mode especially will become underdamped or even unstable as speed increases, and the motorcycle will become dangerous. The stiffness required depends strongly on the speed range of the machine. High-performance machines need to be stiffer than others. As the frame stiffness increases, the damping of the weave mode at high speed improves, but the speed at which the wobble mode is minimally damped increases also. There comes a point at which the wobble mode is a greater problem at high speed than the weave mode is. The wobble mode stability is increased very effectively by a steering damper, but this has a bad influence on the weave (see Chapter 35). Racing machines consequently can be characterized as having stiff frames and needing steering dampers. If they wobble, it is at high speed. Touring machines are generally more compliant and have less need for a steering damper, and, if they wobble perceptibly (commonly referred to as "shaking their heads"), it is at more moderate speeds. Anecdotal accounts suggest that such modest-speed wobbling is much less vigorous than the high-speed variety. Usually, it can be controlled by the rider. The idea of planned compliance can be found in Ref. [7].

Presuming that the power train is relatively heavy and that it is located between the wheels, in simple terms, the frame structure can be considered to be in two parts. One part joins the power

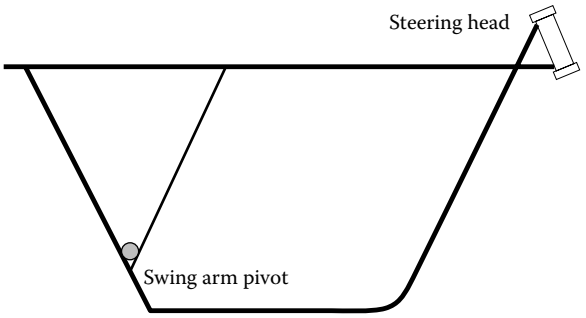

FIGURE 13.1 Diagrammatic representation of a perimeter frame. Such frames are normally made of small-diameter steel tubes and gussets, and they can be constructed with very little manufacturing infrastructure. Most motorcycles coming after the widespread adoption of swinging arm rear suspensions have had such frames. Many examples can be found in. (From Foale, T., *Motorcycle Handling and Chassis Design—The Art and Science*, Tony Foale Designs, Alicante, Spain, 2003 (http://www.tonyfoale.com); Wilson, H., *The Encyclopedia of the Motorcycle*, Dorling Kindersley, London, U.K., 1995.)

train mass to the front wheel, while the other joins it to the rear wheel. Usually, the structural route to the front wheel contact patch entails joining the engine to the steering head and the steering head to the contact patch, through the front suspension mechanism, the wheel bearings, and the wheel and tire compliances. Normally, also, the structural route to the rear wheel contact patch entails joining the power train to the swing arm pivot and the swing arm pivot to the contact patch through the swing arm, wheel bearings, and wheel and tire compliance. The point of thinking about the frame structure in this way is that the main sources of external force on the motorcycle are the contact patches and the main source of inertial resistance to motion in response to those forces is provided by the power train. Further, the power train itself may be used as part of the structure, in which case the main structure literally is in two parts, joining engine to steering head at the front and gearbox to swing arm pivot at the rear. The compliances of the structural parts and of the tire can be thought of as in series with the frame compliances, so that there is little point in stiffening the structural parts further, once they are much stiffer than the tire carcass.

It is relatively easy to achieve the necessary torsional stiffness in the rear one of these substructures, since no steering is involved and the load paths are quite direct. Calculations have shown that diminishing returns for increasing torsional stiffness of a swing arm set in at about 12 k Nm/rad [8], while the stiffness of a contemporary superbike swing arm is around 50 k Nm/rad [5]. Provided that the design details are good [4], it appears not difficult to obtain high quality of performance in this area. The front structure is a different matter. The load path is usually long and tortuous, and both steering and suspension joints are included in the path. With conventional geometry, it is difficult to make the structural parts as stiff laterally as the front tire carcass. As a consequence, many variations on the conventional steering arrangements have been used [4,5], with strong implications for the frame design.

Some alternative frame structural concepts are illustrated in Figures 13.1 through 13.5, the first four of which rely on joining the steering head to the swing arm pivot while supporting the engine, rider, etc. The remaining one employs the power train as part of the structure and may include only subframes for the front and rear. If the mechanical balancing of the engine is poor, using the engine as part of the structure may well lead to vibration problems.

13.2.2 Rear Suspension

The swinging arm rear suspension is now almost universal. It is considered not worthwhile to discuss other possibilities. Torque steer is an issue with swing arm suspension. Ideally, neither driving nor braking will lead to any steer deflection of the rear wheel. In the braking case, ensuring

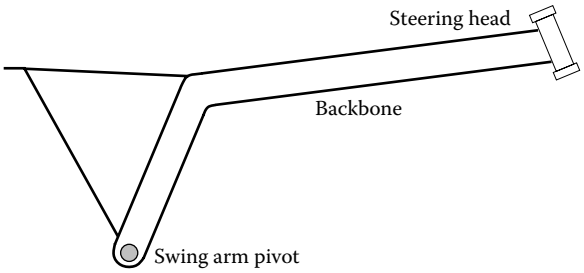

FIGURE 13.2 Diagrammatic representation of a backbone frame. Torsional stiffness comes mainly from one large-diameter tube, which is bent to clear the power train as necessary. (From Foale, T., *Motorcycle Handling and Chassis Design—The Art and Science*, Tony Foale Designs, Alicante, Spain, 2003 (http://www.tonyfoale.com).)

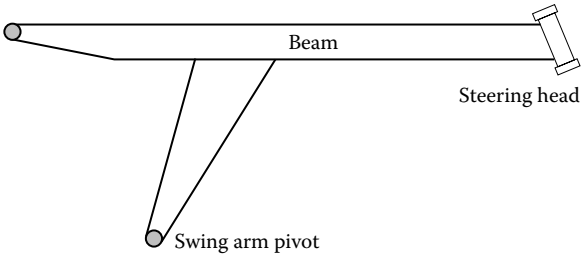

FIGURE 13.3 Diagrammatic representation of a beam frame. Such a frame is normally made of steel pressings, implying a strong connection with large-scale production. The Ariel Leader and Arrow are examples. (From Foale, T., *Motorcycle Handling and Chassis Design—The Art and Science*, Tony Foale Designs, Alicante, Spain, 2003 (http://www.tonyfoale.com); Wilson, H., *The Encyclopedia of the Motorcycle*, Dorling Kindersley, London, U.K., 1995.)

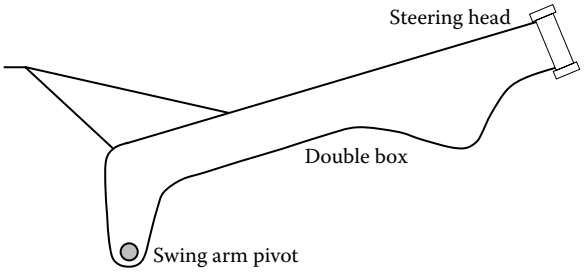

FIGURE 13.4 Diagrammatic representation of a double-box frame. A pair of closed section boxes straddle the top of the power train. These modern frames are normally made of aluminum alloy. (From Foale, T., *Motorcycle Handling and Chassis Design—The Art and Science*, Tony Foale Designs, Alicante, Spain, 2003 (http://www.tonyfoale.com); Cameron, K., *Sportbike Performance Handbook*, MBI Publishing, Osceola WI, 1998; Wilson, H., *The Encyclopedia of the Motorcycle*, Dorling Kindersley, London, U.K., 1995.)

lateral symmetry is one approach to eliminating torque steer, implying the need for brake discs and calipers on both left and right. For driving by shaft, left/right symmetry would be perfect but is unlikely to occur, due to the drive arrangements. For driving by chain, the ideal would be to have the lateral elastic center of the swing arm a little inside the line of the chain, so that the swing arm simply translates longitudinally, without yawing, when the chain tension changes and the corresponding, much smaller, longitudinal tire force is generated. These ideals may be mutually exclusive or impractical, so that a small amount of torque steer may have to be allowed. Obviously, high stiffness will help to lower the influence of any geometric imperfections in a design.

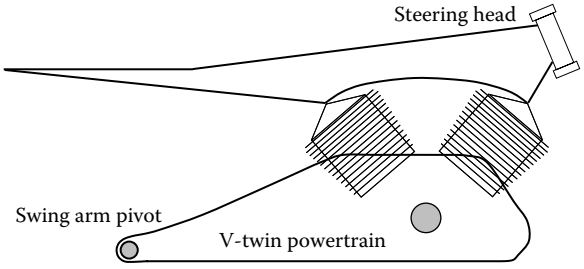

FIGURE 13.5 Diagrammatic representation of a two-part frame, utilizing the power train as the main structural component. Such a frame concept may involve small-diameter tubing with triangulation to make a "space frame." (From Foale, T., *Motorcycle Handling and Chassis Design—The Art and Science*, Tony Foale Designs, Alicante, Spain, 2003 (http://www.tonyfoale.com); Wilson, H., *The Encyclopedia of the Motorcycle*, Dorling Kindersley, London, U.K., 1995.)

Most modern motorcycles have a single spring/damper unit at the rear, a so-called monoshock, with a multilink system connecting it to the swing arm and the frame. The suspension unit is likely to include elastic bump and rebound stops, which give the system a "hardening" property (the spring stiffness increases as the deflection from nominal increases) as the spring deflection increases toward the travel limit. Much is often made of the possibility of using the linkage design, or the spring design itself, to shape the suspension stiffness [7], but it seems likely that such shaping will be overwhelmed by the limit stops and therefore is not important. Also, analysis often reveals a substantially linear characteristic to the mechanism involved [10].

Monoshock arrangements are many and varied. Examples can be found in Refs. [4,5], and several different geometries are analyzed in Ref. [11]. The main considerations in selecting a monoshock design appear to be minimizing part count, cost, and mass; packaging the components neatly in the space available; and reducing the need for main structure aft of the swing arm pivot line.

Under driving or braking, the attitude of a motorcycle will change in response to the tire longitudinal forces responsible for the motion. The forces act at ground level, and the inertial reactions to the forces are all above ground level, so that, corresponding to an acceleration, there must be a load transfer from front to rear tires and conversely (Figure 13.6).

Rear suspension and transmission system geometries influence the attitude changes and the extent to which the limited suspension travel is used to accommodate accelerating or braking. Let us first consider a swing arm geometry, which involves a more or less horizontal swing arm at the nominal state, combined with a single-jointed shaft drive. The shaft joint needs to be aligned with

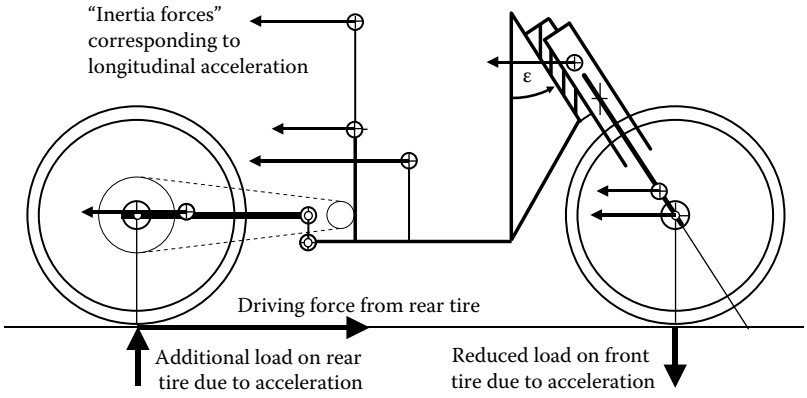

FIGURE 13.6 Illustration of load transfer from front to rear under acceleration caused by drive thrust at the rear tire contact patch. The load transfer must occur to account for the equilibrium in pitch of the whole system, irrespective of the internal suspension and transmission details.

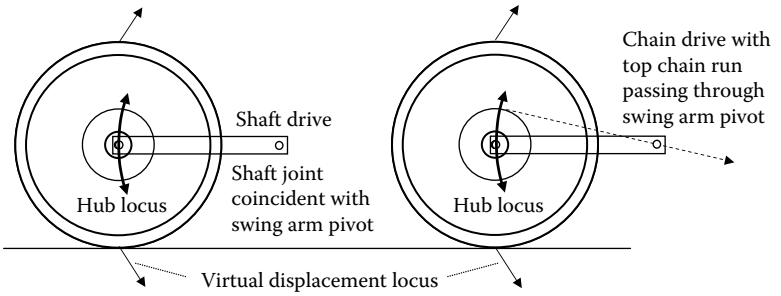

FIGURE 13.7 Shaft and chain drive rear suspensions with strong antisquat property. In each case, the swing arm is horizontal. A single-joint shaft-driven wheel and a chain-driven wheel with top chain run passing through the swing arm pivot are equivalent systems with respect to squatting, for small perturbations.

the swing arm pivot. Since we are dealing with a multibody system, we must use the principle of virtual work or virtual power to examine equilibrium states [12]. Imagine a virtual displacement in which the swing arm rotates toward rebound (positive), while the transmission system does not rotate in spin at all, implying that no work is done by the drive system. The drive then implies that the road wheel rotates with the swing arm as if the road wheel and the arm were one body. In the virtual displacement, the wheel center moves vertically, while the tire contact center moves in a direction perpendicular to the line joining it to the swing arm pivot. The longitudinal driving force moves along its line of action, and this force pulls the suspension into rebound, opposing the motion in bump corresponding to the load transfer. The system has a strong antisquat character, the more so the shorter is the swing arm [13]. A motorcycle with this layout may lift perceptibly when accelerating hard, the rear rising due to the suspension and transmission geometry, the front rising due to the load transfer from front to rear [4]. If we replace the shaft drive with chain drive and we consider the special case in which the upper chain line passes through the swing arm pivot, the argument and the conclusion are the same as before. The two cases are illustrated in Figure 13.7.

If an additional joint is included in the drive shaft and the swing arm is replaced by a parallelogram linkage as shown in Figure 13.8, the locus of the tire contact center in a virtual displacement in which the drive shaft does no work is vertical, since the road wheel simply translates without rotating. Further, if the driving sprocket of the swing arm, chain drive system is raised from its former position so that the upper chain run is parallel to the swing arm and horizontal, the virtual displacement in which the drive system does no work similarly involves the road wheel in translating without spinning in an absolute sense, when the swing arm moves in rebound. The road wheel has a rotation relative to the swing arm, which is equal and opposite to that of the swing arm. The contact center moves vertically, and the driving force does no work on the system. In each of these cases, the driving force exerts no kinematic influence on the suspension, which has a zero antisquat property.

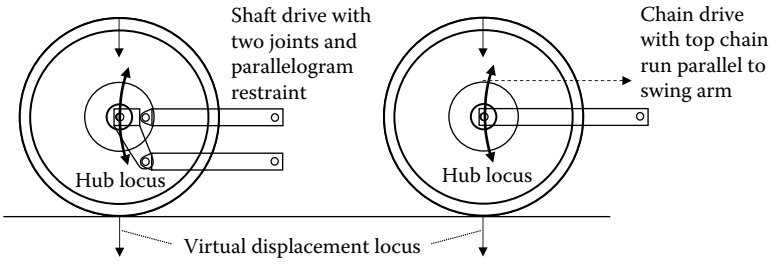

FIGURE 13.8 Shaft and chain drive rear suspensions with zero antisquat property. Generalizing the results, as the declination of the top chain run to the front increases, so the virtual displacement loci change and the degree of antisquat increases.

Thus, with the most common swing arm suspension with chain drive, the system has an antisquat character, which becomes stronger as the upper chain run declines to the front more steeply. These arguments are not changed fundamentally by inclination of the swing arm.

Rather intricate measurements or simulation results are necessary to illustrate antisquat properties more fully [11]. The study of the transient behavior, in particular, is likely to be ineffectual unless sophisticated methods are used. The results of [11] confirm the earlier findings qualitatively and add to them quantitatively. Those results also show that there is a price to pay for using antisquat kinematics to control attitude changes in acceleration, which is that transient load transfers are made more rapid and oscillatory than they otherwise would be (see Ref. [13] in addition). The rider's task of exercising good control while carrying out a serious maneuver is made more difficult by such rapidly changing tire loading.

The corresponding antidive problem in braking is qualitatively similar but is not such a big issue quantitatively since braking the rear wheel of a motorcycle usually needs to be done with reserve. The short wheelbase and the high-mass center imply that the load will come off the rear wheel almost entirely in a serious deceleration and, consequently, very little braking force can be generated there. The antidive kinematics depend on the caliper mounting arrangements, as previously the properties depended on the drive arrangements. Mostly, calipers are anchored on the swing arm, yielding the same character in braking as depicted for driving in the left-hand case of Figure 13.7. With such geometry, rear braking only will give a pitch down response by virtue of the front suspension compressing corresponding to the load transfer, while the swing arm's suspension movement is very small.

A notable feature of the rear suspension is the extent of the load change that typically occurs, with variations in operating circumstances. First, the difference between a static load of one small person and of two large people and some luggage is large in percentage terms. Secondly, the bank-to-turn cornering behavior implies that the suspension loading in a near limit turn is about 1.4 times the static load. The simplest device to cope with this large range of variation is the common manual adjustment of spring preload. A better but more expensive alternative is self-leveling, usually by means of a gas spring, a pump, and valves, for example, the Boge Nivomat unit [4]. A third way worth mentioning is the manually adjustable mechanical advantage or variable geometry system used by Velocette [4]. Such a variable geometry system can, in principle, be automated to give an active, low-power suspension with particular advantage in the application due to the special problems described. Such a system can also be designed to add damping usefully to the potentially problematic weave mode of a high-performance machine [14].

13.2.3 Front Suspension

The numerically dominant front suspension type for motorcycles is the telescopic fork. Typically, the fork legs are held in a "triple clamp" at the steering head with a small offset between the steering axis and the fork axis. The steer axis and the fork axis are normally parallel. Springs and dampers are contained within the forks and constitute part of the steering assembly. The sliding joints in the forks are quite critical components. They are required to provide friction-free movement, to accommodate bending loads especially in braking and to seal against dirt ingress and damper fluid leakage. The steering inertia is quite low, since the masses are concentrated near to the steering axis, but the structure is far from ideal, since the lateral support at the steering head is so far removed from the contact center. Stiffening of the fork structures conflicts, to some extent, with free movement at the joints and exaggerates the need for precise manufacture or fitting of the parts. Such forks have negative antidive kinematics when the brake calipers are anchored to the lower forks, depending on the fork rake. This is because the contact center moves rearward corresponding to a suspension displacement in bump, in which the braking torque does no work. Most of the available suspension motion may be used up in heavy braking. Increasing fork compression damping in response to front braking torque has been used as a means of reducing dive [7], but the practice is not common on current machines.

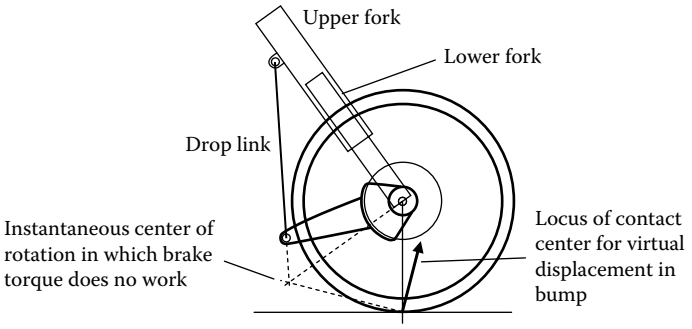

FIGURE 13.9 Telescopic fork with brake caliper rotation controlled by linkage to upper fork. The negative antidive property of the standard system, with caliper attached to fork lower leg, is replaced by antidive here. (From Foale, T., *Motorcycle Handling and Chassis Design—The Art and Science*, Tony Foale Designs, Alicante, Spain, 2003. http://www.tonyfoale.com)

If the rotation of the brake calipers is controlled by linking to the upper forks, antidive can be designed into a telescopic fork (Figure 13.9), but it will have the same implications, as mentioned earlier, that front braking will lead to a more rapid and oscillatory change of loading of the front tire than with no antidive, challenging the rider's control capabilities to obtain vigorous deceleration smoothly. In an actual braking event, the geometry will change as the maneuver progresses, such that simulation is needed to get a full picture of the transient and the final equilibrium state [11,13]. Torque steer under braking is an issue as before. The solution by symmetry implies the need for similar discs and calipers on left and right forks.

Leading or trailing link systems are pin-jointed alternatives to the sliding joints of the telescopic fork, having potential kinematic advantage in terms of reduced friction and elimination of bending loads [4,5,9], but the stiffness-to-mass ratio properties are likely to be worse than with telescopics, and the distribution of mass away from the steer axis implied will increase the steering inertia, bringing down the wobble mode frequency and making weave and wobble conflicts greater than before and probably harder to resolve.

Continuing with systems in which the steering parts are exterior with respect to the wheel and tire, the point in the center plane just above the wheel is a key point structurally. Lateral support for the wheel assembly at this point is advantageous, since the distance from the support point to the contact center is minimized in comparison with any other points in the class. Various alternatives to the telescopic fork system use this key point. Typically, a ball joint that helps to define the steer axis will be located on a bridging member between the lower fork legs [4,7,9]. The joint can be associated with a McPherson strut-like Telelever (Figure 13.10) or a double-wishbone-like Hossack or Britten system [4,7] (Figure 13.11). The Telelever system retains the sliding joints of the telescopic forks, but the bending moments from braking are reduced. The antidive kinematics are quite different from those of the original. Structurally and kinematically, the Hossack design appears advantageous, although the steering linkage to the handlebars is more elaborate than normal. Both systems are good from the point of view of steering inertia, with one spring/damper unit not steered.

If we now consider front suspension and steering systems in which the wheel interior space is employed for parts, the essential feature is the location of a steering joint in the central plane and near to the wheel center. There are two ways in which this can be done. One of the ways involves deeply dishing the wheel, in car style, to make room for a wheel carrier or upright to have a spherical joint at the required location. There must also be a second joint on the upright in the wheel center plane to define the steering axis, and this second joint may be placed inside the wheel's interior space or above the wheel's orbit (Figure 13.12). The systems are sketched from the side in Figure 13.13.

The alternative way to locate a joint near the wheel center is to mount the wheel on a two-sided frame with a hollow cylinder at its heart, using large-diameter wheel bearings running on the

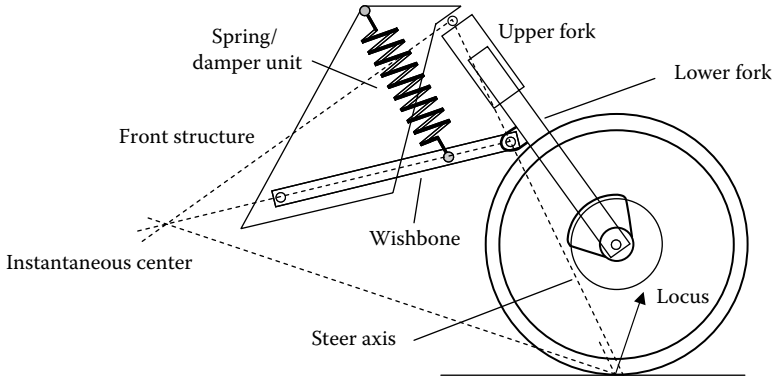

FIGURE 13.10 Telelever front suspension and steering system with ball-jointed support for the wheel assembly just above the wheel.

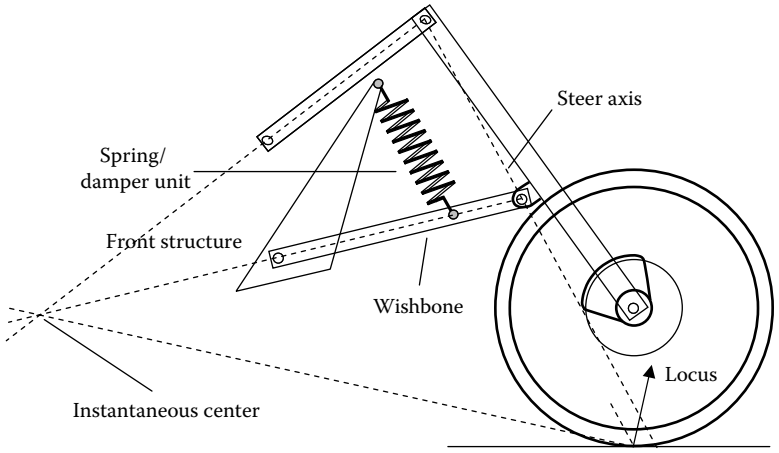

FIGURE 13.11 Hossack-type front suspension and steering system with ball-jointed support for the wheel assembly just above the wheel.

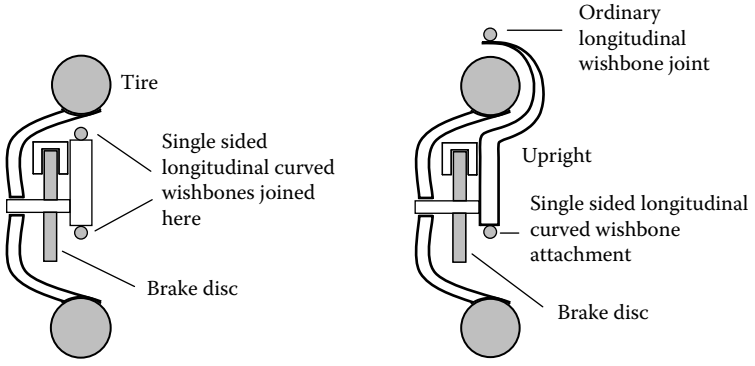

FIGURE 13.12 Diagrammatic illustration of front suspension arrangements using the wheel interior space for structural elements. On the left, both joints are interior, and both longitudinal suspension arms need to be curved to clear the tire on full lock. On the right, the upper suspension arm is exterior and is relatively unrestricted.

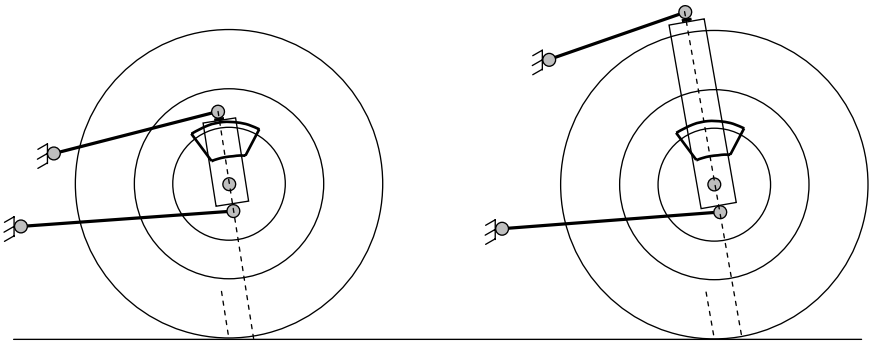

FIGURE 13.13 Diagrammatic side view of suspension systems shown in Figure 13.12, illustrating the freedoms to set the rake angle, the trail, and the antidive properties as desired. Note the implications of the choices made for the main frame.

hollow drum. The interior of the drum is used to locate the required joint. The lower suspension arm that relates to this joint may be two sided and must support a beam that passes through the drum. The drum must have sufficient diameter relative to its width to allow a reasonable steering lock (Figure 13.14). Note that the Bimota Tesi design dispenses with the upper wishbone and joint by using a revolute or pin joint at the hub interior and reacting the brake caliper force through a separate tension link [4,9]. Substantially, the same design freedoms as illustrated in Figure 13.13 exist. Several photographic illustrations of real systems of the types described are included in Refs. [4,9].

These so-called hub-center-steered systems shorten the load path from the front tire contact patch to the power train and thereby offer structural advantages. However, they all imply a restricted steering lock, due mainly to the need for the lower suspension member to clear the wheel and tire when the steering is on full lock and to not be so wide at the base as to ground in vigorous cornering. The restricted steering lock is more likely to be acceptable in racing than in a road machine.

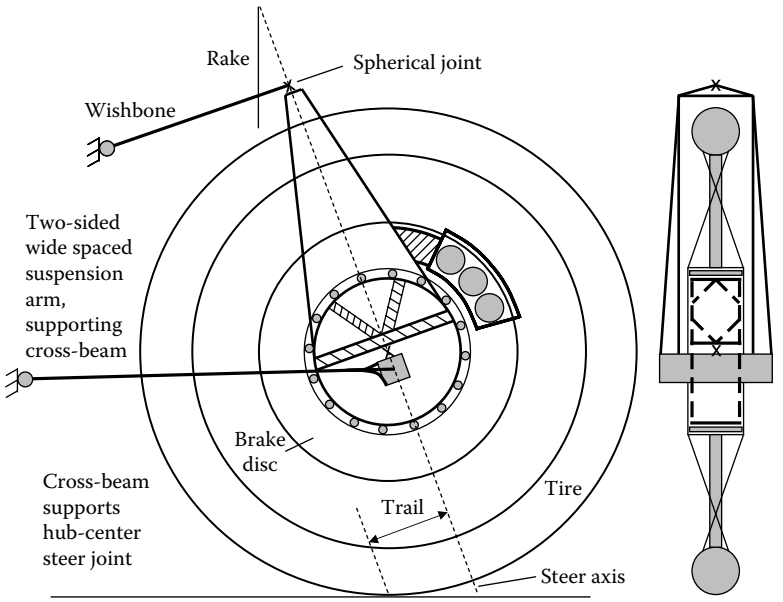

FIGURE 13.14 Location of steering joint near to wheel center inside a hollow cylinder supporting large-diameter wheel bearings. Beam and cylinder, and lower suspension arms and tire, must be shaped to allow a reasonable steering lock.

Once a motorcycle is traveling at reasonable speed, the steer angles used for control are usually small, so only the very low-speed behavior is prejudiced by limited lock.

13.3 THREE-WHEELED VEHICLES

Three-wheeled vehicles will be divided into rigid-framed or nontilting and pivot-framed or tilting classes. Essentially, the former class has more in common with the car than the motorcycle, and only a brief account will be given. Tilting three-wheelers include machines that are free tilting and steer much like a motorcycle and those with steering responses modified by an active tilt-control system. For ease of reference, we will use the designations 1F2R to represent a vehicle with one wheel at the front and two at the rear and 2F1R for the obvious alternative.

13.3.1 Nontilting Three-Wheelers

It is substantially true of both 1F2R and 2F1R designs that the total load needs to be shared roughly equally between the wheels statically. This requirement stems from the need to maneuver both longitudinally and laterally to a reasonable level while keeping the tires in contact with the ground. If all three tires are similar, 1F2R versions will tend to limit oversteer and static instability in yaw, while 2F1R versions will have the opposite tendency. This kind of behavior stems from the fact that all the lateral load transfer in cornering must occur at the pair of wheels, implying that the limit turning of a 1F2R on a good surface involves about one-third of the vehicle weight being supported by the front tire and about two-thirds being supported by the outside rear tire, with hardly any load on the inside rear tire. The rear axle is likely to saturate first as the cornering effort increases, despite that the front tire will camber with the vehicle body roll. A converse argument applies to the 2F1R design. This likely yaw imbalance of the three-wheeler is a fundamental disadvantage of the type.

Another disadvantage is that the overturning potential is significantly greater than with a corresponding four-wheeler, due to the near-zero track width at one end of the vehicle. To a certain extent, the nontilting three-wheeler has a greater need for width of track at its two-wheeled end, compared with a conventional car, to contain the rollover problem. Locating the mass center nearer to the two-wheeled end will reduce the overturning problem but will exacerbate the yaw imbalance problem. These disadvantages are not much offset by reduced weight or cost. Rigid-framed three-wheelers that have had a commercial life have generally owed it to legislation, giving them tax advantages in comparison with four-wheelers. A low-mass center reduces the severity of the problems mentioned, but that is not technically novel or interesting, since it is true of two-track vehicles generally.

13.3.2 Tilting Three-Wheelers

One possible purpose for a three-wheeler is that it behaves much like a two-wheeler but has a much increased potential for including weather protection, crashworthiness, and luggage carrying. In such a case, the rolling motion of the vehicle body is likely to be controlled by the rider, in the manner of the motorcycle. A potentially useful way of thinking about the roll control of a tilter is furnished by considering the vehicle to consist of an inverted pendulum pivoted longitudinally to a nonrolling trolley, illustrated in Figure 13.15. The Ariel 3 [15,16] was a commercial moped with this form of construction, as also were the Honda Gyro, the Honda Canopy, and the Honda Stream [16]. A more recent vehicle of this basic design is the GM Lean Machine [16]. The height of the joint between nonrolling and rolling sections is a design issue, as is the inclination of the joint to the horizontal, influencing roll steer. Locating the rolling joint near to ground level enhances the influence of tilting on the lateral load transfer, which is one of the main features. The Ariel 3 included a weak torsion bar in the pivot joint, so that the tilting frame would remain upright when the rider dismounted. Other designs have a lean locking brake, for operation by the rider at low speeds [16].

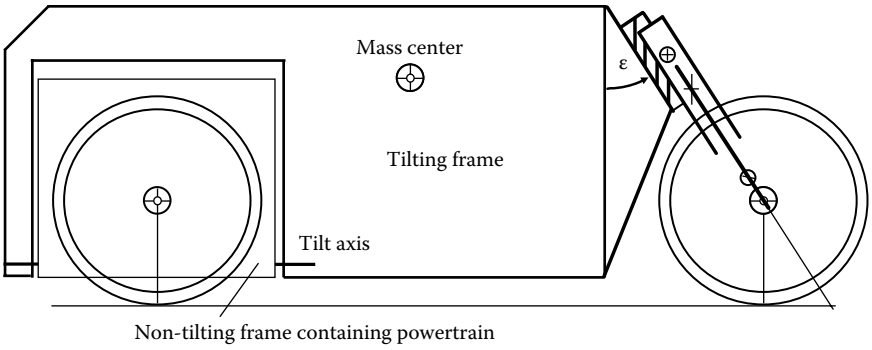

FIGURE 13.15 A diagrammatic view of a trolley and inverted pendulum type of tilting three-wheeled vehicle, in which the front is like a motorcycle and the rear more like a car. A rolling joint links the two frames together. It is shown horizontal here, but it may be inclined, leading to some roll steer.

FIGURE 13.16 Millennium Tracer all wheel tilting prototype (From http://www.members.iinet.net.au).

With this kind of vehicle design, the rear tires develop lateral forces primarily by sideslipping, while the front tires do so by cambering. There is a strong case for using car tires on the rear and a motorcycle tire on the front.

An alternative kinematic arrangement involves tilting all three wheels as the structure rolls. The Australian Millennium Tracer (Figure 13.16) and the U.S. Calleja are examples [16]. The Mercedes Life Jet experimental vehicle may also be included (Figure 13.17). These vehicles require a suspension design associated with the wheel pair, which provides bump stiffness, with very little roll stiffness. Linking the left and right wheels with a freely rolling transverse beam with its pivot axis restrained vertically by springing and damping will suffice, and putting a rider-operated or automatic brake on the pivot allows elimination of the body roll at parking speeds. In these cases, all the tires operate at high camber angles and need to be of motorcycle type. The Tracer and the Life Jet are 2F1R types, while the remainder are 1F2R.

13.3.2.1 Tilt Control and General Handling Properties

Free-tilting or largely free-tilting vehicles have their rolling motions controlled by the rider, and the straight-line stability and response properties are similar to those of motorcycles [15]. This implies that they have potential appeal only to people who already can ride a bicycle. The overturning problem that looms large with narrow two-track vehicles is dealt with effectively by the rider

FIGURE 13.17 Mercedes Life Jet all wheel tilting prototype leaning into a turn. (From Foale, T., *Some Technical Aspects of Tilting Trikes*, Tony Foale Designs, Alicante, Spain, 1999, pp. 24, http://www.motochassis.com with kind permission of Tony Foale.)

knowing how to steer and balance at the same time. Counter-steering for fast turn entry, slow lateral responses compared with cars, and long look-ahead times for riders are consequences of motorcycle-type steering [17].

The limit behavior is substantially unknown in a scientific sense, although some anecdotal accounts suggest a very pleasant riding sensation and safety at the limit [18]. From a fundamental standpoint, one might imagine that breakaway at the front would be rare, as with motorcycles, and that the breakaway behavior at the rear would be more progressive and informative than with motorcycles. This thinking stems from the idea that reaching the adhesion limit with a sideslipping tire is the culmination of a process in which the sliding region in the tire/road contact extends further and further forward until it is all embracing. In this process, the sideslipping increases observably, and the driver is warned of the impending limit. The system dynamics are identifiable. The corresponding behavior of a motorcycle tire is less benign. Since side-force generation by camber does not involve sideslipping, reaching the adhesion limit is more sudden and less informative. Thus, it may well be that the three-wheeler of the type under discussion has advantageous limit characteristics.

Some researchers have considered it essential to the mass appeal of tilters that they respond to steering control more like a car [19–21] and, therefore, they need active tilt-control systems. To react the roll torque of the body tilt system, either a nonrolling frame is necessary or the suspension system at the two-wheeled end of the tricycle must be made active, so that the torque reaction is taken at the tire contacts with the ground. By means of tilt control, it is imagined that a much greater proportion of the population will be potential purchasers. Car-like steering can be characterized as involving steering wheel position control and lateral acceleration response at the mass center in the same sense as the steering input. If this is to be achieved with a tilter, the roll control system must be designed to yield leaning-in at the commencement of a lateral maneuver, continuing on to a sufficiently leaned-in steady turning state to substantially reduce or eliminate lateral load transfer.

During the transient, the nonrolling body on the one hand or the whole controlled vehicle on the other hand has to avoid overturning. In the case of a vehicle of the type shown in Figure 13.15, overturning is potentially a response to lateral forces developed at the nonrolling frame tires at ground level but also to those applied to it at the rolling joint and to the reaction torque to that applied to control the tilting frame. Under transient conditions, the nonrolling body is more vulnerable to overturning than a rigid-framed three-wheeler, which is quite unsatisfactory. The situation is similar in principle with an actively suspended tricycle. The more vigorously the tilt-control system deals with the steady-state load transfer problem, the more risky is the transient response to

FIGURE 13.18 The Vandenbrink Carver, showing the front suspension and steering system of the type shown in the right-hand parts of Figures 13.12 and 13.13. (From http://www.carver-technology.com)

a rapid steering input. An unequivocal account of this important difference between the transient and the steady-state behavior of a car-like tilter is given in Ref. [21], but it appears not to have been thought of in Refs. [19,20], where analysis was based on a mathematical model allowing no roll of the trolley, thereby blocking out the problem. However, even in Ref. [21], the rollover problem is not addressed fully.

General user experience with road vehicles that rely on driver restraint to avoid overturning suggests that such vehicles are dangerous and will overturn in practice to a problematic degree. Overturning is a process that includes little in the way of warning. It is difficult for drivers to learn how to avoid it, without employing totally conservative strategies, since, if one nearly overturns, little indication of near disaster is felt and the existing situation persists.

To avoid overturning both under transient and steady-state conditions, with a narrow and relatively tall vehicle, it seems that an active tilt system will have to compromise between car-like and motorcycle-like responses. A trade-off must be made between speed of response to a rapid steering control input and the overturning risk. Full and detailed simulation studies or extensive experimentation is needed to yield appropriate designs. Even then, it may well transpire that some motorcycle-like properties, like counter-steering, will have to be accommodated. It appears doubtful that active tilt control brings enough benefits to compensate for the costs, although there is no doubt that vehicles like the Carver (Figure 13.18) have a very special appeal. The Carver, which is now near to production, has a hydraulic steer by wire system and appears to respond to steering wheel displacements like a car. Running at modest speeds on gravel, it appears to be controllable when sliding both front and rear ends. A crucial test would appear to be one in which rapid steering displacements are applied in high-speed straight-running on high-friction surfaces, this being most challenging in respect of overturning.

13.3.2.2 Stability and Response Properties of the Ariel 3

The results of the straight-line stability analysis of the Ariel 3 tricycle in Ref. [15] are now revisited. Modern multibody systems software can be brought to bear on the problem. and more elaborate

FIGURE 13.19 Ariel 3 front wheel tilting tricycle produced commercially by BSA in the late 1960s and early 1970s (from http://www.mopedarmy.com). The center frame tilts around a slightly inclined longitudinal joint with the rear frame, restrained by a torsion bar, stiff enough that the tricycle remains upright with no rider aboard. The origins of the Ariel 3 are discussed in. (From Jackson, S., The Ariel 3 was classified as an articulated three wheeled moped, http://www.users.globalnet.co.uk.)

models than were previously practical can be built without particular difficulty. The model of [15] has been rebuilt using AutoSim [11], with the modest elaboration that the tires are now radially compliant and the turn-slip terms in the tire forces and moments have been omitted. All the parameter values describing the Ariel 3 tricycle can be found in the original paper. The machine itself is shown in Figure 13.19.

Characteristic root real parts are shown as functions of speed, over the range of 0.5–32 m/s in Figure 13.20, for variations in the stiffness of the roll-restraining torsion bar. Cases treated involve no torsion bar, the standard bar, and a torsion bar with twice the nominal stiffness. These stability properties are similar to those of motorcycles, with the roll instability apparent at low speeds, self-stabilization at about 5 m/s, and weave and wobble oscillatory modes. The stiffness of the roll-restraining torsion bar influences the rider's balancing problem at speeds above 5 m/s, but it is unlikely that a rider would sense much difference between the cases, since the balancing is not difficult in any of them.

Some responses to a sinusoidal steering torque input with magnitude 3.2 Nm and circular frequency 2 rad/s when traveling at 20 m/s are shown in Figures 13.21 through 13.23. The maneuver is somewhat arbitrary, being chosen to show the buildup of large responses over several seconds.

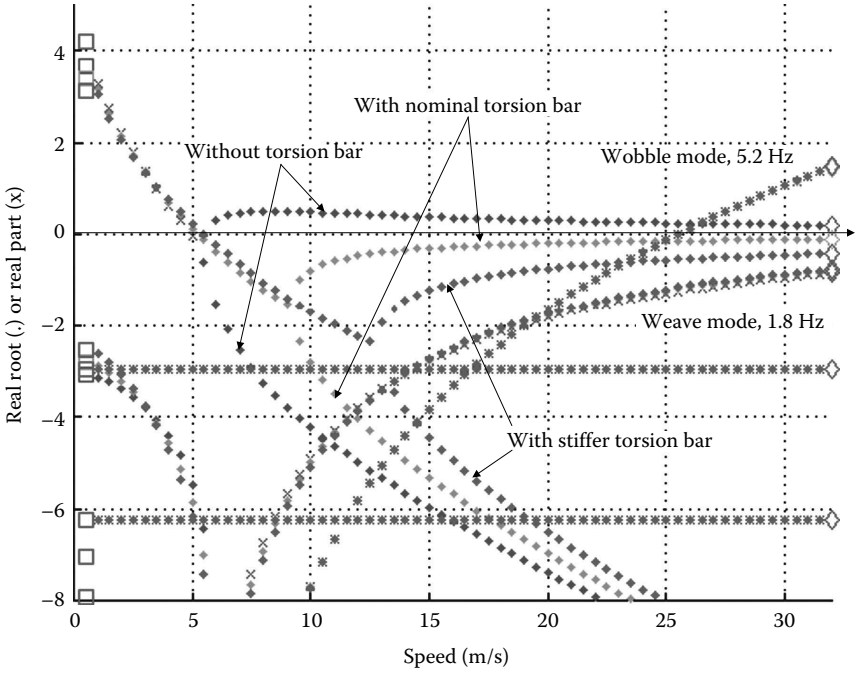

FIGURE 13.20 Ariel 3 real parts of roots as functions of speed without torsion bar, with nominal torsion bar, and with a torsion bar with twice the nominal stiffness. The tricycle can be seen to have weave and wobble modes, with the wobble mode becoming unstable at about 25 m/s speed in all three cases. The weave mode is also substantially uninfluenced by the torsion bar, but the torsion bar does stabilize the capsize motion above about 5 m/s.

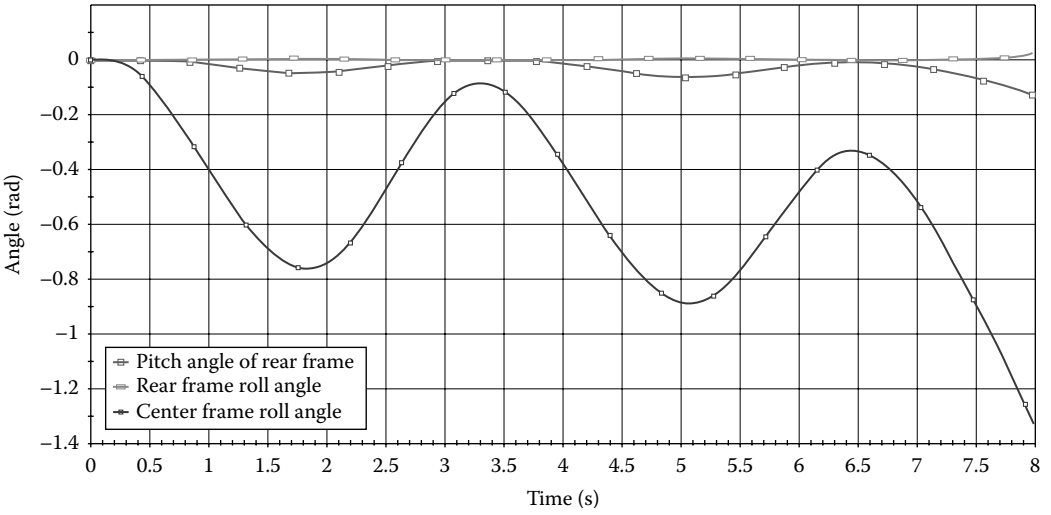

FIGURE 13.21 Ariel 3 pitch and roll angle responses to a sinusoidal steering torque input when traveling straight at 20 m/s.

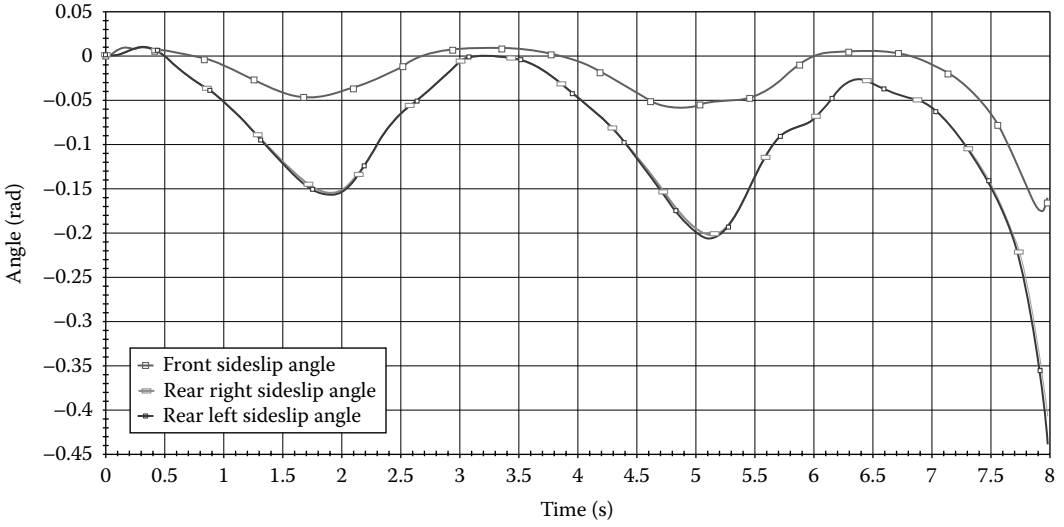

FIGURE 13.22 Ariel 3 sideslip angle responses to a sinusoidal steering torque input when traveling straight at 20 m/s.

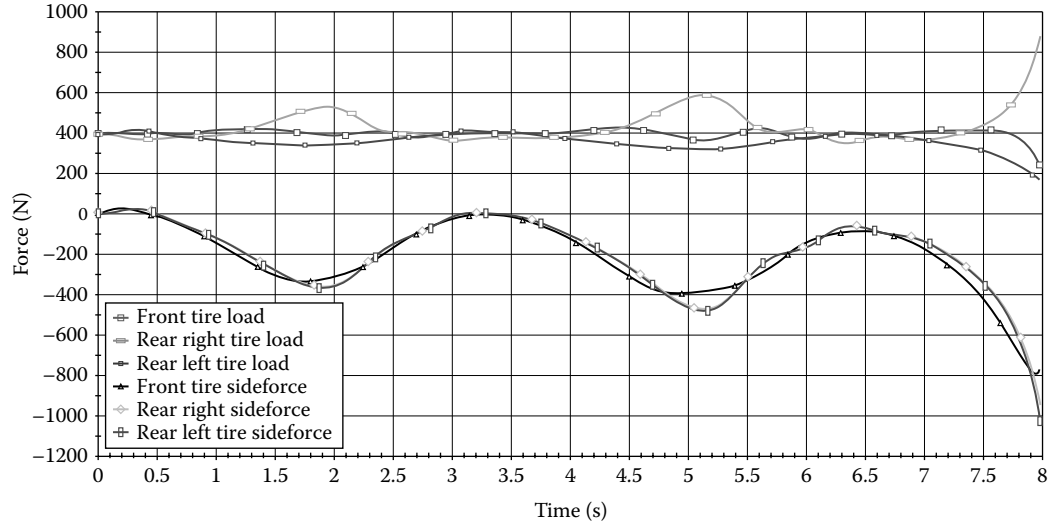

FIGURE 13.23 Ariel 3 tire load and side-force responses to a sinusoidal steering torque input when traveling straight at 20 m/s.

The responses show the buildup of a center frame roll angle larger than 1 rad, while the rear frame roll angle remains small and the load transfers are quite modest. Near to the end of the run, the rear tire sideslip angles grow very large, with that at the front about half as big.

13.4 CONCLUSIONS

How two-wheeled vehicles operate and what matters in their design have been discussed. Types of motorcycle frames, suspension and steering systems, and the antidive and antisquat properties, in particular, have been described. Contrasting types of front suspension and steering systems have

been examined, with their strengths and weaknesses highlighted. A brief consideration of nontilting three-wheeled vehicles is followed by a more detailed account of tilters. Special attention is paid to rollover. This is not a problem with three-wheelers that are controlled in the manner of a motorcycle with the relatively slow responses of a bank-to-turn machine, but it is crucial that it is dealt with effectively in the case of a tricycle intended to steer like a car. A small number of free-tilters have been made commercially, among them the Ariel 3. A new approach in the form of the Carver is near to commercial manufacture. The Carver has an active tilt-control system and appears to steer like a car while banking like a motorcycle. The limit behavior has certainly been tested extensively at moderate speeds on loose surfaces, as evidenced by video material that can be seen on the Carver website.

Tilting tricycles have been analyzed to only a very small extent, with some analyses spoiled by the oversimplified models employed. It is possible to build realistic models of such systems using contemporary multibody software, and the point is illustrated by revisiting an analysis of the Ariel 3 straight-line stability properties, with additional limited results on responses to steer torque control. Load transfers across the rear axle are shown to be small until extreme roll angles of the center frame occur. Controllability of the limit behavior is a vital issue, in respect of which scientific data are lacking. There seems to be an opportunity to apply "worst-case methodology" using optimal control theory [22], to determine the set of initial conditions and control inputs posing the greatest challenge to the rollover immunity.

14.1 INTRODUCTION

The sport of motor racing is heavily constrained by the money and the time to design, build, and develop a car ready for the race events.

Winning in the sport of motor racing requires not only to exploit, to the very maximum extent, the rules that define tires, transmission, engine, and aerodynamics but also to achieve the most efficient driver/vehicle combination for the actual race conditions.

In every motor racing series, the driver/vehicle system operates under stressful conditions where the overall performance is affected by decisions taken before and during the events, usually with

insufficient time or data [1]: In fact, the sport of motor racing occurs within a poorly controllable environment (ambient and track surface conditions, traffic situations), and the final result depends on the interaction between the driver and the vehicle, on how well physically trained the driver is to sustain the various and prolonged physical efforts, and how mentally strong the driver is to consistently control the vehicle [2–4].

Motor racing covers many diverse forms of competitions (endurance, sprint, rally, hill climb), of tracks (permanent or temporary circuits), of vehicle layouts (front-, rear-, or four-wheel drive), and of vehicles (cars, motorcycles, motorboats, quads, etc.) and requires a fair amount of qualified technical personnel (mechanics, engineers, designers, etc.) and also skilled people in the administration, logistics, managing, etc.; all the aforementioned people contribute to a winning car [5].

Some subjects of road car vehicle dynamics are of limited or even marginal significance in motor racing, like driver comfort requirements and active suspensions, while others are generally banned as illegal, like ABS and ESP, since they diminish the importance of the driver on the final result [6].

The following section essentially refers to rear-engine four-wheel passive suspension road racing cars competing in closed circuits, with the traction available only at the rear axle and the steering limited to the front axle.

14.2 VEHICLE DYNAMICS FOR MOTOR RACING

The dynamics of the car body is similar to the dynamics of the aircraft body. In the past, some cross-fertilization between the aircraft dynamics and the ground vehicle dynamics has given fruitful results (see [2,7–9]), even if aircraft dynamics does not deal with the highly nonlinear behavior of the tires (Figure 14.1).

Vehicle dynamics for motor racing (VDMR) is an engineering discipline that studies the interdependencies between driveline, aerodynamics, chassis, suspensions, and tires by means of simulation techniques and verifications on the field, most of the times the actual race

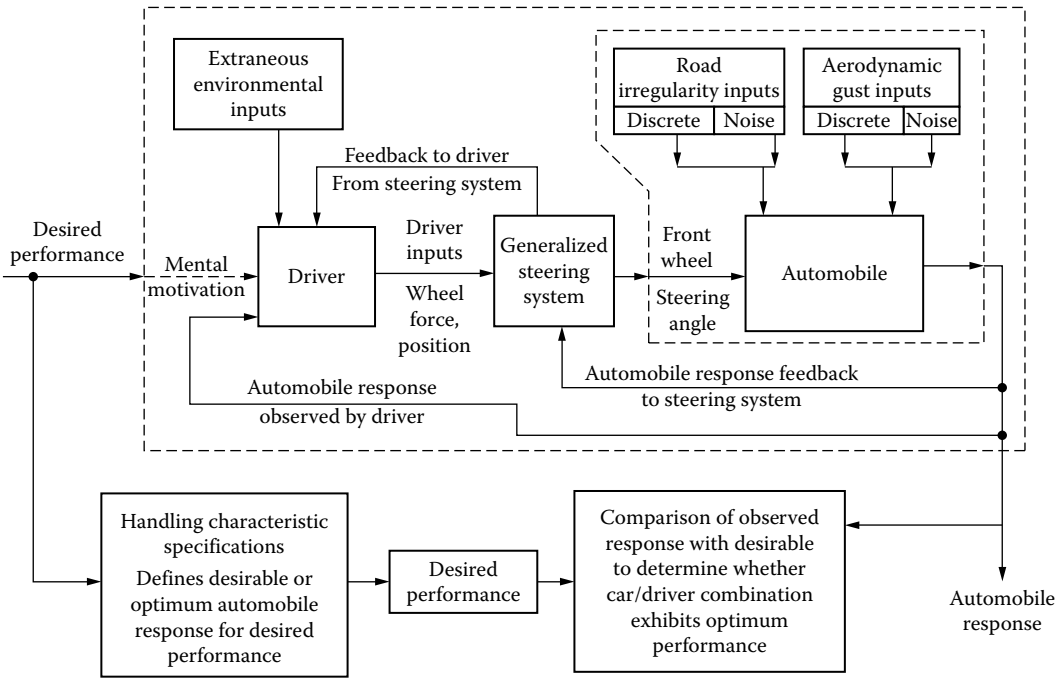

FIGURE 14.1 Car/driver combination: generalized block diagram.

tracks, with the ultimate goal to minimize the lap time, with adequate handling stability and controllability, and with acceptable ride qualities [10].

Some typical basic competences required to the VDMR engineer are straight line and cornering performance simulation, aerodynamics force optimization, tire modeling, onboard-recorded track data correlation with simulated maneuvers, analysis of the driver-to-vehicle interaction, and derivation of the loads onto the main chassis structures and components [1,11,12].

VDMR therefore provides a solid foundation for the vehicle initial concept and guides the ongoing development imposed by the challenges raised by other competitors or by new available technology: in this respect, VDMR is of strategic relevance alongside the vehicle structural and mechanical design, the aerodynamic research, and the manufacturing process.

At a higher complexity level, VDMR also focuses on enabling the racing driver to race consistently, lap after lap, with the highest possible acceleration in the appropriate directions. Accelerations are the direct consequences of forces and moments produced by tires and aerodynamic field. The driver/vehicle system able to consistently generate the highest forces generally wins.

In a reference system fixed with the moving vehicle, accelerations are not limited to the longitudinal axis (velocity modulus variation in braking and acceleration phases) but are also generated along the transverse axis (due to either a modulus or a direction variation of the vehicle speed) and along the vertical axis (due to wheel load variations produced by the road irregularities and in general by forces and moments generated by any means) [2].

Maximum acceleration out of a corner, maximum deceleration while braking into a corner, maximum lateral acceleration in a corner, maximum combined longitudinal and lateral accelerations during the entire corner, and minimum vertical wheel accelerations over the road irregularities are, therefore, fundamental to achieve the optimum performance with the nonobvious consequence that, in motor racing, the car velocity should vary as quickly as possible. Exceptions to the goal of always maximizing the accelerations might occur in temporary or intentional situations like endurance race events, traffic situations, safety and reliability concerns, and intended fuel strategy.

It is common practice for the vehicle dynamics engineer to correlate the longitudinal and the lateral accelerations, either simulated or recorded, so as to determine the maximum combined car acceleration envelope, or g–g diagram, at different speeds or for different cornering radii and to study ways to further widen it [13,14].

One of the biggest challenges for the VDMR expert in correlating the simulation models with the real vehicle is that the acceleration envelope depends on the current environment and track conditions, on many and often nonlinear suspension parameters, on engine characteristics, on the always changing overall weight (due to fuel consumption), on many nonlinear aerodynamics settings, on hardly repeatable driver inputs, and on limited useful life of some fundamental components like the engine, the racing tires, the transmission gears, the wheel bearings, and the suspension ball joint.

The focus of VDMR is not only limited to widening the acceleration envelope but also to offering an adequate level of controllability and stability near the limit of the acceleration envelope. The handling parameters have to suit each individual driver like a “haute-couture” handmade dressing to let him or her consistently drive, race, and win: The same racing car cannot be driven in the same way by two different drivers because of the different physical and mental preferences in terms of inherent vehicle stability, gain, and response time to the driver controls, like brakes, throttle, gearshift, and steering. These quite individual characteristics require, at a high level of vehicle dynamics analysis, a deep knowledge of the driver as a unique performer and thus involve psychology, ergonomics, and neurology competences.

Ride performances (like driver comfort [see Chapter 36], sprung mass accelerations, suspension wheel travel, engine vibration insulation, aerodynamic noise) are not generally a priority in motor racing [15].

Since maximum chassis torsional stiffness and minimum suspension compliance (due to joint stiffness, mounting bracket stiffness, wheel bearing stiffness, wishbone deformation, etc.) are needed to achieve the highest efficiency in applying the forces at the four wheels, the racing car has

all the mechanical parts mounted rigidly, without ride-compliant or vibration-insulation devices, either to assemble the suspension elements or to support the engine and the driveline [16].

Ride quality comes into consideration only if its level is so poor as to endanger the overall lap time performance. If, for example, over curbs or over a local track surface irregularity, the vertical forces at the four wheels vary too much, then the longitudinal and the lateral forces produced inevitably affect the car's handling. To overcome these local ride problems, springs and dampers are tuned for the specific race track but always with particular attention to the handling performance over the entire lap [17].

To study these particular problems and to improve the ride quality performance above an acceptable level, tests are carried out at dedicated indoor test rigs, where four, seven, or even more independent actuators simultaneously act on the car and reproduce any generic road irregularity and even any specific race track profile [18].

14.3 RACING CAR CONCEPT

Racing cars are special vehicles to be driven in competition only; therefore, dedicated design, manufacturing, test, and maintenance techniques are required.

The design cannot always be verified on the field and for the actual conditions of use due to the often rule-limited available track time; moreover, racing cars are produced in limited quantities (8 cars/year for Formula 1, 60 cars/year for a Formula 3), are expected to race for limited time (one or two seasons), are assumed to be continuously developed to match fast-evolving rules and competitors' performance, and are required to be easily tuned for the specific environment or race track conditions.

The frame, or monocoque or tub as it is sometimes referred to, is the most important structure of the racing car. The front suspension and the engine, generally a stressed member, are directly bolted on.

The frame also incorporates the fuel compartment and the survival cell, where the driver is seated. The transmission is mounted on the rear face of the engine, and the rear suspension is bolted on the transmission. The frame, the engine, and the transmission define the spine that, together with the driver, accounts for almost all the sprung mass and where all the remaining auxiliary systems, such as bodywork, aerodynamic devices (if allowed), cooling elements, safety devices, and electronics, are attached to (Figure 14.2).

14.3.1 Metrics

Performance in motor racing, for a complete vehicle and for its single components, is evaluated with few metrics, essentially weight, cost, time, and functions; examples of component functions are the capability of aerodynamic parts to generate downforce or drag, the ability of suspension elements to manage the wheel load variations during the maneuvers and to transmit torque and loads between the tire and the ground, stiffness or strength of structural parts, cooling efficiency,

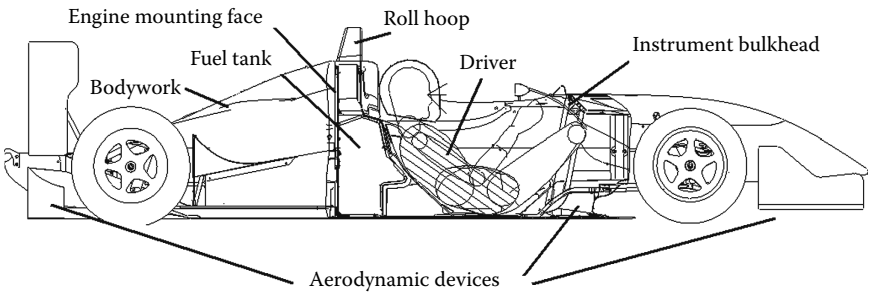

FIGURE 14.2 Racing car layout.

TABLE 14.1
Main Racing and High-Performance Car Characteristics

	Race	Road
Dry mass (no driver) (kg)	450–750	1300–1800
Wheelbase (mm)	2700–3000	2500–2700
Yaw inertia (kg m^2)	900–1150	1700–2500
Downforce (@50 m/s)/weight (%)	100–200	3–5
Power (kW)	150–550	150–500
Power/mass (kW/kg)	0.30–0.80	0.15–0.30
Tire adherence coefficient	1.3–1.7	1.0–1.1
Max acceleration (lateral/longitudinal) (g)	2.5–4.5	1.1–1.3
Center of gravity height (mm)	225–275	350–450

brake distance, steering effort with different steering wheel angles, engine available torque, easy access for tuning and replacement, etc.

When compared to a road car, the racing car has much fewer parameters to be optimized, but these parameters have to be really excellent; the limited set of performance metrics inevitably determines a simple and extremely efficient layout.

The typical wheelbase of racing cars is higher than the one for the high-performance road car, but the weight and the yaw inertia are much lower. So the racing car is subjected to much stronger external (aerodynamics) and internal (braking, engine) forces and moments, and the consequent accelerations are much higher.

A comparison between racing and high-performance road car basic parameters is given in Table 14.1.

14.3.1.1 Functions

The structural function is one of the preliminary ones for all racing components: stiffness is a factor for heavily stressed structural components, like suspension parts and aerodynamic devices, up to the point that sometimes stiffness is more important than ultimate strength. Stiffness versus strength is the typical dilemma in motor racing, not only for the designer, but also for the vehicle dynamics expert, since higher stiffness generally requires more weight or increased cost, if more exotic materials are used.

The most important performance functions of a racing car, as a complete vehicle, are the reliability, the ease of adjustment and replacement, and, above all, the lap time.

A useless part can fail and must not be mounted on any racing car and a necessary part has to fail shortly after the required life.

The racing car must be reliable enough to consistently finish the race and each component has to be designed and manufactured for the appropriate life (and not much more). A part with no evidence of pitting, fatigue, plastic deformation, corrosion, superficial damage, etc., at the end of the targeted life cycle is too heavy and potentially subjected to a redesign. The life cycle can be one race only (like in Formula 1 or in sports car for the 24 h race of Le Mans) or one complete season for a commercially available racing car like a Formula 3.

Redesign can allow for a lighter component, with positive drawbacks on the weight budget, but can carry negative consequences on the money budget and on the production timing.

The racing car must also be easily adjustable, and the design must account for the adequate tuning parameters in order to cover all the potential needs, in terms of cooling, cockpit controls, suspension and aerodynamic settings, etc.

The design must also account for frequent installation and removal of parts, like the engine, the gears, the dampers, and the coolers as the time available at the race track is limited.

For example, valuable track time can be gained if a spring change requires less time: actually, lap time performance is related not only to the car suspension and/or aerodynamic configuration but also to the driver's confidence in the car's expected reactions to the control inputs and to the detailed and fresh memory of the most lap time-efficient driving trajectory.

Lap time is by far the most important performance index for any racing car and it will be covered in a dedicated section.

14.3.1.2 Weight

There is no useless piece in a racing car!

The racing car must be light enough not to exceed the minimum weight limit imposed by the rules but also strong enough not to cause the failure of any component under racing use.

Weight is a primary consideration for the overall performance of any racing car. An overweight car produces less accelerations in all directions for the same amount of generated forces. The weight budget is carefully allocated and continuously adjusted among the different systems and components during the design and development phases: it is the responsibility of the VDMR expert to help the designer allocate the weight budget and to decide over the conflicts between reliability, weight, costs, performance, production time, etc.

To emphasize the characteristics of short transient response, the VDMR and the designer always try to move the heavy components (engine, driver, fuel, transmission, brakes) as close as possible to the center of gravity where even a few millimeters do make a noticeable difference for the expert driver.

Another responsibility for the VDMR expert is the optimal location of the center of gravity between the two axles. The longitudinal location is driven by the tire adhesion and wear properties, the extent of aerodynamic forces and their distribution between the front and the rear axle, the traction torque available at the rear wheels, and the specific race track (i.e., a twisty and tight corner complex or a high-speed speedway).

The design and test efforts to continuously reduce the weight of the components are justified by the quest of lowering the vertical location of the center of gravity to the point that sometimes the accessibility to the components and to the auxiliary systems (like suspension elements, engine boxes, and electric looms) lose priority. If the car is reliably designed underweight, the available ballast, typically between 3% and 10% of the overall car weight and function of the time and money budget limitations, can be secured underneath the car.

A still open question refers on how the inertia tensor can be optimized by adding ballast.

Since lap time performance changes with the overall car weight, the fuel consumption and refueling strategy in the pits are additional aspects studied by the VDMR expert.

14.3.1.3 Time

The time metric considers the interval between the design concept and the race-ready conditions. A car able to compete in an event, but not ready at its maximum performance potential, is the evidence of a big time-planning mistake.

The time schedule to design and build a complete racing car is very tight, and the design, production, and development phases are pretty much overlapped over each other; careful management of all critical aspects like frequent data exchanges between the departments, possible conflicts of responsibilities, and stressed interpersonal relationships are essential (Figure 14.3).

The design review and the test development phases are the most important ones, and multiple iterations are needed up to the point where it becomes impossible to separate the two. Production is always in the loop as new development parts have to be designed in a very short time, be quickly manufactured with high quality and in small quantities, and be tested up until the last minute before a race event. Sometimes, this cycle does not stop even after the race if the results have not been satisfactory, provided that the rules or the budget allows.

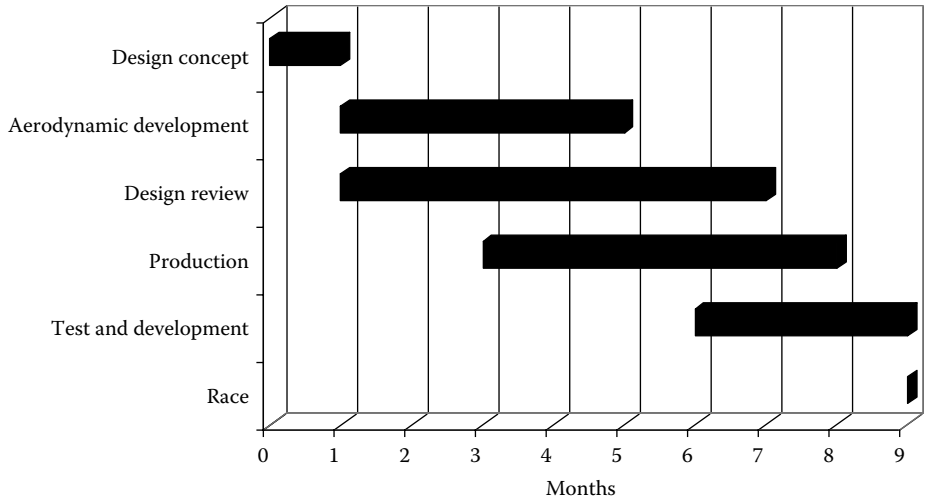

FIGURE 14.3 Time frame to design/build and run a racing car (representative of a Formula 3 project).

The previous aspects very well highlight why a racing car is so different from a road production car. For the racing car, the prototype and the final product do coincide, the product engineering phase is essentially the product development phase, the design is a continuous design review, the time to market is a matter of a few months, and the production costs are marginal if compared to the design, research and development, and testing ones.

Here, the VDMR expert has a pivotal role in the never-ending cycle "design–production–test and development" to objectively predict the lap time reduction per reduced weight and per increased cost or time allocated in the design, production, and test phases.

14.3.1.4 Cost

The racing car as a global vehicle, and every component of it in detail, must be essential and simple in order to maintain the manufacturing time and costs under control.

One piece with multiple functions is usually lighter and cheaper than two pieces with separate functions.

Due to the low production volume and to the identity between the prototype and the actual race car, the production costs are generally lower than the design, test, and development costs.

Attention to costs is always important in all forms of racing competition, since the money budget for any motor racing organization, whether a racing team or a chassis manufacturer, has direct and immediate consequences on the overall car performance (Table 14.2).

TABLE 14.2
Main Racing Car Characteristics for Three Single-Seater Racing Cars (2005)

	a	*b*	*c*
Budget (euro × 1000 as June 2006)	300	800	3,000
Involved people	6	12	40
Complete car mass (no driver/no fuel) (kg)	475	600	710
Engine power (kW)	160	315	510
Mileage per season (km)	12,000	10,000	15,000
Running cost (euro/km)	25	80	200

14.4 RACING CAR KEY COMPONENTS

The three most distinctive subsystems of a racing car, if compared to a road car, are the frame, the suspensions, and the aerodynamics.

14.4.1 "Frame"

The frame of a racing car has two main functions, namely, safety and stiffness. (For additional details on frames, see Chapter 26.)

The frame, or at least a part of it, has to ensure adequate protection both to the driver and to the fuel tank.

The rules governing the racing car design clearly define a set of required tests to assess the frame static stiffness in crucial areas like the fuel tank, the instrument and pedal bulkheads, the ultimate strength in the roll hoop area, and the dynamic strength to survive in severe frontal and lateral crash tests [6].

Provided that the frame does resist all the safety tests, the structure has to be as stiff as possible in torsion, in order to allow the appropriate roll stiffness setting between the front and the rear axle [19,20].

An increase in the frame torsional stiffness is always a positive factor, but it has to be achieved with the minimum weight increase. For this reason, when comparing different frames, or different design alternatives, the frame torsional stiffness is usually normalized to the frame mass (see Table 14.3).

The search for the optimum frame stiffness versus weight has driven the racing car manufacturers to develop composite construction structures, derived from the military and the aeronautic industries. The anisotropic mechanical properties of the composite fibers, like carbon, Kevlar™, and fiberglass (pasted by means of resins, like epoxy and phenolic ones), can be exploited with great advantage to increase stiffness and reduce weight, but as long as the load path distribution is known within an acceptable accuracy. The low production volume of racing cars and the high cost of the raw material and the manufacturing process do limit the applications only to professional racing car series [21].

The frame is only one of the three elements that constitute the "spine;" the other two, in series with the frame, are the engine and the transmission casing, when mounted as stressed members.

The frame stiffness or, in a broader sense, the "spine" stiffness is not the total wheel-to-wheel stiffness, which is the determining factor in defining the four vertical wheel loads in every load conditions, either steady state or transient: here, the missing essential contributor to the overall wheel-to-wheel stiffness is the suspension compliance, due to the wheel bearings, the suspension ball joints, the suspension mountings, the suspension arms, the bell-crank (or rocker) post, etc. [19].

TABLE 14.3
Frame Weight and Stiffness

	a	*b*	*c*
Complete car mass (no driver/no fuel) (kg)	475	600	710
Frame mass (kg)	45	58	67
Engine mass (kg)	105	130	145
Transmission mass (kg)	55	75	80
Frame torsional stiffness (N m/rad)	15,000	22,000	26,000
Frame torsional stiffness/frame mass ($m^2/s^2/rad$)	333.3	379.3	388.0
Frame mass/car mass	0.095	0.097	0.094
Spine mass/car mass	0.43	0.44	0.41
Wheel-to-wheel torsional stiffness (N m/rad)	7,850	9,300	11,300

Wheel-to-wheel torsional stiffness is usually defined and measured without taking into account the tire stiffness.

Since the designer and the VDMR expert have little influence on the engine or driveline torsional stiffness, the frame weight, cost, and stiffness are of main interest.

14.4.2 Suspensions

As for any four-wheeled vehicle, the distribution of the contact loads between the wheels and the ground is not statically determined. (For additional details on suspensions, see Chapter 21.)

14.4.2.1 Contact Patch Forces

Suspension systems for racing cars are designed, developed, and tuned primarily to manage the wheel force distribution between the four wheels during all the maneuvers and to minimize the wheel force variation at the contact patches over the road irregularities. The problem has a difficult solution because the optimum suspension parameter settings are variable with the particular maneuver, driver's input, road irregularities, car speed, and instantaneous accelerations. The vertical wheel forces as well as the lateral and the longitudinal forces at the ground depend on the inertia of the sprung and unsprung masses and on the suspension stiffness and damping.

Every variation of the vertical wheel load at the contact patch affects the tire ability to generate grip, the tire instantaneous working temperature, and the tire wear.

Since tire grip, temperature, and wear have to be balanced front to rear and since every suspension adjustment at one wheel corner does influence the loads at the same wheel corner and at all the other three wheel corners, the quest of the correct balance at the highest possible level of grip requires very sophisticated modeling techniques, continuous cross validations with the real vehicle, and detailed indoor and outdoor measurements of the many and highly nonlinear suspension parameters like vertical and roll stiffness, damping, suspension compliance, friction, backlash, and hysteresis, some of them variable with the working temperature and wear.

The spring stiffness selection is essentially based on the target sprung mass resonance frequencies at the front and at the rear axle, which is a function of the tire stiffness, unsprung mass, relevance of the aerodynamic loads, and aerodynamic load variations with front and rear ride height (RH) (see later Section 3.3), vertical suspension compliance, etc.; other factors coming into play are the engine to power ratio and the race track typology that might have a preponderance of heavy braking or hard acceleration or twisty corners or bumpy sections.

The roll stiffness and its distribution between the front and the rear axles is determined by the race track characteristics, the typical lateral accelerations and cornering speeds, the center of gravity height to the track width ratio, and the tire characteristics in the terminal nonlinear range of slip and camber angles.

The damping characteristic selection follows the spring and the roll stiffness choice, which is responsible for defining the RH in the straights and the roll angle in the center of the corner. Dampers, in fact, are effective and powerful devices to tune the handling of the car during the transient maneuvers, where the wheels have a significant inherent velocity relative to the unsprung mass.

14.4.2.2 Steering and Driver Feedback

The second function of the suspension system of racing cars is to provide the driver with the correct feeling, in terms of vehicle response time, vehicle response gains, steering effort, etc., so the driver can "read" the car at the limit of performance and set the desired trajectory.

The human brain tends to prefer a proportional input–output relationship to be able to subconsciously predict the response to a different input; similarly, a racing driver appreciates when the car reactions to the control inputs are linear. Consequently, all suspension nonlinearities, like motion ratios, roll and ride stiffness, bump rubbers, and spring preloads, have to be carefully considered as they reduce the car predictability.

TABLE 14.4
Steering Ratio (Steering Wheel/Front Wheel)

	a	*b*	*c*
Steering ratio	11.0–14.0	12.0–15.0	12.5–16.0

The driver controls the racing car in a complex way, partially in open-loop control mode and partially in feedback control mode. Because of the reduction of the yaw damping with speed, the higher the vehicle speed, the more the driver has to drive in an open-loop mode. For racing on ovals, for example, the speed is very high, up to 240 mph (over 100 m/s): There is no time to finely readjust the control inputs, and it is necessary to apply the precise steering input to have the vehicle take a set on the intended trajectory at the end of the turn, seconds later, away from the inside and outside walls [2,11].

On the very opposite, for rally races, where the speed is much lower, the vehicle is driven almost in closed loop, and an instant feel of the car attitude (yaw, sideslip, and roll) is needed for the driver to control the car on a highly variable grip surface.

The aforementioned two extremes of driving a race car clearly require different suspension settings not only to maximize, at every instant, the contact between each tire and the ground and to optimize the distribution of the vertical loads between the four wheels but also to give the driver the correct feedback information in the appropriate time, neither too late or too soon, depending on the vehicle speed and weight, engine power, race track geometry, tire properties, etc. (Table 14.4).

Cars running on oval tracks at very high speed and for prolonged time do require "slower" steering ratios, both to reduce the steering effort for the driver and to provide a higher angular resolution at the steering wheel.

14.4.2.3 Suspension Tuning

Tuning the car's handling by adjusting the vehicle reaction times and output overshoot is of primary relevance in racing where the steady-state conditions are such a marginal percentage of the overall lap time. The understeer/oversteer characteristics are not exhaustive enough to judge on the handling performance [2,22]. Tuning a racing car means changing its handling balance, or in other terms redistributing the produced grip between the front and the rear tires.

The racing tires have to be exploited at or near the maximum of their adherence capabilities, which happens in their nonlinear range of operation. The efficiency of the settings of springs, dampers, antiroll bars, and roll and pitch centers is to be evaluated away from the linear range of the tire working characteristics. Due to the nonlinear nature of the tire characteristics, the amount of lateral grip available on one axle depends on the lateral load transfer between the inner and the outer wheel and on the distribution of the roll stiffness between the two axles; therefore, the management of the vertical wheel loads is the key to tune the racing car [23].

14.4.3 Aerodynamics

14.4.3.1 Aerodynamic Loads

Aerodynamic forces acting on racing cars are roughly proportional to the square of the car speed and are comparable with the vehicle weight [24,25]. (For additional details on aerodynamics, see Chapter 16.) The main focus of vehicle dynamics when dealing with aerodynamic forces is to handle their violent variation with speed and their distribution between the front and the rear axles.

The aerodynamic forces are usually decomposed in three terms, either total downforce, drag, and total downforce balance front to rear or front axle downforce, rear axle downforce, and drag. Aerodynamic efficiency is defined as the ratio between the total downforce and the drag and comparison between two different aerodynamic configurations is not a straightforward operation since, given the same efficiency, the aero balance or the drag might be different.

TABLE 14.5
Total Aerodynamic Loads at (50 m/s), Air Density at 18°C, 0% Relative Humidity, Atmospheric Pressure 1013 mb

	a	*b*	*c*
Complete car mass (no driver/no fuel) (kg)	475	600	710
Downforce (N)	3500	5800	6900
Aero balance (%front)	42	40	38
Drag (N)	1550	1650	2550

Some aerodynamic loads, for the three representative vehicles mentioned earlier, are listed in Table 14.5.

The indirect but important effect of the aerodynamic forces on handling comes through the tires. Provided that the tires are able to generate grip (lateral or longitudinal or both combined), based on the vertical load applied, an increase in vertical load improves the capability of the tire to generate grip. Aerodynamics is a very powerful and delicate tool to achieve handling characteristics that vary with speed [26].

At a given speed, a racing car running in close proximity to the ground produces forces primarily dependent on the front and rear RH as measured at the wheel axle. This concept is referred with the term "aeromap" that is the tabular or graphical representation of the variation of how the aerodynamic parameters like front downforce, rear downforce, total downforce, aero balance, and aerodynamic efficiency and drag vary with front and rear RH (Table 14.6).

Aerodynamic forces also depend on other parameters like the heading of the car to the wind (determined by the car yaw angle), the roll angle (which primarily influences the aerodynamic loads generated by the underside of the car), and the steering angle of the front wheels (particularly important for open wheel racing cars). In the last example, the objective is to minimize the aero-balance variation due to the steering wheel angle or to achieve a desired relationship so as to modify the handling qualities for specific speeds or cornering radii during turn-in, mid-corner, power-on application maneuvers. This analysis requires a highly nonlinear simulation model because the required steering angle is function of the grip generated by the tires that

TABLE 14.6
Front Downforce Load (N) at 180 km/h (50 m/s), Air Density at 18°C, 0% Humidity, Atmospheric Pressure 1013 mb

	Front Downforce (*N*)
Front RH = 10 mm/rear RH = 15 mm	2800
Front RH = 10 mm/rear RH = 20 mm	2850
Front RH = 10 mm/rear RH = 25 mm	2880
Front RH = 15 mm/rear RH = 15 mm	2540
Front RH = 15 mm/rear RH = 20 mm	2580
Front RH = 15 mm/rear RH = 25 mm	2630
Front RH = 20 mm/rear RH = 15 mm	2400
Front RH = 20 mm/rear RH = 20 mm	2480
Front RH = 20 mm/rear RH = 25 mm	2540

in turns depends on the vertical loads, variable with front and rear RH, roll, yaw and steering angle, speed, longitudinal and lateral accelerations, etc.

As a further refinement, some aerodynamic transient loads are generated by variable car speed and variable front and rear RH that occurs when the car is maneuvering in violent braking, turn-in, and power-on phases.

Aerodynamic forces are measured in specialized wind tunnels equipped with rolling belts, able to simulate the ground traveling at the same speed as the air speed, or are computed by dedicated "computational fluid dynamics" (CFD) softwares [27,28]. It is also possible to measure the aerodynamic loads while the car is running, either at dedicated facilities instrumented with load cells embedded in the ground or directly at the race tracks with cars equipped with speed and acceleration sensors and with suspension load cells on the suspension elements.

Aerodynamic forces and their distribution between the front and the rear axle are also greatly influenced by traffic conditions, and for this reason, dedicated measurements are carried out with complex layouts in the wind tunnels or at the race tracks, to study the effects on cars running at a few lengths from each other, and within total or partial slip stream.

The big difficulty with outdoor testing is that the improvements sought are very small, in the order of a few percent between one complete car and its predecessor of the previous season, and the environment conditions are never fully controllable and repeatable. Therefore, outdoor testing, including coast-down tests [29], is becoming less and less relevant for racing applications because their cost is comparable with the cost associated with running a scale model in the wind tunnel or a virtual model with a CFD software.

14.4.3.2 Pitch Sensitivity

Another factor affecting the vehicle dynamics is the aerodynamic pitch sensitivity, generated by the variability of the aerodynamic forces with front and rear RH, and it is usually modeled by means of nonlinear skyhook speed-dependent springs and dampers that reduce the effective suspension stiffness and damping between the sprung mass and the unsprung masses [30].

Since the aerodynamic loads are speed dependent, the effect on the ride dynamics is the reduction of the static and the dynamic stability margins with speed, while the effect on handling is the redistribution of the vertical tire loads between the front and the rear axles [31].

14.4.3.3 Polar Curve and Aerodynamic Tuning

Downforce and drag forces can be adjusted by means of a great variety of parameters, like the angle of attack of the wing elements, gurney flaps, splitters, bargeboards, and inlet and exit radiator shutters; all these possible aerodynamic adjustments define an envelope curve that is referred as the car aerodynamic "polar" curve, since an excellent approximation of the curve is achieved with a second-order polynomial function relating total downforce to drag (Figure 14.4).

For a given set of car weight, engine power, and ambient conditions, the lap average speed for every race track is calculated for reasonable ranges of drag and downforce levels: Each pair of drag and downforce produces a defined result in terms of lap time, where more downforce usually increases the lap average speed up to the point that corners are coped easily at full throttle; conversely, more drag typically reduces the lap average speed as it reduces the net available longitudinal acceleration on the straights (Figure 14.5).

The lap time (or the lap average speed) is primarily a function of the car weight (full tank versus qualifying with minimum fuel) and of available engine power (race engine versus a qualifying engine, air density). The aerodynamic polar curve is a function of the ambient conditions through the air density factor. The fundamental task of the VDMR expert, when dealing with aerodynamic data, is to identify the optimal range of aerodynamic configurations that minimize the lap time for each race track, modeled as a peculiar set of cornering radii, straight-line lengths, local grip coefficient, banking, and slope changes.

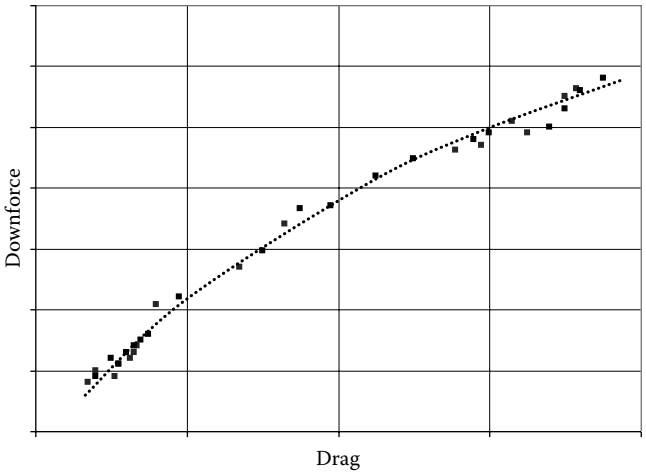

FIGURE 14.4 Polar curve as the envelope of all possible aerodynamic configurations and settings.

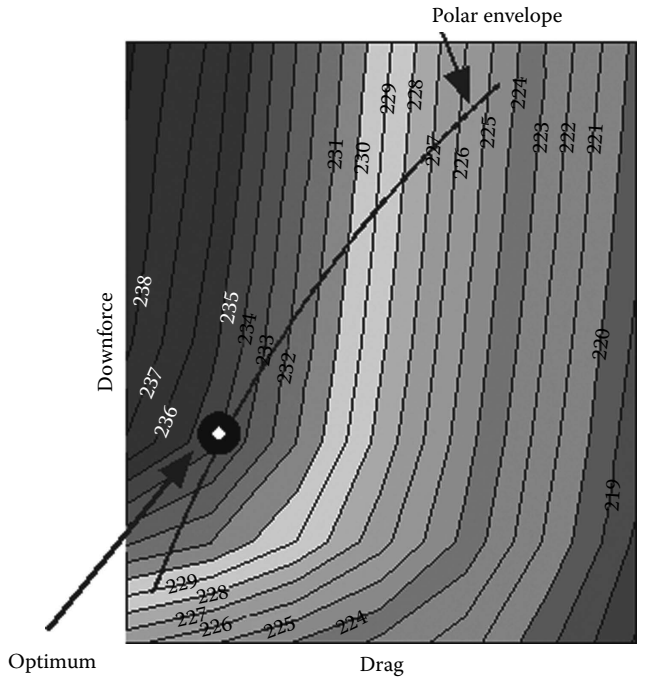

FIGURE 14.5 Polar curve and the average lap speed (km/h) matrix. Best aerodynamic configuration found.

At a more advanced level, the total downforce and front to rear aerodynamic balance have to be optimized to overcome a localized event on the race track, that is, to improve a local situation where the vehicle longitudinal or lateral or combined accelerations are limited by ride qualities over a local surface irregularity or by handling characteristics under severe maneuvers.

14.5 RACING CAR PERFORMANCE: LAP TIME

Lap time reduction is the ultimate goal of all people involved in racing [32].

Besides the aforementioned addressed engineering aspects, other hardly quantifiable aspects can affect lap time performance, especially for endurance races. They are the driver's

TABLE 14.7
Typical Lap Time Reduction (s)

	a	*b*	*c*
Weight decrease 1%	0.25	0.20	0.17
Center of gravity height decrease 1%	0.02	0.02	0.03
Level of grip (track/tire) increase 1%	0.30	0.32	0.35
Downforce increase 1%	0.05	0.07	0.08
Drag decrease 1%	0.13	0.12	0.10
Engine power increase 1%	0.15	0.14	0.12

psychology, the seat position, the visibility through the windscreen, the instinctive access to the car controls, and the cockpit temperature.

14.5.1 Car Performance

Let us base our lap time considerations on a typical 100 s lap (1 min 40 s).

For the same reference vehicles listed earlier (*a*, *b*, *c*), the following table shows the typical lap time reduction (in seconds) expected by improvements of the main performance parameters. Over a 100 s lap time, 1 s lap time reduction corresponds to one-hundredth performance improvement, and one-tenth of a second lap time reduction corresponds to one-thousandth performance improvement (Table 14.7).

From the aforementioned typical data, it appears that a one-hundredth improvement for the most important car parameters, like weight, engine power, tires, downforce, and drag, does not achieve anything close to a one-hundredth lap time improvement: all resulting lap time improvements are one order of magnitude smaller!

The aforementioned parameters are the *mean focus* of all vehicle dynamics analysis and do require very detailed and proven vehicle models as they drive the decision-making process of allocating the technical and human resources between design, structural analysis, wind tunnel testing, production, and track testing.

Also, each race track has distinctive lap time sensitivities to weight, engine power, tires, downforce, or drag adjustments.

These factors are generally constrained as it is difficult and very expensive to increase the engine power without losing reliability and it is not possible to run below the minimum legal weight or are interdependent as an increase in downforce is most of the time achieved at the expense of additional drag.

14.5.2 Car Development

14.5.2.1 Setup

"Setup" is a general term used in motor racing to define the set of all possible parameters/options/configurations of a racing car. Since the racing car is essentially an always evolving prototype, the setup has to be at the same time a rather flexible list in order to account for new development options and, on the other side, a very meticulous one in order to document, down to the small details, the particular configuration of the car so to reproduce its performance and baseline it to test further development components [2].

The setup has to be specific for the running conditions: the qualifying setup aims at letting the car achieve in a short-run maximum grip and ultimately the minimum single lap time even at the expense of high tire wear, partial driver discomfort, and temporary overstress on some car components.

The race setup is optimized to achieve the minimum overall race time, over a multiple sequence of long runs where it is difficult to predict the stabilized thermal working equilibrium of the four tires after ten or twenty consecutive laps.

In a very broad sense, the determining factor to achieve the minimum overall race time is the ability to predict, either by calculations or by experimental evidence, the performance decays of all systems, including the driver, over a prolonged time: typical and clear examples are the 24 h of Le Mans and the Indy 500.

Many factors do have an influence on lap time [2]; examples are given to highlight some conflicting requirements:

- Hotter ambient conditions do affect downforce and drag by the same amount through the decrease of the air density.
- Higher tire pressure reduces rolling resistance and wear but reduces grip.
- Less aero downforce increases the tire wear.
- Higher steering effort might allow the driver to get closer to the tire performance limit but can tire the driver.
- Higher camber angles might allow higher speed in the corner but increase wear and reduce straight-line performance in braking and acceleration.
- Less fuel load improves lap time due to the reduced overall weight but requires more frequent stops for refueling or the adoption of a leaner fuel injection engine map.

All vehicle dynamics aspects in a racing car, like aerodynamics, engine power, car weight, braking components, suspension components, and frame stiffness, ultimately rely on the tire properties to generate adequate grip, to wear evenly front to rear, and to work within a narrow temperature range.

The tire behavior ultimately dictates the final decisions over the desired handling properties, the driver's confidence, and the suspension and aerodynamics settings, especially in the long run (>30 laps).

The minimum lap time target depends also on the actual racing car trajectory ("the racing line"), which is hardly repeatable over the 10–14 corners of a typical road course circuit. To make the matter more complicated, the racing line is also influenced by the setup.

For example, more downforce allows a more violent braking into the corner and an earlier power application out of the corner and increases the cornering speed with effects on RH and on the suspension working point. The race line and the setup also depend on the particular driving style and on the characteristic skills of each driver.

Consequently, the minimum lap time might not have a unique solution or if unique, not a robust one [33].

14.5.2.2 Tires

The most important factor to optimize the lap time performance is the tire (Table 14.6). (For additional details on tires, see Part III.) The ability to predict how to tune the setup for the ambient conditions (level of grip of the track surface, track temperature, and ambient temperature) associated with the knowledge of the tire optimal working temperature, wear, and grip capability are the key factors to winning [34,35].

By taking the average time spent, over the course of one complete racing season, by single-seater cars racing on permanent circuits, it is possible to find out that for 45%–55% of the time, the car is in cornering situations, with high levels of yaw rate or yaw accelerations (steady-state or transient cornering maneuvers); for 35%–40% of the time, the engine is producing a fair amount of torque with significant level of longitudinal accelerations (on-throttle phases) and, finally, for 10%–15% of the time, the brakes are applied to produce violent longitudinal decelerations.

The total of the three aforementioned cases is more than 100% since the racing driver is always trying to use the engine power as early as possible out of the corner and to brake as late as possible into the corner.

While cornering, and in particular during transient cornering maneuvers, the front tires are stressed more than the rear tires; similarly, due to the heavy longitudinal load transfer while braking, the front tires are producing around 60% of the total braking forces.

It is therefore necessary, in order to optimize the tire load capacity, the grip demand, and the wear resistance between the front and the rear tires, to have the rear tires perform the driving function: this is one of the main reasons why the vast majority of racing cars are rear-wheel driven.

The tire is a combination of many elastomeric materials with a pronounced nonlinear ability to produce longitudinal and lateral grip based on the applied vertical load and on some geometry variables like camber, slip, and longitudinal slip. The geometry variables also influence the tire contact patch shape, tread pressure distribution, and wear. Moreover, the racing tire performance is dependent on the tread working temperature and on the micro- and macrotrack surface roughness, which is specific for every circuit.

Unfortunately, the generally available tire models do not describe the grip dependency from the temperature and from the surface roughness and therefore are of limited application in racing [36].

The role of the VDMR expert when dealing with tires is to build and tune the tire models to make the simulations representative of the reality, so as to produce reliable lap time predictions for the entire range of vehicle performance design and setup variables [34,37].

14.5.2.3 Driver

The racing driver is a very important factor in the overall performance. (For additional details on driver models, see Chapter 38.)

In order to achieve the highest performance of the vehicle/driver system, it is crucial to optimize the seat position, the easy access to all controls (gearshift, steering, throttle and brake pedals, switches, etc.), and the feedback from the steering wheel and the disturbances from the environment (front, rear, and side visibility, windscreen and helmet buffeting, etc.).

Two professional race drivers, driving the same chassis and the same engine for the same team, typically achieve a lap time performance within 0.2 s from each other over a 100 s lap time, so we can realize how efficient and repeatable machines the professional racing drivers are inasmuch as they are repeatable within 99.8%.

Racing, above all, is a mental sport.

The psychology and the character affect the driver performance over the course of a season and are the deciding factors for a professional racing driver to become a race winner or, ultimately, a champion. It is rather easy to win some races, but it is not easy to be consistently fast and bear the stress raised by the competitors and the technical and sporting challenges.

Every aspect on the car that reduces the level of stress of the driver while racing at the limit can be the subject of a vehicle dynamics study.

The professional racing driver is generally young, 8–14 years old in go-karting to 25–30 years old in single-seater Formulas like F3 to F1, and a vast majority of these professional racing drivers have had to stop, rather prematurely, attending the regular school classes in order to race.

The young age and the sometimes incomplete scholastic experience can make a driver reluctant to deeply learn some important technical aspects of the racing car and to stand criticisms, comments, and judgments or even to discriminate between true or false technical information.

Finally, in order to be successful, the professional racing driver has to have a very strong self-achievement motivation, sometimes even at the expense of his or her teammate or of all the people working in the same racing team.

Since the VDMR expert has to continuously deal with the interaction between the driver and the car, it is important for the VDMR expert to work together with the driver psychologist or the personal trainer, if available. In more general terms, the VDMR expert has to understand, properly value, and eventually influence the working relationships inside the racing team in order to let the racing driver become a mature, conscious, consistent, and reliable performer.

Steady-state situations like steering pads or maneuvers in prolonged constant radius corners do require a well-defined steering wheel angle to maintain the car in equilibrium at the maximum available speed and, therefore, do not depend much on the driver's ability. Non steady-state maneuvers, and racing is

all about handling in non steady-state maneuvers, require the driver to apply his or her controls (brakes, throttle, steering, gear shift), to judge on the car reactions, and sometimes to further finely adjust his or her inputs in a never-ending process [38]. Driver models are, therefore, very important to perform any type of race car simulations to the extent that it becomes difficult to discriminate between the car and the driver performance because the car and the driver are essentially a single symbiotic system [39,40].

Driving a race car, professionally and consistently, requires dedicated training and continuous race track practice, which are available at specialized racing schools [41–44].

The race driver has some characteristics in common with the aircraft pilot, like terminology, safety procedures, debrief, and even clothing and apparel [45], but there are some differences: A race car simulator is a luxury limited to the biggest Formula 1 teams and not available to the general driver; the racing driver has a rather short span and a generally limited technical preparation. Also, race driving is an individual sport, and there is no chance or reason why professional test drivers might develop the car for other racing drivers.

Racing is quite similar to a duel between multiple aircraft military pilots: the drivers and the pilots have to get ready for the race or the mission, properly determined in their mind to overcome at any cost the opponents.

Racing drivers and military aircraft pilots have to conserve their rationale up to the point that to win a race or to survive a military flight duel, they cannot hate their competitor or enemy as this irrational feeling absorbs mental energy and makes them focus too much on the details and finally loses their spatial perception of the global environment and the time-ordered hierarchy of their actions and reactions.

To be a successful race driver or an excellent military aircraft pilot, it is necessary to psychologically stress the competitors, to make them lose their concentration, and finally, to make a mistake.

It is very instructive, at the end of a race, to watch the drivers leave their cars: those drivers who are able to show a calm attitude, to cheer to the fans, and to their competitors have greater chances to win than nervous drivers who lost their temper because of a racing accident or simply because everything did not go as desired.

14.5.2.4 Driving Simulator for Race and High Performance Cars

Driving simulators are increasingly used for race applications [47]. They can be particularly useful for driver coaching. They can also be used for the development of setups (e.g., to assess tire thermal effects for both qualifying and race setups) and for data analysis (e.g., to analyze tire forces).

A new generation driving simulator (Figure 14.6) features nine degrees of freedom and is designed to take full advantage of the motion cueing algorithm [48–51] based on an MPC approach

FIGURE 14.6 Driving simulator at Ferrari.

with in-the-loop real-time optimization. It consists of a hexapod mounted on a triangular-shaped frame, sliding on an even and stiff steel surface by means of a combination of air and magnetic bearings. The hexapod generates vertical, pitch, and roll movements, as well as small yawing movements and movements in longitudinal and lateral directions. The sliding frame makes the driver feel the longitudinal, lateral, and yaw accelerations. The driving simulator platform is suitable for testing both vehicle dynamics and ride comfort.

14.6 CONCLUSIONS

VDMR is an engineering discipline that covers many aspects of the racing car performance and therefore has a strategic role, from the initial concept down to the final tuning, to help the designer, the production manager, the race engineer, and the aerodynamicist optimize the overall lap time performance and to ensure adequate handling and ride qualities.

The racing driver is a fundamental part of the driver/vehicle system, and his or her individual driving preferences are pivotal to the overall lap time. For these reasons, vehicle dynamics has to translate the subjective feedback from the racing driver into objective performance indexes.

15.1 INTRODUCTION

The main purpose of this chapter is to explain the importance and complexity of the brake system for a racing car.

The importance of the braking system refers to both reducing the number and severity of accidents and reducing lap times. Hence, braking is one of the most critical areas of racing car.

In this chapter, the experience and data gathered by some of the authors in Formula 1 (F1) races are included. It is important to highlight that the numbers reported in the following tables are representative of an F1 car of years 1999–2002, but the approach and the modeling remain relevant today.

This chapter is divided into four main topics:

1. F1 car behavior under straight-line braking
2. F1 braking system layout
3. Brake energy dissipation during a single lap
4. Brake caliper design and friction material characteristics

Braking is important for race cars because shorter stopping distances also mean that the engine can be at full power for a longer time and the car's lap time can be dramatically improved. (For more details on race cars, see Chapter 14.)

15.2 F1 CAR BEHAVIOR UNDER STRAIGHT-LINE BRAKING

The main phenomena that affect the car during the braking maneuver are addressed.

The mathematical formula that gives the ideal braking force that the car can exert and the ideal braking balance (front-to-rear ratio) during braking is given.

In Table 15.1, the main parameters for the description of a braking F1 car are reported along with their respective typical values.

TABLE 15.1
Car Parameters

Parameter	Typical Value	Name
μ	1.5	Tire friction, constant and equal for all tires
m	600 (kg)	Mass (including driver, empty condition)
$\alpha = \frac{Z_f}{Z_f + Z_r}$	0.42	Front weight distribution
h	0.285 (mm)	Center of gravity height
h_{cp}	0.285 (mm)	Center of pressure height
l	2955 (mm)	Wheelbase
ρ	1.225 (kg/m^3)	Air density
S	1.45 (m^2)	Car frontal area
C_{zT}	2.4	Total lift coefficient
$k_a(v) = k_1 v^2 + k_2 v + k_3$	$k_1 = 0$ (s^2/m^2) $k_2 = 0$ (s/m) $k_3 = 0.35$	Aerodynamic balance of the car as ratio between front and total downforce. In general, it is function of speed (v).
$C_{zf} = k_a \times C_{zT}$	0.84	Front lift coefficient
$C_{zr} = (1 - k_a) \times C_{zT}$	1.56	Rear lift coefficient
C_x	0.98	Drag coefficient

Source: B. Breuer and K.H. Bill, *Brake Technology Handbook*, SAE, Troy, MI, 2008.

During a braking maneuver, three important aerodynamic forces are acting on the car. These forces are also present in a normal production car but due to their very low values are normally neglected. These three forces (aerodynamic downforces at the front and rear axles, respectively, and aerodynamic drag at the center of gravity) affect the overall braking performance of the car.

Referring to Figure 15.1 and considering the parameters of Table 15.1, the following formulas describe longitudinal (Equation 15.1) and vertical (Equation 15.2) equilibrium and rotational equilibrium around front (Equation 15.3) and rear (Equation 15.4) contact points:

$$X_f + X_r + F_d = ma \tag{15.1}$$

$$Z_f + Z_r = F_{lf} + F_{lr} + mg \tag{15.2}$$

$$Z_f l - F_{lf} l - mgl_r - mah + F_d h_{cp} = 0 \tag{15.3}$$

$$Z_r l - F_{lr} l - mgl_f + mah - F_d h_{cp} = 0 \tag{15.4}$$

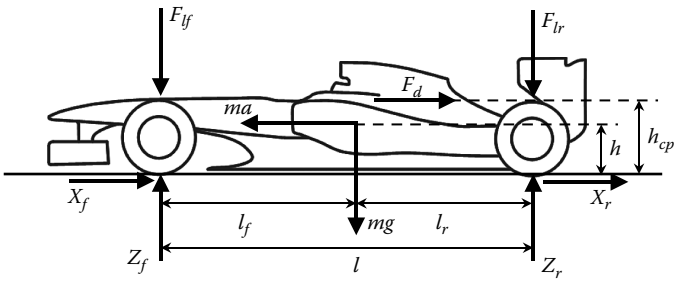

FIGURE 15.1 Forces acting on a racing car during braking.

When approaching locking conditions, $X_f = \mu Z_f$ and $X_r = \mu Z_r$. From Equations 15.3 and 15.4, the longitudinal forces can be computed as

$$X_f = \mu Z_f = \mu m\left(g\frac{l_r}{l} + a\frac{h}{l}\right) + \mu F_{lf} - \mu F_d\frac{h_{cp}}{l} \tag{15.5}$$

$$X_r = \mu Z_r = \mu m\left(g\frac{l_f}{l} - a\frac{h}{l}\right) + \mu F_{lr} + \mu F_d\frac{h_{cp}}{l} \tag{15.6}$$

From Equations 15.1 and 15.2, the longitudinal acceleration can be computed as

$$X_f + X_r = \mu(Z_f + Z_r) = ma - F_d \Rightarrow a = \frac{\mu}{m}(Z_f + Z_r) + \frac{F_d}{m} = \frac{\mu}{m}(F_{lf} + F_{lr} + mg) + \frac{F_d}{m} \tag{15.7}$$

Finally, by replacing Equation 15.7 in Equations 15.5 and 15.6, the front and rear longitudinal forces read

$$X_f = \frac{\mu mg}{l}(l_r + \mu h) + \mu\left(\mu\frac{h}{l}(F_{lf} + F_{lr}) + F_{lf} - F_d\frac{h_{cp} - h}{l}\right) \tag{15.8}$$

$$X_r = \frac{\mu mg}{l}(l_f - \mu h) + \mu\left(\mu\frac{h}{l}(F_{lf} + F_{lr}) + F_{lr} + F_d\frac{h_{cp} - h}{l}\right) \tag{15.9}$$

Equations 15.8 and 15.9 can be rewritten as a function of the car parameters by considering the expression of the aerodynamic lift forces* and the weight balance of the car:

$$X_f = \mu mg\left(\alpha + \mu\frac{h}{l}\right) + \frac{1}{2}\rho v^2 S\mu\left(\mu\frac{h}{l}C_{zT} + C_{zF} - C_x\frac{h_{cp} - h}{l}\right) \tag{15.10}$$

$$X_r = \mu mg\left(1 - \alpha - \mu\frac{h}{l}\right) + \frac{1}{2}\rho v^2 S\mu\left(-\mu\frac{h}{l}C_{zT} + C_{zR} + C_x\frac{h_{cp} - h}{l}\right) \tag{15.11}$$

The brake balance of the car can be defined as

$$F_{B,dist}(v,\mu) = \frac{X_f(v,\mu)}{X_f(v,\mu) + X_r(v,\mu)} \tag{15.12}$$

Equations 15.10 through 15.12 give the ideal brake force distribution, provided that the friction is equal at front and rear tires and that front and rear tires work at adherence limit.

The considered equations have been derived from the equilibrium of the vehicle; thus, this formulation is still valid in case car parameters vary during braking, provided that the constant parameters are replaced by the corresponding functions. In this case, actual tire properties (friction variation due

* The aerodynamic lift forces can be computed as [3]

$$F_{lf} = \frac{1}{2}\rho C_{zF} S v^2, \quad F_{lr} = \frac{1}{2}\rho C_{zR} S v^2, \quad F_{lT} = F_{lf} + F_{lr} = \frac{1}{2}\rho C_{zT} S v^2, \quad F_D = \frac{1}{2}\rho C_x S v^2$$

to temperature, vertical load, and rolling speed), realistic and speed-dependent aerodynamic data, car suspension geometry (antidive effects), and center of gravity and wheelbase variations due to load variation have to be taken into account. Very complex models have to be developed in order to derive the functions describing the dependence of the car parameters on such variations.

Referring to aerodynamic forces (lift and drag coefficients), it has been proven, both mathematically and experimentally [1,2], that such forces are functions of the attitude of the car. In particular, during braking, a certain amount of pitch and heave is present, depending on suspension and tire stiffness, varying the height of the front and rear of the vehicle. In [3], it has been shown that variation of the front and rear heights of the vehicle (depending on the heave of the center of gravity and on the pitch angle) are responsible of sensible variations in the front and rear lift coefficients. The maps of the kind of the ones shown in Figure 15.2 can be used to relate the lift coefficients to the current front and rear heights during the maneuver. Experience has shown that in case of a braking maneuver of an F1 car, the variation of these coefficients has effects on the dynamic of the vehicle up to the second derivative.

In Figure 15.3, the ideal braking balance of an F1 car has been depicted by considering the variations of friction and aerodynamic coefficients during a braking maneuver from 300 to 120 km/h.

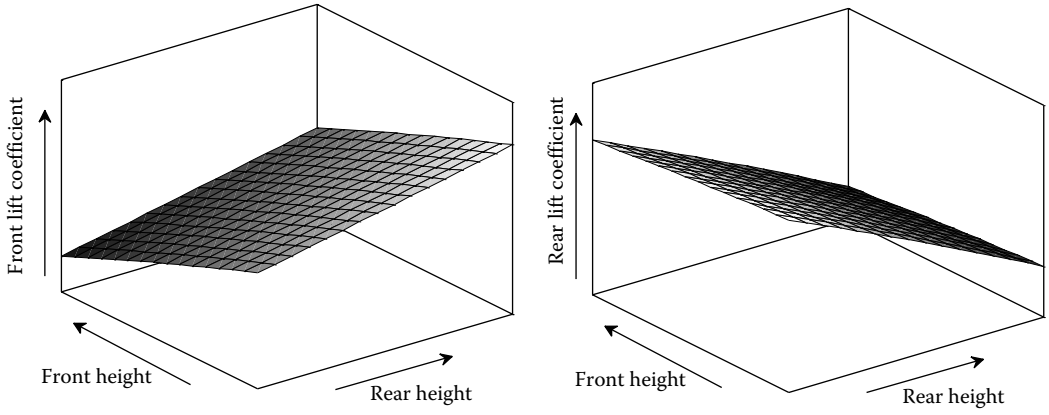

FIGURE 15.2 Maps for front and rear lift coefficients as a function of front and rear height. (From C. Doniselli et al., Aerodynamic effects on ride comfort and road holding of automobiles, *Proceedings of the XIV IAVSD Symposium*, Swets & Zeitlinger, Ann Arbor, MI, 1995.)

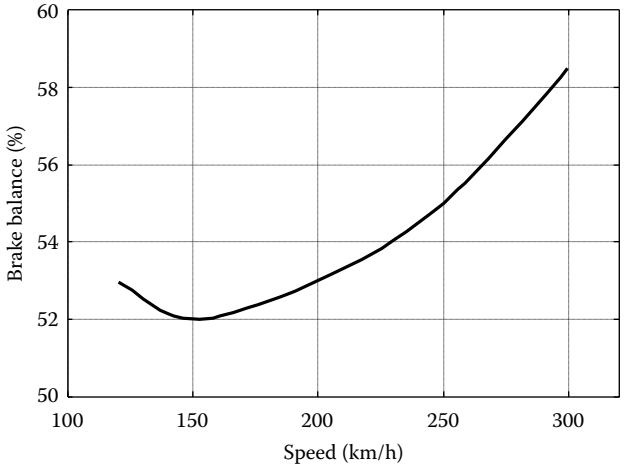

FIGURE 15.3 Ideal brake balance distribution for an F1 car.

In comprehensive models, some other extra braking forces acting on the car have to be considered. These forces, mostly in the direction of the aerodynamic drag, act on the rear axle and are due to the engine that provides substantial braking torque during the braking maneuver, being the throttle not open in this situation. This enhances the braking at the rear axle by means of the torque transmitted by the gearbox and the final drive ratio.

As depicted in Figure 15.3, the theoretical braking force balance between front and rear of an F1 car is not constant. That is, the ratio between front and rear braking forces varies during the braking maneuver.

At higher speed, more front braking force is required for car stability. At lower speed, the brake balance is shifted toward the rear axle to avoid front wheel locking.

The general tendency of front-to-rear brake balance and its speed dependency has been confirmed by practical track testing during the last years.

15.3 F1 CAR BRAKING SYSTEM LAYOUT

Figure 15.4 shows the typical layout of a braking system for an F1 car. The two master cylinders are connected via a kinematic device, namely, the balance bar, which distributes the pedal force to the pushrods of the two master cylinders and thus to the two separate circuits for the front and rear brakes. The pedal works as a lever, increasing the force applied by the driver, with a ratio between 3:1 and 4:1. The choice of master cylinder diameters influences the driver's effort and his or her feedback in terms of the force applied and pedal travel. In most cases, the brake master cylinders are fed by two separate reservoirs.

The hydraulic circuit is realized by means of two lines starting from each master cylinder and specific to each axle. The lines consist of a partly rigid and a partly flexible piping with diameters from 2 to 3 mm. The two circuits terminate at the brake calipers.

The caliper clearly plays a fundamental role in the brake system, and it has several requirements. Firstly, the caliper has to be light, as it adds to the weight of unsprung mass. A stiff caliper is essential for assuring that the action of the fluid under pressure is used for generating braking power, rather than deforming the caliper itself. It should also protect the brake fluid from high temperatures caused by the friction between the pads and the disk. Finally, it must guarantee a high level of safety by maintaining easy bleeding.

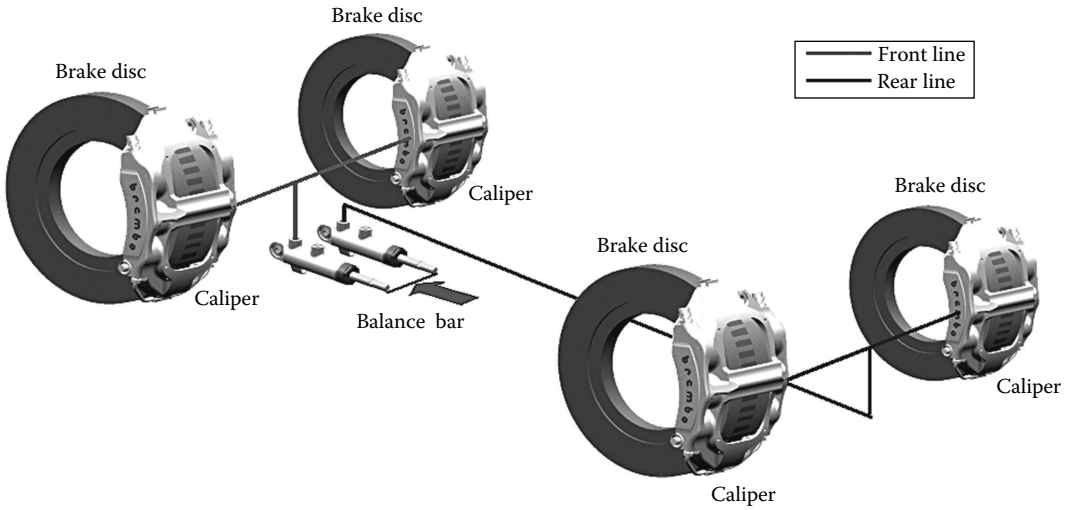

FIGURE 15.4 Typical brake system configuration. (Adapted from B. Breuer and K. H. Bill, *Brake Technology Handbook*, SAE, Troy, MI, 2008.)

The disk of racing cars is usually realized in two parts, the friction surface and the bell. The friction surface is the part devoted to the contact with the pads, and the bell represents the drive element of the disk.

In the case of an F1 car, as it can be noticed from Figure 15.3, no ABS hydraulic unit is present, as the current Federation Internationale de l'Automobile (FIA) regulations do not allow any form of electronically controlled systems in the braking area. In the past, in early 1990s, some ABS units were fitted in F1 cars with very encouraging results, but subsequent FIA regulations stopped this research field in order of cost reductions. Currently, no form of driver aids is allowed in the braking system, the braking performance of the car must be under the exclusive control of the driver, and even servo units are not allowed and thus not present in the system layout. The result is a very simple braking system. The steps for the generation of braking torque are the following:

- The driver supplies mechanical energy to the system by pushing the pedal. The energy supplied by the driver (E_D) can be computed as

$$E_D = F_P T_p$$

  where
  F_p is the force applied by the driver
  T_p is the travel of the pedal

- The pedal ratio multiplies the force exerted by the driver
- Brake pressure is generated inside each of the master cylinders, according to the displacement of the corresponding rod
- The pressure is transmitted to the brake caliper where the brake torque is generated by means of the friction between brake disk and pads

The brake balance of the car is obtained by means of the balance bar placed between pedal and master cylinders. The driver can change the brake balance by moving the balance bar with a mechanical rotary switch. The balance bar acts as a lever, and a change of its position changes the lever ratio between the two rods giving a different ratio between front and rear pressure. In case the balance bar is in its middle position and the two master cylinders have the same size, the same level of pressure is obtained in the two circuits. If the balance is placed closer to one of the master cylinders, in the correspondent circuit, a higher brake pressure is obtained than in the other one.

By remembering Equations 15.10 through 15.12, ideal pressures for front and rear braking circuits can be computed as follows:

$$P_f(v,\mu) = \frac{X_f(v,\mu) r_f}{2 r_{df} \mu_{disc} A_f} \tag{15.13}$$

$$P_r(v,\mu) = \frac{X_r(v,\mu) r_r}{2 r_{dr} \mu_{disc} A_r} \tag{15.14}$$

$$P_{tot}(v,\mu) = P_f(v,\mu) + P_r(v,\mu) \tag{15.15}$$

$$P_{dist}(v,\mu) = \frac{P_f(v,\mu)}{P_f(v,\mu) + P_r(v,\mu)} \tag{15.16}$$

The total pressure (P_{tot}) defined in Equation 15.15 does not have any physical meaning. However, since the two master cylinders have the same (or very similar) area, this quantity is proportional to

TABLE 15.2
Brake System Parameters

Parameter	Typical Value	Name
A_f	5800 (mm^2)	Front caliper area
A_r	5000 (mm^2)	Rear caliper area
r_{df}	117 (mm)	Front disk effective radius
r_{dr}	117 (mm)	Rear disk effective radius
r_f	315 (mm)	Front tire effective radius
r_r	317 (mm)	Rear tire effective radius
μ_{disk}	0.45	Friction coefficient between disk and pad

the pedal force, and it can be used as an index of the utilization of the brake system. The explanation of the symbols employed in the equation is reported in Table 15.2 along with their typical values. Equations 15.13 through 15.16 are very informative regarding

- Ideal front brake pressure for ideal front braking force (Equation 15.13)
- Ideal rear brake pressure for ideal rear braking force (Equation 15.14)
- Ideal total pressure for total braking force for the car. From the value of the total pressure, the total energy and power can be easily computed
- Ideal brake pressure balance for ideal car brake distribution

Figure 15.5 shows the ideal car brake balance and the ideal pressure balance as a function of the total braking pressure. These pictures can be obtained by combining the equations for the computation of the braking forces (Equations 15.10 through 15.12) and the equations for the computations of the brake pressures (Equations 15.13 through 15.16). Higher total pressure corresponds to higher car speed.

In particular, the knowledge of Figure 15.5b is most important for the design of the braking system of the car. In fact, the brake system should be designed in order to achieve a brake distribution (i.e., front and rear pressure and brake pressure balance) as close as possible to the one shown in this figure.

In the case of F1 cars, under current FIA rules and constraints, only a constant pressure balance can be employed. In Figure 15.6, the comparison between a fixed pressure balance (horizontal line) and the ideal pressure balance is shown. By inspecting this figure, one can notice that the choice of the fixed level of pressure balance is a compromise between the different needs at higher and lower speeds. By adjusting the balance bar position, the driver has the opportunity to find the best compromise for each braking maneuver according to current track conditions and tire wear.

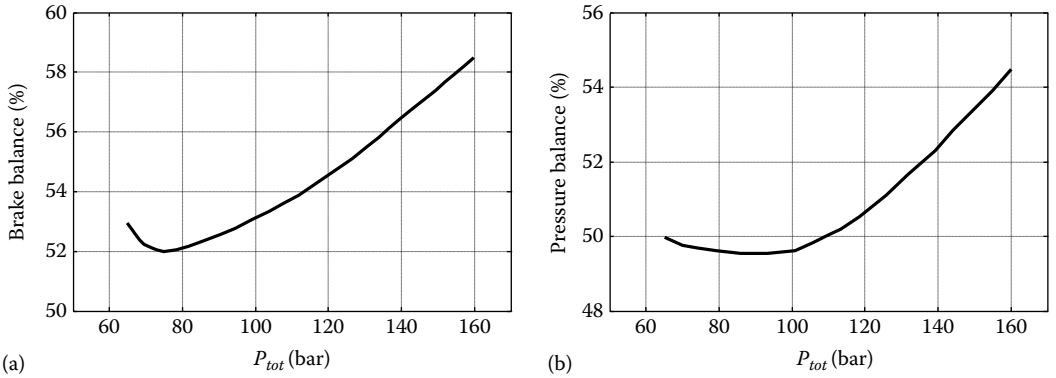

FIGURE 15.5 (a) Ideal brake balance as a function of the total braking pressure. (b) Ideal pressure balance as a function of the total braking pressure.

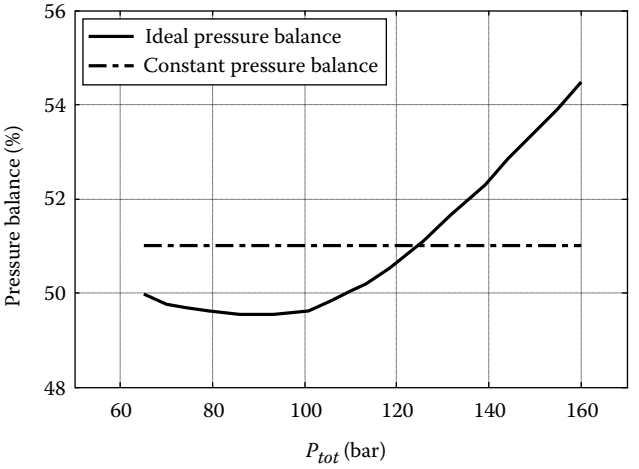

FIGURE 15.6 Ideal braking balance as a function of the total braking pressure and comparison with a constant balance situation.

From a technological point of view, a brake distribution very close to the ideal one could be obtained by employing electronic valves and controls. Currently, this is not allowed in F1 races, as FIA has decided to leave the braking system under the sole control of the driver.

Considering a fixed brake balance β, the effective rear brake force can be computed as (see Equation 15.12)

$$X_{rb}(v,\mu) = \frac{X_f(v,\mu)}{\beta} - X_f(v,\mu) \tag{15.17}$$

The car deceleration is

$$a(v,\mu) = \frac{X_f + X_{rb} + F_d}{m} = \frac{X_f \beta^{-1} + F_d}{m} \tag{15.18}$$

In [4], it is pointed out that this simplified formulation can give very good approximation when compared with experimental data. In Figure 15.7, the predicted acceleration (Equation 15.18) is compared with the acceleration measured by telemetry during an actual braking.

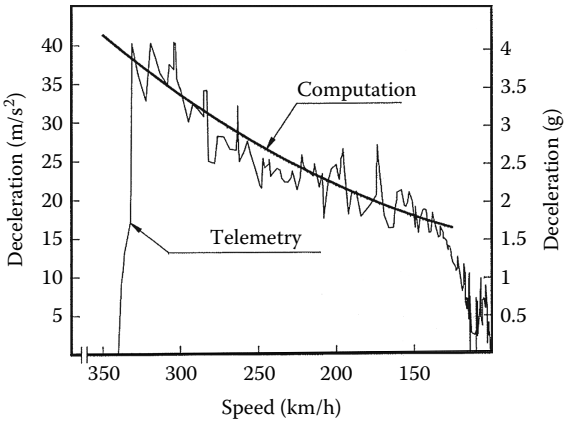

FIGURE 15.7 Comparison between measured and computed deceleration of an F1 car during braking. (Adapted from E. Benzing, *Dall'aerodinamica alla Potenza in Formula 1*, Giorgio Nada Editore, Vimodrone, Italy, 2004.)

15.4 BRAKE ENERGY DISSIPATION DURING A LAP

In this section, the circuit of Melbourne, current location of the F1 Grand Prix of Australia, is considered as reference track for the computation of the energy dissipated by the braking system for a single lap and for the computation of the required braking power. Figure 15.8 shows a map of the reference track on which the most significant speeds, corners numbering, and sectors times are reported.

For a standard vehicle (i.e., no aerodynamic surfaces) on a plane road, the kinetic energy is completely dissipated by the braking system, being negligible the energy dissipated by the aerodynamic drag. In this case, the dissipated energy can be computed as the difference between the kinetic energy before and after braking.

In case of a racing car, the energy dissipated by the aerodynamic drag must be considered. For the computation of the energy dissipated by the braking system, the deceleration of the vehicle (Equation 15.18), depending on speed, has to be integrated between initial and final velocities. For each integration instant, braking forces (Equations 15.10 and 15.17) and aerodynamic drag have to be computed. Brake and drag instantaneous power can be estimated by multiplying these forces by the current velocity. Finally, brake and drag dissipated energy can be obtained by time integration of the previously computed powers. Figure 15.9 shows brake and drag dissipated energy and power computed for a braking maneuver from 300 to 100 km/h by considering all the parameters of the car as constants and by neglecting the dynamic of the brake system (i.e., the brakes apply instantaneously all the required braking torque to have the maximum braking forces). The last hypothesis overestimates the braking power in the first part of the maneuver. The brake balance has been considered fixed and equal to 0.53.

In Table 15.3, computed values of brake dissipated energy are reported for the significant braking maneuvers of the reference track, computed by a complete model considering all the main effects of the braking system. In the considered case, eight relevant braking actions can be identified at the corners reported in the table.

By inspecting the values of Table 15.3, one can immediately have an idea of the huge amount of energy that the brake system has to dissipate in a very short time.

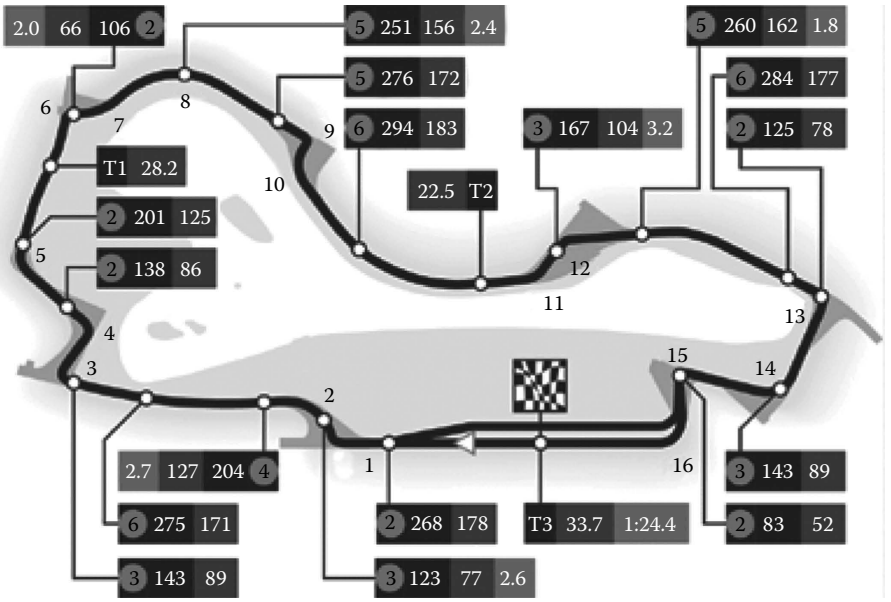

FIGURE 15.8 Melbourne circuit (reference track).

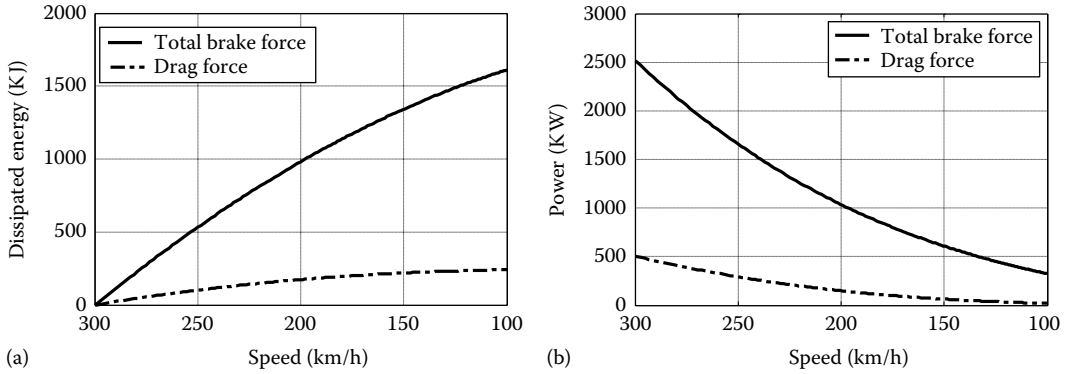

FIGURE 15.9 (a) Computed brake and drag dissipated energy. (b) Computed brake and drag power. Data in Table 15.1.

TABLE 15.3
Brake Dissipated Energy and Braking Power for the Reference Track

Corner Number (No. 1, 2, …, 15)	Initial Speed (km/h)	Final Speed (km/h)	Braking Time (s)	Braking Energy (kJ)	Braking Power (Peak Value) (kW)
1	320	156	1.60	1.30×10^3	1.66×10^3
3	308	93	2.35	1.43×10^3	1.58×10^3
6	301	146	1.50	1.10×10^3	1.34×10^3
9	300	114	1.90	1.28×10^3	1.62×10^3
12	312	250	0.80	0.52×10^3	1.02×10^3
13	313	160	1.50	1.22×10^3	1.66×10^3
14	245	213	0.60	0.21×10^3	0.57×10^3
15	254	106	1.75	0.87×10^3	0.99×10^3

Corners numbering in Figure 15.8.

In particular situations, severe circuit or high grip configurations, the braking power can exceed 2000 horse power. For withstanding such huge powers and energy dissipation, which generates high thermal and mechanical stresses, the brake system design must be extremely accurate and robust, especially at wheel level.

15.5 BRAKE CALIPER DESIGN AND FRICTION MATERIAL

15.5.1 Caliper Design

In designing racing brake calipers, two fundamental requirements have to be considered: stiffness, crucial for obtaining short pedal strokes, and lightness, important in racing cars where mass distribution strongly influences performances.

As a result, brake calipers for race cars are usually very stiff. In this situation, floating disk and bell assemblies are employed to provide the necessary clearance.

The design of the brake caliper, in terms of stiffness and lightness, depends strongly on the rules of the championship they are designed for. In most cases, rules impose limits on brake systems, in terms of allowed structures and materials. Referring to the F1 championship, the material used for manufacturing brake calipers must have an elastic modulus of less than 80 GPa; this requires alloys with a stiffness as close as possible to this limit but with the lowest possible density.

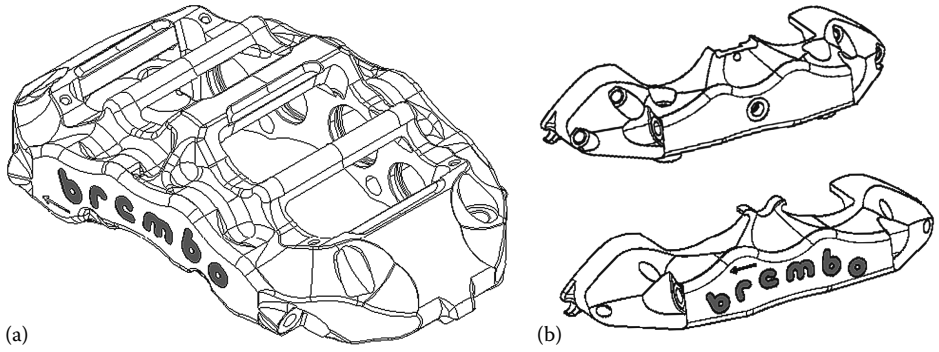

FIGURE 15.10 Brake calipers. (a) Monobloc caliper. (b) Two-piece caliper. (Adapted from B. Breuer and K. H. Bill, *Brake Technology Handbook*, SAE, Troy, MI, 2008.)

A caliper is composed of

Caliper body. A monobloc is usually employed, derived from a billet or a forging. Alternatively, a two-piece assembly can be used, which is usually machined from an aluminum billet (Figure 15.10). The caliper undergoes hard anodizing or nickel-plating or other surface treatments in order to make it resistant to possible collisions (stones, rubble, etc.).

Pistons are made from aluminum and subjected to anodizing. A titanium insert is used as isolation from heat coming from the pad. The machining tolerances are very tight.

Crossover pipe. Usually made of stainless steel, it allows the fluid to reach the caliper side opposite the inlet side [5].

Seals are very important for controlling roll-back, i.e., piston dynamics, and for guaranteeing a hydraulic seal even at high temperatures. If the seal does not allow the piston to return to its resting position, some residual torques arise between the pads and disk. Vice versa, if the piston returns too much, the driver will notice a lengthening of the pedal travel.

Bleed screws are used for bleeding the system and to eliminate air bubbles in the caliper.

15.5.2 Friction Material

To achieve the maximum performances of a braking system for race applications, the friction material has to guarantee both high friction and high stability. During long deceleration, disk and pad temperatures can rise dramatically, and if the friction material changes its characteristics with temperature, the modulation of the braking force can become very difficult. In Figure 15.11,

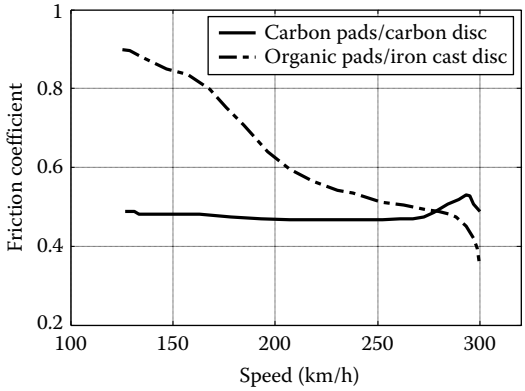

FIGURE 15.11 Comparison of friction properties as a function of speed between an organic pad coupled with a cast iron disk (dot–dash line) and a carbon pad coupled with a carbon disk (solid line).

the tendencies of the friction coefficient as a function of speed during a braking maneuver from 300 to 120 km/h are reported for the two main kinds of friction materials, namely, organic or semisintered pads coupled with cast iron disk and carbon pads coupled with carbon disk. From the figure, it can be noted the very high stability of the carbon pads, which also show a higher values of friction coefficient at the very beginning of the maneuver. This early stage of the braking is very important because in this phase the braking system is usually not able to lock the wheels and the driver can exert all its force to achieve the maximum possible deceleration. A sharp speed decrement at the beginning of the maneuver is important for reducing the braking space.

Another advantage of carbon pads and carbon disk is the lower density of carbon with respect to cast iron (about five times less), which allow for the production of much lighter brakes, thus reducing the unsprung mass of the vehicle. Moreover, being carbon a composite material, the fiber arrangement can be designed in order to give preferential conductivity direction.

In comparison with organic or semisintered pads coupled with cast iron, carbon pads coupled with carbon disk are up to ten times more expensive.

15.6 CONCLUSIONS

In this chapter, the main issues concerning the braking system of a racing car are described. At first, the simplified equations for the computation of the braking forces and the braking balance of a car with aerodynamic surfaces are derived.

Then, the brake balance of a racing car is discussed. In this case, the ideal brake balance is the function of the actual speed and varies during braking. An adaptive balance regulator should be employed for optimizing the braking performances; however, most racing regulations allow only constant brake balancing, so a compromise has to be found between higher and lower speeds. The braking system of an F1 car is described empathizing the devices for the regulation of the brake balance.

Finally, starting from the computation of the dissipated energy during braking and the required peak braking power, the main requirements in the design of the braking system are defined, with particular attention to braking calipers and pads.

The information reported in this chapter allows the interested reader to understand the basics of race car dynamics during braking. A designer can use this approach as a starting point for braking performance calculations.

16.1 INTRODUCTION

Particular attention has already been paid to the interfaces between aerodynamics and vehicle dynamics. This is increasingly important in the modern development process. Knowledge of both technical areas is required when a vehicle is in the development stage. The aim of this chapter is to provide a basic understanding of these interfaces.

First, an explanation will be given on how aerodynamic forces arise and how they interact with each other. It will be shown how aerodynamic forces depend on the design of the basic shape of the vehicle, particularly the shape of the rear end. The relationship between lift and drag assumes a central role. That illustrates what types of conflicts arise between goals in aerodynamic development.

Furthermore, it will be shown how aerodynamic forces and moments affect the behavior of the vehicle. One central topic in this regard is the effect of lift, while another is the vehicle's response to crosswind. A study of the crosswind behavior in particular requires a comprehensive consideration of the driver–vehicle system with its aerodynamic and chassis characteristics. Finally, aerodynamic effects on the vehicle in unsteady flow conditions will be discussed.

This chapter deliberately avoids going into the measures that can be adopted to optimize the shape of the vehicle with respect to, for example, reducing drag. The aim is rather to address aerodynamic influences and its interfaces with vehicle dynamics.

16.2 DEFINITION OF AERODYNAMIC FORCES AND MOMENTS

The air flowing around the vehicle causes a resulting force and a resulting moment. Figure 16.1 shows them broken down into three forces and three moments in a coordinate system specific to the vehicle. A position centrally located along the wheelbase is selected as the reference point. The lift force F_L and the pitch moment M_y as well as the lateral force F_S and the yaw moment M_z can each be substituted by forces acting at the ground level on the wheels. By using this definition, the aerodynamic forces at the front and rear axles can be considered. The substitute forces are given by the following relationships:

Lift:

$$F_L = F_{Lf} + F_{Lr} \quad M_y = (F_{Lf} - F_{Lr}) \cdot \frac{l_0}{2}$$

Lateral force:

$$F_S = F_{Sf} + F_{Sr} \quad M_Z = (F_{Sf} - F_{Sr}) \cdot \frac{l_0}{2}$$

Forces and moments are not stated in absolute terms in aerodynamics. The so-called aerodynamic coefficients are used instead. The most readily recognized is the drag coefficient c_D, often shortened to "c_D value." The derivation of the drag coefficient is given by Equation 16.1. The numerator can be interpreted as the longitudinal force, which would arise, if the entire kinetic energy of the flow was imparted to the vehicle. The denominator equals the measured drag. The ratio of both produces a dimensionless parameter that describes the quality of the shape from an aerodynamic point of view. The c_D value is (largely) independent of the flow velocity:

$$c_D = \frac{F_D}{(\rho/2) \cdot A \cdot v^2} \tag{16.1}$$

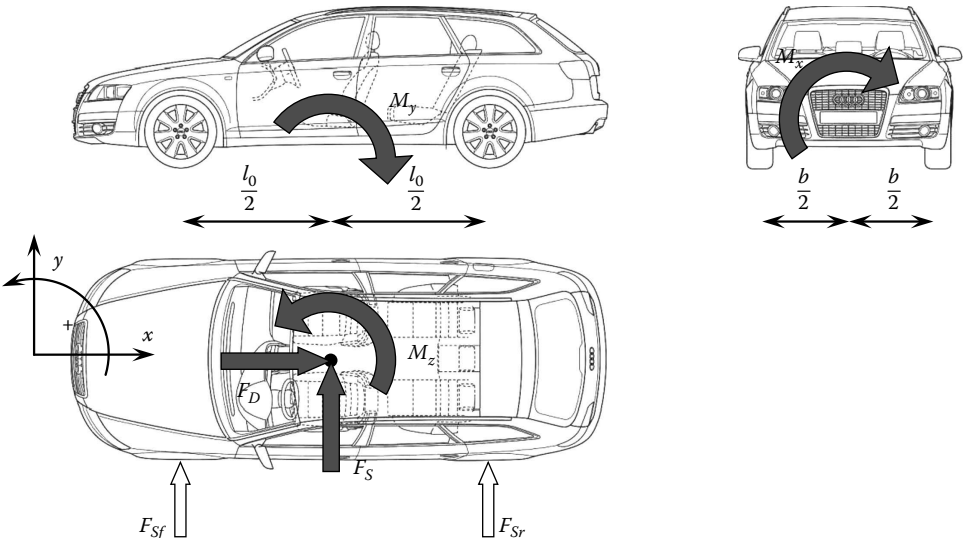

FIGURE 16.1 Definition of aerodynamic forces and moments.

The other aerodynamic coefficients are formed in a similar fashion to Equation 16.1. The aerodynamic coefficients of a vehicle are measured in wind tunnels (see Section 16.4). The following equations are used to calculate the aerodynamic forces and moments:

Drag force:

$$F_D = \frac{\rho}{2} \cdot c_D \cdot A \cdot v^2 \tag{16.2}$$

Lateral force:

$$F_S = \frac{\rho}{2} \cdot c_S \cdot A \cdot v^2 = \frac{\rho}{2} \cdot (c_{Sf} + c_{Sr}) \cdot A \cdot v^2 \tag{16.3}$$

Lift:

$$F_L = \frac{\rho}{2} \cdot c_L \cdot A \cdot v^2 = \frac{\rho}{2} \cdot (c_{Lf} + c_{Lr}) \cdot A \cdot v^2 \tag{16.4}$$

Roll moment:

$$M_x = \frac{\rho}{2} \cdot c_{Mx} \cdot l_0 \cdot A \cdot v^2 \tag{16.5}$$

Pitch moment:

$$M_y = \frac{\rho}{2} \cdot c_{My} \cdot l_0 \cdot A \cdot v^2 \tag{16.6}$$

Yaw moment:

$$M_z = \frac{\rho}{2} \cdot c_{Mz} \cdot l_0 \cdot A \cdot v^2 \tag{16.7}$$

The aerodynamic coefficients depend on the vehicle's angle of incidence (angle of attack). Figure 16.2 shows the aerodynamic coefficients and their dependency on the angle of attack for a production vehicle referring to a notchback as an example.

In addition to engine power and gear ratios, drag is a contributory factor determining top speed and fuel consumption of a vehicle. Lift forces and the pitch moment affect vehicle dynamics. The lateral force and the roll and yaw moments are of particular interest when looking at unsteady flow conditions, such as crosswind.

16.3 OCCURRENCE OF AERODYNAMIC FORCES AND MOMENTS

16.3.1 Airflow around the Vehicle

As a vehicle moves, the surrounding air must diverge around the body of the vehicle. As a result, accelerations and decelerations occur in the surrounding airflow. These deviations can be made visible by introducing smoke into the airstream in front of the vehicle (Figure 16.3). The so-called

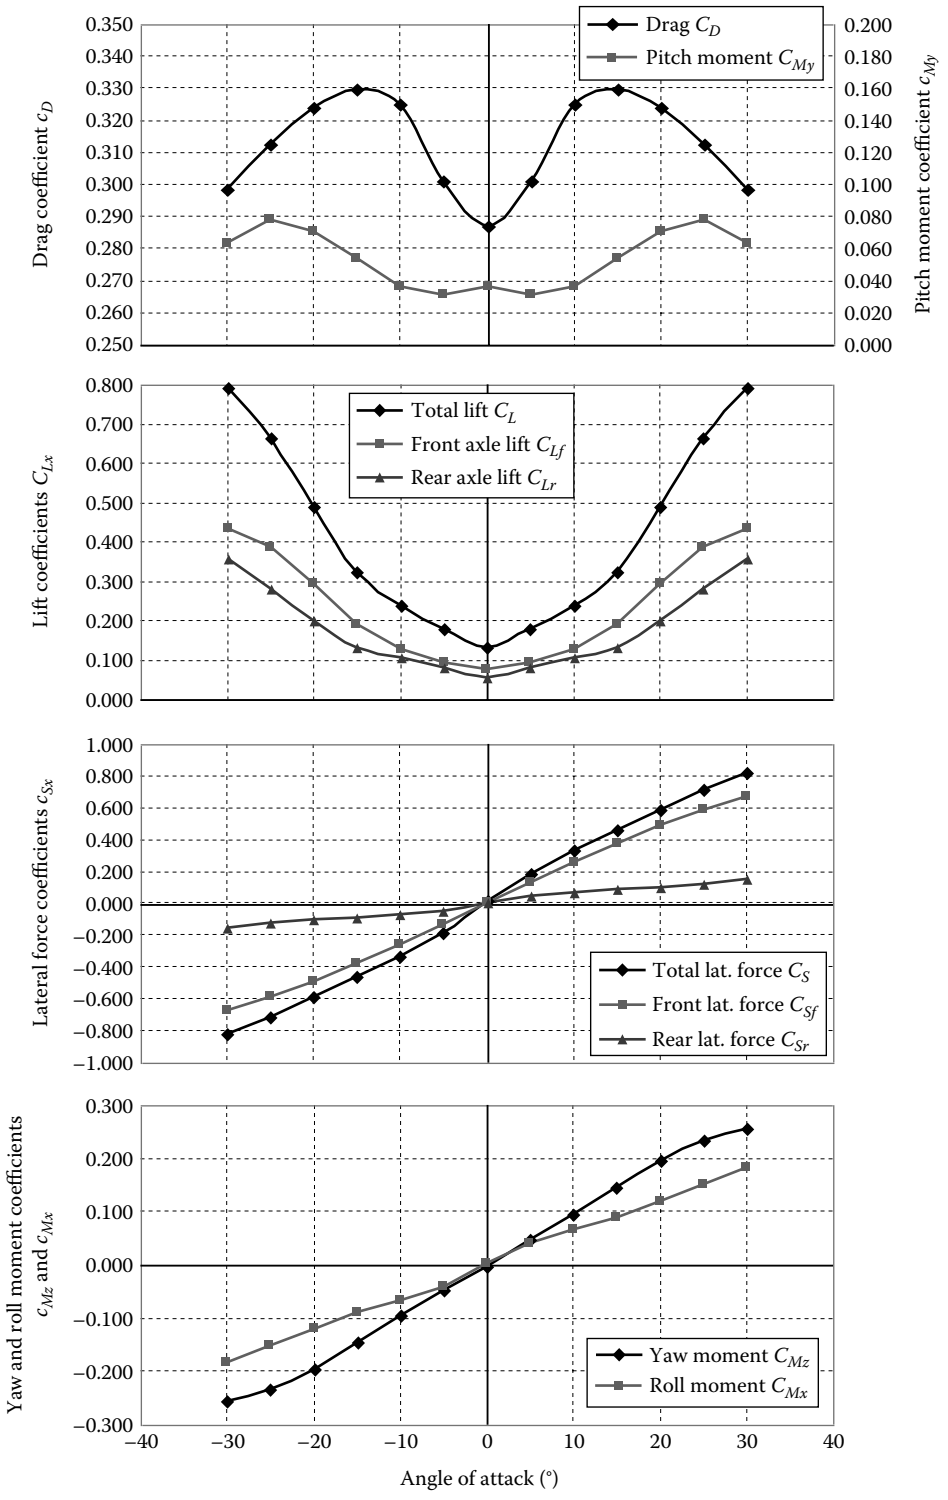

FIGURE 16.2 Aerodynamic coefficients for a production car (notchback). (Courtesy of Audi AG, Ingolstadt, Germany.)

FIGURE 16.3 Airflow around a vehicle. (Courtesy of Audi AG, Ingolstadt, Germany.)

streamlines become visible, which are bent corresponding to the vehicle's shape. In areas where the streamlines are compressed, the flow accelerates. Regions with widened streamlines indicate decelerations in the airflow. If frictionless flow is considered, the physical relationships within the airflow can be described by the Bernoulli equation [1]:

$$\frac{p}{\rho} + \frac{v^2}{2} = const. \tag{16.8}$$

Simple but nevertheless important relationships can be derived using this equation. It states clearly that the energy contained in the airflow is stored in the form of pressure work and kinetic energy (velocity). Between both forms of energy, an exchange can take place. High flow velocities lead to low pressures in the airflow and vice versa. Considering the airflow around the vehicle in Figure 16.3, the pressure decreases when the flow accelerates (compression of the streamlines), whereas positive pressure gradients are produced where the flow decelerates (widening of the streamlines). This energy exchange results in a pressure distribution over the outer skin of the vehicle, which is shown diagrammatically in Figure 16.4 for a notchback vehicle.

Forces and moments can be determined by integrating the pressures over the vehicle's skin. In the case of attached flow, the pressure distribution is produced by accelerations and decelerations in

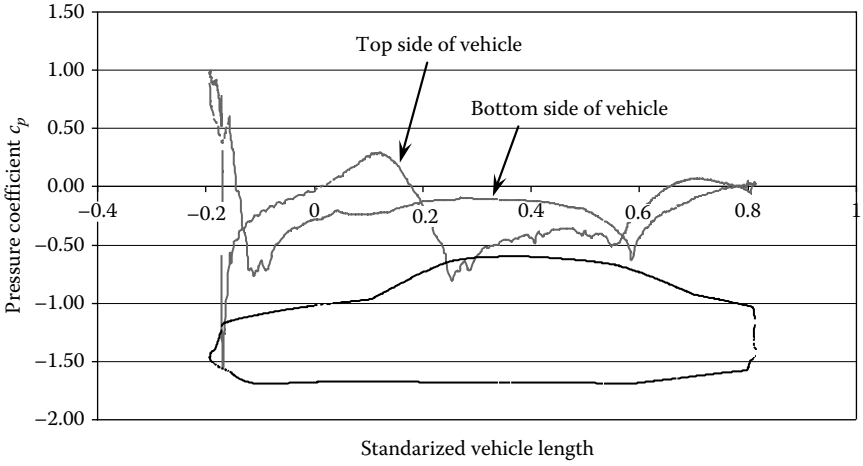

FIGURE 16.4 Pressures induced by an airflow around a vehicle. (Courtesy of FKFS, Stuttgart, Germany.)

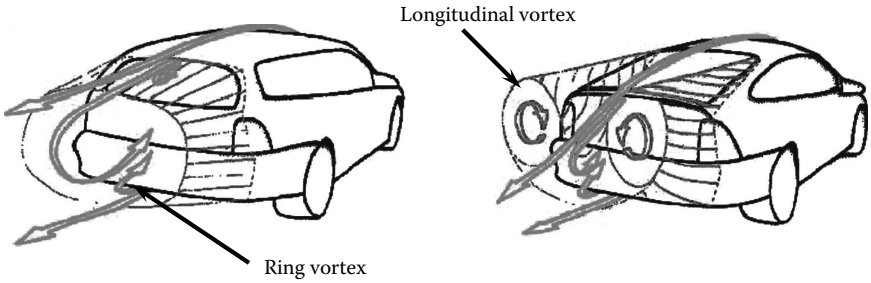

FIGURE 16.5 Types of vortex in a vehicle's wake. (From Howell, J., Shape and drag, in *Using Aerodynamics to Improve the Properties of Cars*, International Short Course on Vehicle Aerodynamics at FKFS, Stuttgart, Germany, 1998.)

the airflow. In the area of the vehicle's rear end, the flow deviates sharply, which causes high positive pressure gradients (widening of streamlines in Figure 16.3). As a result of these positive pressure gradients, the flow separates and forms a separation bubble behind the vehicle. This so-called wake is marked by pronounced vortices in the flow. Vortices are high energy flow forms containing not only rotational energy but also frictional losses. They generally result in low-pressure regions. The Bernoulli equation (16.8) is no longer suitable to describe their physical state. This type of flow is described by the so-called Navier–Stokes equations [1–4].

Due to high kinetic energies and friction losses, the pressures inside a vortex are low. In addition, vortices induce high flow velocities in their surrounding, which finally lead to low-pressure regions. The origination and formation of vortices at the rear of a vehicle therefore affect, to a large extent, the dynamic forces and moments. Two types of vortex can be observed in a vehicle's wake (Figure 16.5).

The first type is created at sharp edges at the rear of the vehicle that runs perpendicular to the flow direction (such as the rear edge of the trunk lid). These vortices rotate around an axis that is parallel to the separation line and form the vehicle's wake. For distinction purposes, this type of vortex will be called "ring vortex." The second type of vortex formation is created at edges running obliquely to the direction of flow. The flow separates along these edges and begins to form tube-shaped horseshoe vortices with rotational axes in the direction of flow. They continue to roll further on this axis along the flow direction. Their existence is not limited to the vehicle's wake. These vortices occur in pairs at the rear of the vehicle and cause a so-called downwash in the vehicle's wake. High flow rates predominate in this downwash, resulting in low pressures.

In particular, the longitudinal vortices create regions with very low pressures and, as a result, have a great effect on drag and lift. Both types of vortex (longitudinal and ring vortices) can be found with any vehicle. However, depending on the shape of the vehicle, one or the other of these types is prevalent. The intensity of the particular vortex type is determined by the shape of the rear. This will be explained in the next section.

16.3.2 Drag and Lift with Different Rear End Shapes

In aerodynamic terms, a distinction has to be made between three rear end shapes—squareback, notchback, and fastback. Each of these rear end shapes is associated with a characteristic form of vortices (cf. [1,5–7]). The following illustrations will clarify this aspect.

Figure 16.6 shows the flow past the rear of a squareback. The separation edges at the rear run more or less perpendicular to the flow direction. Ring vortices are formed that constitute the vehicle's wake. As a result, low pressures predominate in the wake. Due to their geometry, squareback vehicles, compared with other rear shapes, have a large wake. That is, in conjunction with the comparatively large contact surfaces, the low pressures cause a higher drag. The type of flow at the rear end of the vehicle also affects the lift forces in particular at the rear axle. Typical for this type of rear flow pattern is a tendency to negative lift or at least very low levels of lift at the rear axle.

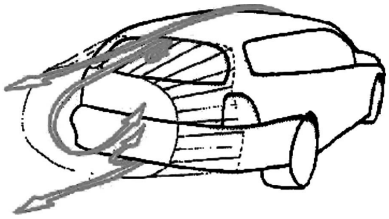

FIGURE 16.6 Diagram illustrating the flow leaving the rear of a squareback vehicle. (From Howell, J., Shape and drag, in *Using Aerodynamics to Improve the Properties of Cars*, International Short Course on Vehicle Aerodynamics at FKFS, Stuttgart, Germany, 1998.)

Figure 16.7 shows a diagram of the flow past the rear end of a notchback. It has mainly the same type of separation at the rear of the vehicle as with a squareback. Ring vortices are formed that run perpendicular to the separation edges. However, the flow partially starts to separate at the *C* pillars (see Chapter 26). Longitudinal vortices roll away, rotating inward and causing a downwash in the wake. Notchbacks therefore have a tendency to rear lift in comparison to squarebacks. Overall, the effect of the ring vortices predominates in the wake. Since the wake of a notchback is comparatively smaller than in a squareback, it has less drag.

Figure 16.8 illustrates the flow down the rear end of a fastback. The flow separates at the sloping edges of the *C* pillars and begins to form longitudinal vortices that rotate inward, dominating the separation pattern. They create a strong downwash behind the vehicle. Furthermore, they continue to roll downstream and have still not dissipated some distance behind the vehicle. The longitudinal vortices create low-pressure regions that, compared with the other two rear end shapes, are linked to high drag coupled with high lift values.

Whether ring vortices or longitudinal vortices predominate in a vehicle's wake is largely affected by the slant angle of the rear end shape. The longitudinal vortices form at slanting edges, such as at the *C* pillars. This explains why this type of vortex predominates particularly in fastback shapes. This phenomenon was investigated and studied in detail in [1], where the slant angle of a vehicle's

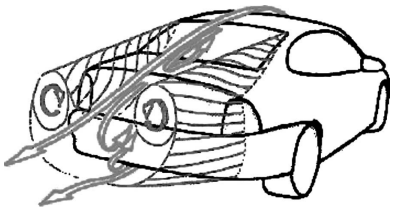

FIGURE 16.7 Diagram illustrating the flow leaving the rear of a notchback vehicle. (From Howell, J., Shape and drag, in *Using Aerodynamics to Improve the Properties of Cars*, International Short Course on Vehicle Aerodynamics at FKFS, Stuttgart, Germany, 1998.)

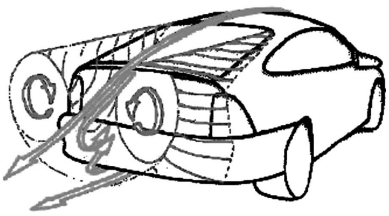

FIGURE 16.8 Diagram illustrating the flow leaving the rear of a fastback vehicle. (From Howell, J., Shape and drag, in *Using Aerodynamics to Improve the Properties of Cars*, International Short Course on Vehicle Aerodynamics at FKFS, Stuttgart, Germany, 1998.)

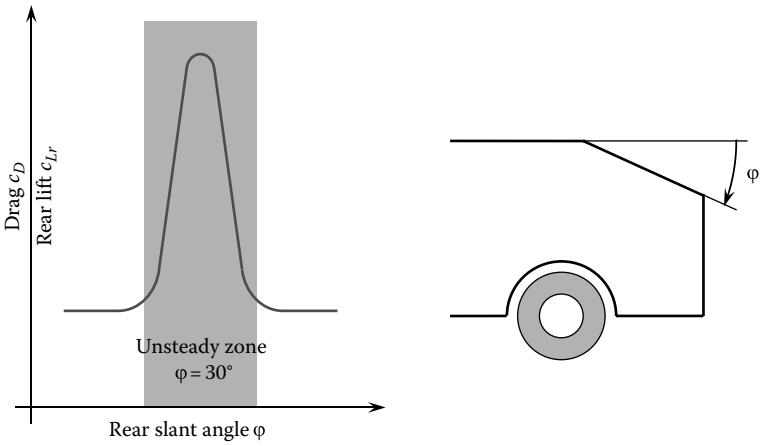

FIGURE 16.9 Effect of slant angle on drag and lift.

rear end was varied in order to observe the effect on lift and drag. Figure 16.9 illustrates the results schematically. The formation of longitudinal vortices reaches a maximum with a slant angle of about 30°. The wake of the vehicle has a marked downwash effect, induced by the inwardly rotating longitudinal vortices. Drag and lift increase significantly in this range.

The quoted slant angle of about 30° was determined on an idealized basic vehicle body. Detailed elements in the design of a rear end, such as radii and geometric tapering of the surfaces, partially diminish the described effects so that this critical angle is subject to scatter within certain limits [1,5].

The quoted example is intended to show that both drag and lift are already determined by the basic shape of the vehicle within a certain window. Rear end shapes with sloping separation edges, particularly fastbacks, favor the formation of longitudinal vortices consuming high energy. Even though significantly less pronounced, those longitudinal vortices separating from the rear of a notchback should be noted. Both rear end shapes exhibit rear lift, depending on the extent of the longitudinal vortices. In squareback vehicles, the separation at the rear is dominated by the formation of ring vortices. This type of rear flow pattern has a tendency to have negative rear lift or at least very low levels of rear lift.

Whether the rear end shape produces positive or negative rear lift is also reflected in the direction of rotation of the vortices behind the vehicle. Notchbacks and fastbacks tend to have positive rear lift. In other words, a higher pressure acts on the underside of the vehicle than on the top of the vehicle. Thus, the pressures equalize at the rear end from "bottom to top." Looking from behind, the vortices rotate inward. The effect is opposite in the case of squarebacks.

16.3.3 Induced Drag (Vortex Drag)

The examples in the previous section show that drag and lift are always influenced by the occurrence of vortices. This is termed the so-called induced drag (cf. [8]). The term induced drag stems originally from aerospace and will be explained below by means of an airfoil.

Figure 16.10 illustrates how drag occurs for an airfoil when lift is created. The drag on the airfoil consists of two components. First, the airfoil itself has its own drag. This is caused by friction effects in the flow that manifest themselves as pressure losses. Secondly, lift is created by the airfoil caused by positive pressure on the underside of the wing (pressure side) and low pressures on the upper side (suction side). This can be produced by either a setting angle of the airfoil or an appropriate shaping of the airfoil profile. Due to the difference in pressure between the pressure and suction sides, pressure has to be equalized at the wing tips. That creates edge vortices that roll off behind the wing, developing into a so-called horseshoe vortex and causing a downwash behind the airfoil. The component of drag that must be used to create this pair of edge vortices is known as induced drag.

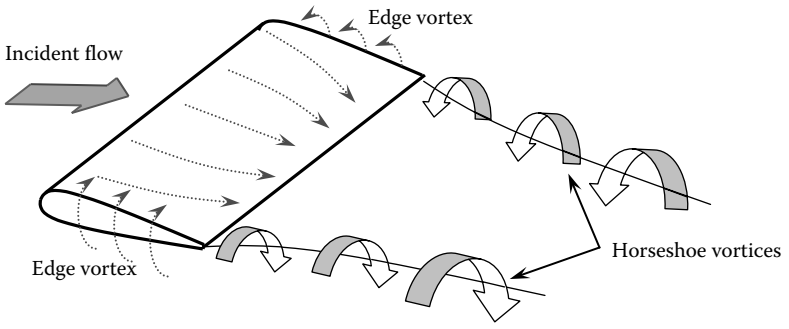

FIGURE 16.10 Illustration of the flow from an airfoil.

The induced drag depends quadratically on the generated lift force, that is, $c_{D,ind} \sim c_L^2$. Considering the airfoil in Figure 16.10, drag is at its lowest when neither positive nor negative lift is created, thus producing no induced drag.

This relationship can be read across, as a general rule, to earth-bound vehicles (cf. [9–12]). Instead of the term "induced drag," "vortex drag" is used in vehicle aerodynamics. Due to the interaction between the vehicle and the road surface, rotating wheels and the cooling air intake flow, etc., the minimum drag does not occur at zero lift but rather at low lift values ($0 < c_{ah} < 0.1$). The creation of positive or negative lift on a vehicle influences vortex formation and drag. In other words, drag and lift depend fundamentally to each other.

By using this model of induced drag or vortex drag, some aerodynamic effects can be better understood. In conjunction with Section 16.3.2, it can be again illustrated why different rear end shapes, due to their design, have lower drag or lower positive or negative lift. Figure 16.11 illustrates the quadratic relationship between drag and lift. As explained in Section 16.3.2, in the case of fastbacks, a pair of longitudinal vortices is formed that causes high lift. The result is high vortex drag and therefore high drag values. Longitudinal vortices are generally not dominant in notchbacks and squarebacks, and they therefore experience little vortex drag. The creation of negative lift in racing cars by adding components such as airfoils or spoilers can therefore also result in high vortex drag. For the sake of completeness, it should be mentioned at this point, however, that racing cars in addition use the so-called ground effects. That is, they achieve their negative lift with only little induced drag by utilizing the interaction between the underside of the vehicle and the road surface (cf. [1]).

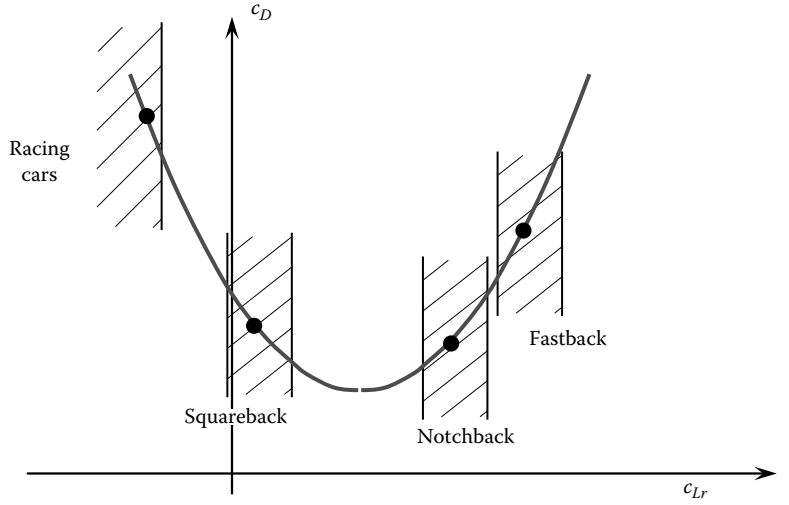

FIGURE 16.11 "Classification" of rear end shapes according to vortex drag.

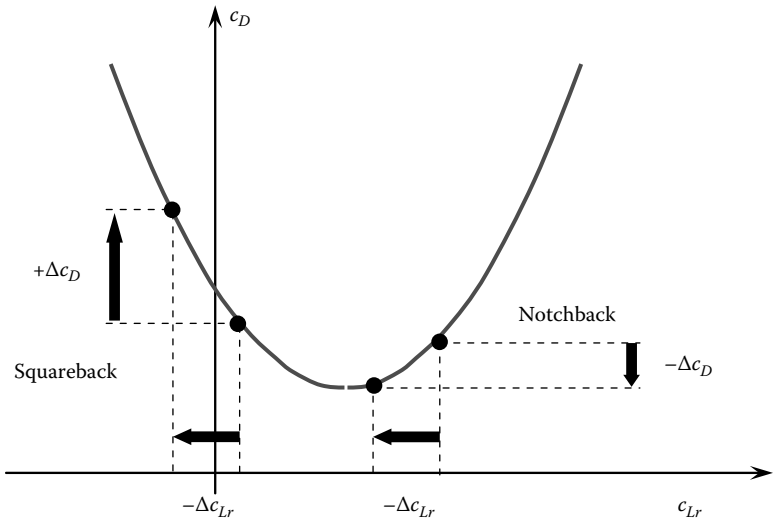

FIGURE 16.12 Relationship between drag and rear axle lift. (From Wagner, A. et al., Einfluss der Bodensimulation auf den induzierten Widerstand von Fahrzeugen. *Proceedings of the 6th International Symposium on Automotive and Engine Technology*, M. Bargende and J. Wiedemann (eds.), Expert-Verlag, Stuttgart, Germany, 2005.)

Utilizing this interpretation of vortex drag helps also to understand why individual rear end shapes must be treated differently to some extent in aerodynamic development [11,12]. As an example, in Figure 16.12, the intention is to fit a rear spoiler to a notchback and a squareback vehicle to generate negative lift. This spoiler is to be incorporated fully into the bodywork to avoid the possibility of having separate vortex systems from the spoiler and from the basic vehicle shape. Due to their lift relationships, notchback vehicles are usually located to the right of the vortex drag parabola's minimum. If the lift of this type of vehicle is reduced by, for example, incorporating a spoiler, the vortex drag reduces and therefore the vehicle's drag also. Since squareback vehicles tend to exhibit negative lift, they are located on the left side of the parabola's minimum. If a spoiler is incorporated in a vehicle with a squareback to produce negative lift, the vortex drag will increase.

This example is meant to illustrate that aerodynamic measures used on a variety of rear end shapes can result in opposite effects on drag.

The aim of aerodynamic development is to create low drag as well as low lift forces. This is achieved, on the one hand, by optimizing a vehicle's design and styling (cf. [1,7,13–17]). On the other hand, vortices induce low-pressure regions and, thus, increase drag and lift. The creation of vortices, particularly the formation of longitudinal vortices at the rear of the vehicle, should be avoided. It must be noted in this context that different rear end shapes, due to the characteristic way in which the airflow separates from their rear end, have built-in aerodynamic characteristics regarding drag and lift that is inherent in their design and styling (see Section 16.3.2). Due to vortex drag, drag and lift cannot be influenced separately from each other.

16.4 DETERMINATION OF AERODYNAMIC FORCES AND MOMENTS

The aerodynamic development of vehicles and the determination of their aerodynamic forces and moments are carried out in wind tunnels (cf. [18–21]). Figure 16.13 shows a typical design of a wind tunnel. The air is accelerated through a fan and through the nozzle into the measurement section, called "plenum." After flowing around the vehicle, the air is captured by the collector and recirculated to the fan. The vehicle is located in the plenum on a balance that determines the aerodynamic forces and moments.

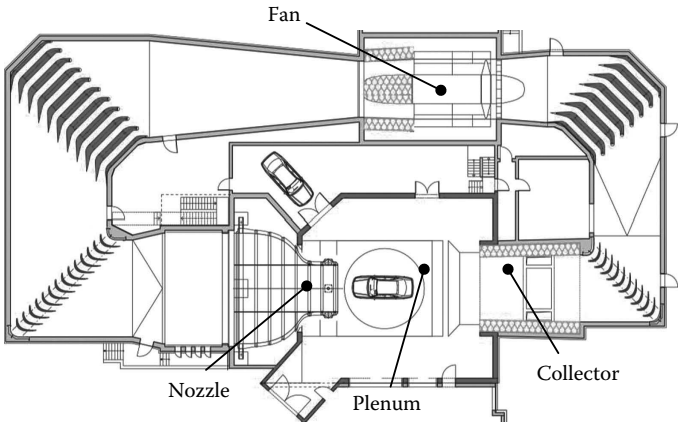

FIGURE 16.13 Layout of a wind tunnel for vehicles. (Courtesy of Audi AG, Ingolstadt, Germany.)

The flow in wind tunnels is an approximation to the flow conditions on road. The quality of this approximation depends on the technical design of the wind tunnel (cf. [22,23]). In real life, a vehicle moves in an "infinitely" large flow field, while the measurement section in a wind tunnel is spatially limited. As a result, the measurement section is blocked by the presence of a vehicle, which means that the air jet has to spread out to flow around the vehicle and to be received by the collector. As a result, pressure gradients are formed as well as accelerations and decelerations that influence the results of the aerodynamic forces depending on the way the wind tunnel was designed. Engineers endeavor to design a wind tunnel in order to minimize these types of effect, to compensate for them, and/or to balance one against the other (cf. [24–26]).

Another approximation to conditions on road has to be seen in the fact that in a wind tunnel, the air is blown around a stationary vehicle, while in real life the vehicle travels through the air. In newly designed wind tunnels, it is therefore possible to apply a so-called ground simulation consisting of several components [27–29] (Figure 16.14). Suction and blowing devices are used to affect the boundary layer existing due to the relative motion between the air and the floor of the wind tunnel. A moving belt operates between the vehicle's tracks to simulate the relative motion between the vehicle and the road surface. The wheels are rotated at the appropriate speed by small moving belts. Thus, the vehicle no longer stands on the balance with the tire's contact patch but instead must be

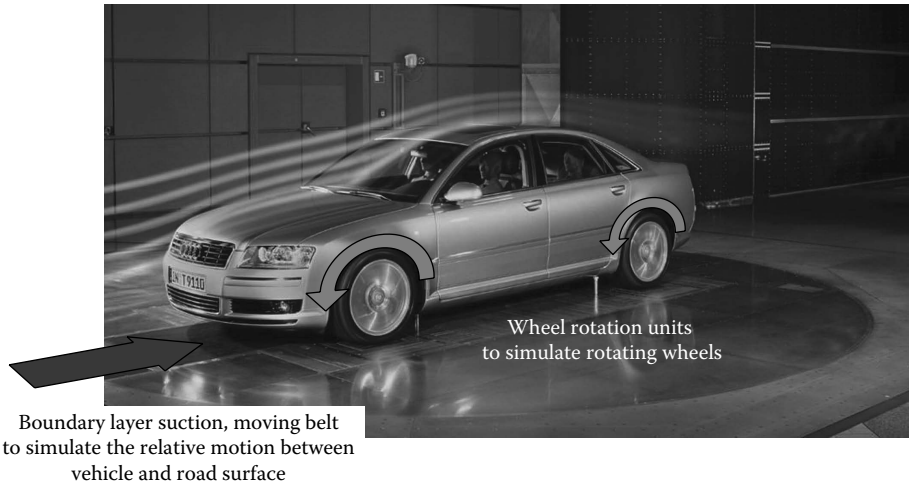

FIGURE 16.14 Ground simulation in the Audi wind tunnel. (Courtesy of Audi AG, Ingolstadt, Germany.)

held using special retainers, on the rockers, for example. The use of ground simulation provides a more precise reproduction of the relationships in actual travel on road [30–34].

Numerical flow simulation (computational fluid dynamics [CFD]) provides a second method of determining aerodynamic forces and moments [1,3,4,35]. The Navier–Stokes equations are used in CFD for a numerical resolution of the flow field. In this method, a number of modeling concepts have to be used, such as modeling the turbulent shear stresses that occur due to the high-frequency, small-scale, turbulent fluctuations in the flow. This so-called turbulence modeling is based on simplified assumptions and represents an approximation to actual physical conditions (cf. [4,36,37]). Both can result in fundamental discrepancies between the actual and simulated flows.

As computing power has increased, the development of CFD has accelerated in the last few years. Using modern methods, it is possible to obtain a particularly good correlation with actual flow conditions. As a result, the use of CFD has become an indispensable tool in vehicle development today: both in the early development stage of a vehicle, when a physical model is not yet available, as well as in later development stages to accompany wind tunnel measurements. The most important benefit of CFD, however, is the possibility to a detailed insight into the flow (cf. [2,38–41]).

16.4.1 Lift Behavior

From a dynamic motion point of view, lift forces on a vehicle are very important, since they can affect both intrinsic steering behavior and braking behavior and, therefore, the ability to control the vehicle (cf. [42–46]). A well-balanced design of vehicle dynamics is reflected in a slightly understeering behavior (see Chapter 27). This requires a targeted and coordinated design of axles, steering system, elasto-kinematics, etc., as well as weight distribution. As shown in Section 16.2, the lift forces increase quadratically with the speed of the incident flow and superimpose on the wheel loads resulting from the weight distribution. This reduces the downforces acting through the wheels dependent on the road speed.

To discuss the results on vehicle dynamics, among others, the tire has to be considered. Tire characteristics are explained in detail in Chapters 17 through 20 and 27. In this chapter, some basic diagrams are illustrated as follows.

Figure 16.15 shows the force distribution in a vehicle traveling in a right turn. For the sake of illustration, only the left-hand side of the vehicle is to be considered. The centrifugal force F_Z resulting from the curved path requires a lateral reactive force F_S, which acts at road surface level and which has to be applied by the tires. Furthermore, due to the centrifugal force F_Z, a shift in wheel load takes place from inside to outside of the curve. This component $\Delta F_{N,dyn}$ superimposes on the

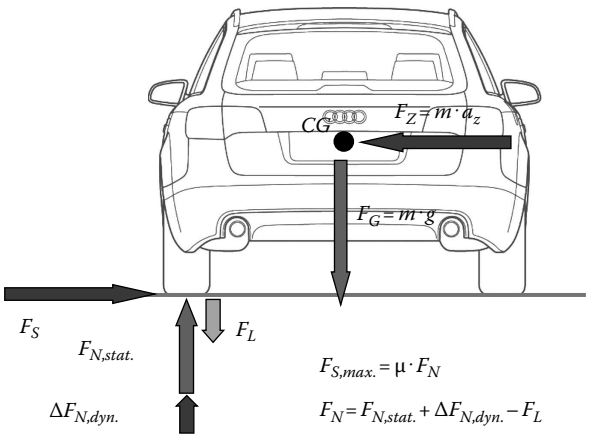

FIGURE 16.15 Force distribution in a vehicle performing a right turn with lift effect (forces at the left side of the vehicle are shown only).

static component of the wheel load $F_{N,stat}$, which results from the weight of the vehicle F_G. The wheel load is increased on the outer side of the curve due to this component. The ability of the tires to apply a lateral reactive force depends on their normal force. As the normal force F_N increases, the tires can apply higher maximum lateral forces $F_{S,max}$.

If a vehicle is subject to lift, the load on the tires is reduced by the lift force F_L. The centrifugal force F_Z and the vehicle weight F_G as well as the resulting reactive forces (F_S, $F_{N,stat}$, $\Delta F_{N,dyn}$) remain unchanged since they depend on the mass of the vehicle. To be able to perform the turn at the same lateral acceleration in Figure 16.15, the tires must apply the same lateral force when lift is present. The normal force F_N is reduced, however, by the lift force F_L. As a result, the ability of the tires to apply a lateral reaction is reduced. In other words, the maximum lateral forces $F_{S,max}$ they can apply are lowered. The result is a decrease in the achievable lateral acceleration a_Z and thus lower speeds when turning.

Figure 16.15 shows the effect of lift, looking at the vehicle's outer side of the curve. To show the effect of lift on the intrinsic steering behavior of a vehicle, it is necessary to consider the lift forces on the front and rear axles separately. The following characteristic diagram for a tire will be a starting point.

Figure 16.16 diagrams the relationship between normal force, sideslip angle, and transferable lateral force for a tire. As the lateral force increases, the sideslip angle increases. With small lateral forces, the tire behavior is approximately linear, that is, a doubling of the lateral force results in a doubling of the sideslip angle. As the lateral force increases further, the tire behaves regressively. Once the maximum transferable lateral force is reached, the tire begins to skid. The sideslip angle increases and higher lateral forces can no longer be sustained. The influence of the normal force on the tire's lateral control force was already mentioned before: an increase of the normal force leads to greater cornering forces and vice versa.

If the lift forces reduce the tire's normal force, the same lateral force can be applied only at greater sideslip angles (see Figure 16.16). As a result, the lateral stiffness of the axle in question decreases. Lift on the rear axle produces a tendency to oversteer, while lift on the front axle results in a tendency to understeer. The opposite is the case for negative lift.

Similar effects are produced in the case of fluctuating lift forces. Figure 16.17 illustrates the dependency of the transferable lateral force of a tire on its normal force. The relationship is regressive since the transferable lateral force cannot be increased to the same extent as the normal force. The normal force is now allowed to fluctuate periodically by varying the lift force around a mean value $F_{N,0}$. This oscillation of the normal force results in a fluctuation in the lateral control force around a mean value $F_{S,0}$. Due to the regressive behavior, the mean value of the lateral control force $F_{S,0}$ is less than the lateral force $F_{S,stat}$, which was assigned to the mean value of the wheel load. Thus, when the normal force fluctuates, the tire can apply less lateral force on the average. However, to be able to counter the lateral forces present, a greater sideslip angle needs to be applied to the tire. Oscillating lift forces on the rear axle alter the intrinsic steering behavior toward oversteering. Oscillating lift forces on the front axle result in a tendency to understeer.

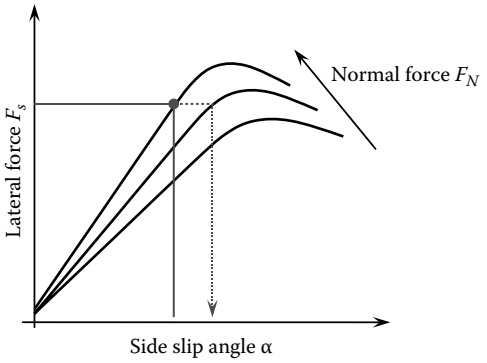

FIGURE 16.16 Relationship between lateral force, normal force, and sideslip angle of a tire.

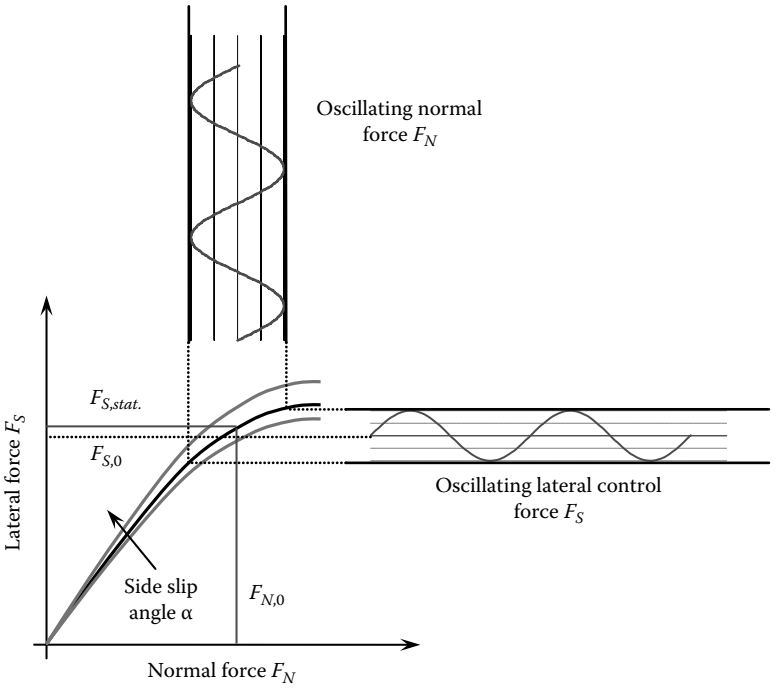

FIGURE 16.17 Effect of an oscillating normal force on the lateral control ability of a tire.

These two examples illustrate the effect of lift forces on the intrinsic steering behavior. Lift forces result in lower normal forces on the tire. When lift is present, the affected axle behaves more elastic in lateral direction. As a result, an increased sideslip angle is required to counter the lateral forces. The opposite happens in the case of negative lift. Negative lift on the rear axle causes an understeering behavior. Negative lift on the front axle results in an oversteering tendency but has a positive effect on steering behavior. High downward pressures on the front axle produce a direct steering sensation and improve the response behavior of the vehicle to steering inputs (e.g., peak response time [Equation 16.16]).

Another aspect of lift is its effect on braking (see also Chapter 15). Figure 16.18 illustrates the force distribution of a braking vehicle affected by lift. The position of the center of gravity (*CG)* and the vehicle mass m causes static normal forces $F_{Nf,stat}$ on the front axle and $F_{Nr,stat}$ on the rear axle. The deceleration from the brake application results in a dynamic wheel load shift from the rear to

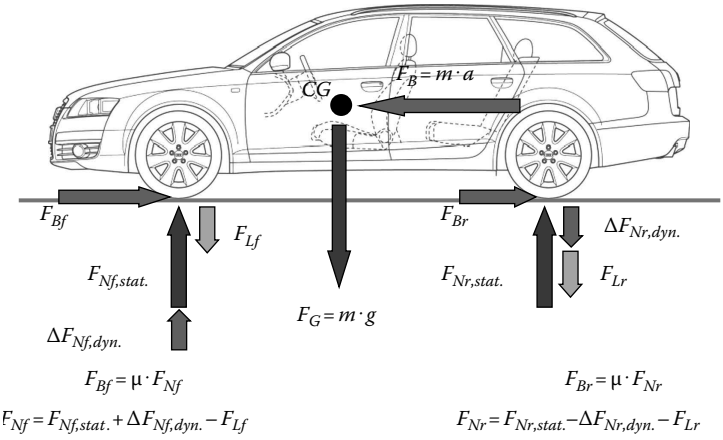

FIGURE 16.18 Force distribution in a vehicle when braking with lift present.

the front axle. The normal force on the front axle is increased by the dynamic component $\Delta F_{Nf,dyn}$ and reduced on the rear axle by the component $\Delta F_{Nr,dyn}$.

In order to be able to achieve maximum braking deceleration, the road grip at the front and rear axles must be exploited uniformly. Thus, the distribution of the braking forces to the front and rear axles F_{Bf} and F_{Br} must be in the same relationship as the normal forces on the front and rear axles F_{Nf} and F_{Nr}. This distribution is known as "ideal brake force distribution" (see also [42]) and is permanently installed in the vehicle for a defined brake deceleration (0.8 g) by designing the brake system accordingly.

If a vehicle is subject to lift, the normal forces on the axle reduce due to the superimposed lift forces. As a result, the maximum braking forces that the tire can apply are reduced, as is the maximum attainable braking deceleration. Furthermore, the ratio of the normal forces at the front and rear axles can be affected by lift in a way that it no longer corresponds to the design criteria for ideal braking force distribution. Rear lift reduces the maximum transferable braking force at the rear axle without affecting the front axle. As a consequence, the road grip at the rear axle is utilized more strongly, which results in a tendency to lock the rear axle with hard braking. Since lift forces, as explained in Section 16.2, increase quadratically with speed, this phenomenon is more pronounced when braking at high speeds.

This tendency, which the rear axle locks first, must be avoided for safety reasons by designing the braking system appropriately. The distribution of the braking forces between the front and rear axles must therefore be designed for braking at high speed, when the rear is subject to maximum lift forces. However, in the case of braking at lower speeds, that is, lower lift forces at the rear, the vehicle is not utilizing the road grip ideally and cannot attain the maximum achievable deceleration.

In racing cars, the aerodynamic development of high negative lift forces to achieve high lateral control forces and therefore high attainable speeds in curves is of great importance (see Chapter 15). For production vehicles, it is desirable to produce only little positive or negative lift to maintain the vehicle dynamics properties over the widest possible range of road speeds. Since lift forces increase quadratically with speed, an unequally decreasing aerodynamic load to the front or the rear axle can lead to a tendency to over- or understeer as a function of driving speed. At the same time, this will also affect braking. The aerodynamic balance, that is, the ratio of front and rear lift, should correspond to the weight distribution. Thus, the load on both axles would be applied or relieved uniformly, that is, lift forces would not change the ratio of the normal forces. In certain circumstances, this can represent a conflict in objectives with the aerodynamic optimization of drag (cf. Section 16.3.3).

16.5 CROSSWIND BEHAVIOR

16.5.1 Vehicle Excitation by Crosswind

Figure 16.19 shows the incident airflow relationships when crosswind is present. The "vehicle motion" airstream v_{veh} flows around the vehicle at approximately the travel speed. A crosswind component with a wind speed of v_{Wind} approaching at an angle of τ_{Wind} is superimposed on the

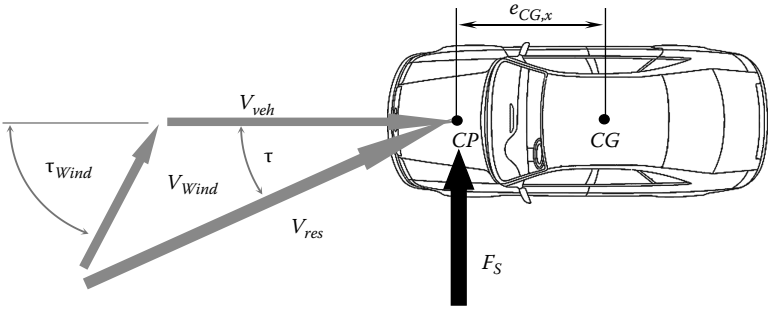

FIGURE 16.19 Resulting flow meeting the vehicle. (From Wagner, A., Ein Verfahren zur Vorhersage und Bewertung der Fahrerreaktion bei Seitenwind, Dissertation, Universität Stuttgart, Stuttgart, Germany, 2003.)

motion airstream. The vector addition of both components produces the resulting airflow meeting the vehicle at a speed of v_{res} at a resulting angle of attack τ:

$$F_S = \frac{\rho}{2} \cdot v_{res}^2 \cdot A \cdot c_S \approx \frac{\rho}{2} \cdot A \cdot k_S \cdot \tau \cdot v_{res}^2 = K \cdot \tau \cdot v_{res}^2 \quad (\text{for } \tau < 15°) \tag{16.9}$$

Equation 16.9 is used to consider the side force created due to crosswind. The aerodynamic lateral force coefficient can be assumed to be linear, to a good approximation, within a range for angles of attack of ±15°. This applies, as a general rule, to production vehicles with different rear end shapes. By assuming a linear relationship for the aerodynamic lateral force coefficient $c_S = k_S\tau$, the crosswind excitation can be expressed by the product τv_{res}^2. This product depends on the wind values v_{Wind} and τ_{Wind} and can be used to express the intensity of crosswind. Normally, the product τv_{res}^2 is used as a measure of the wind disturbance and as a reference value when considering the vehicle's response behavior, such as by means of a magnitude ratio [47,48].

Crosswind induces a yaw moment M_Z as well as a lateral wind-force F_S. The yaw moment can be taken into account, to a reasonable approximation, as the lateral wind-force F_S acts through the nominal center of pressure *CP* with a lever arm $e_{CG,x}$. This lever arm can be determined from the aerodynamic coefficients (Equations 16.3 and 16.7) and is described by means of Equation 16.10 in dependency of the angle of attack. The same procedure applies to consideration of the roll moment, again to a reasonable approximation (not shown in Figure 16.19):

$$e_{CG,x} = \frac{c_{Mz} \cdot l_0}{c_S} + \frac{l_0}{2} - l_r \tag{16.10}$$

A linear, planar, single-track model, acted on by the lateral wind-force in Equation 16.9 (Figure 16.20), will be considered to discuss the vehicle's crosswind behavior. The derivation of the equations of

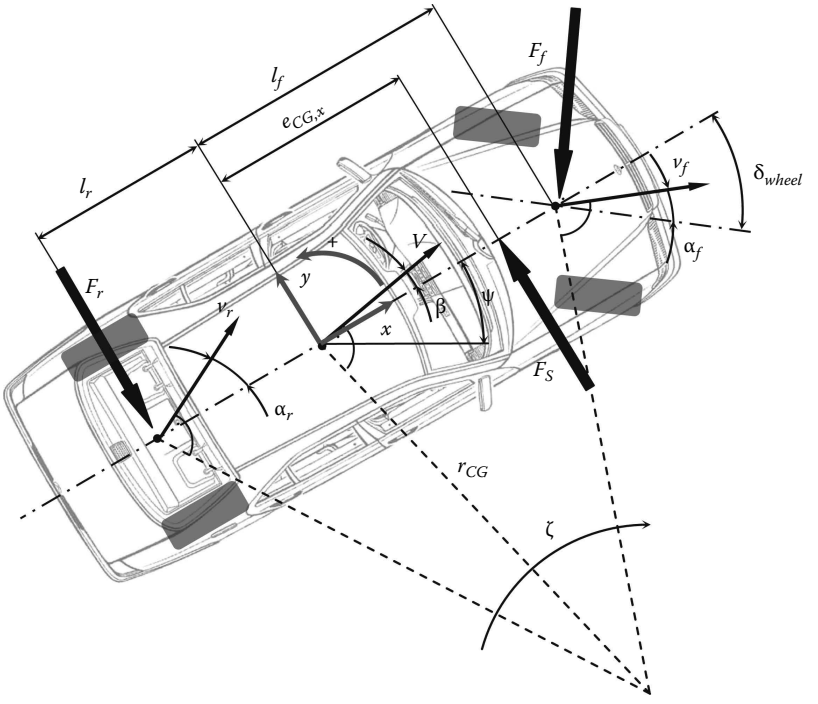

FIGURE 16.20 Single-track model.

motion will not be introduced at this point, and the reader is referred to the literature [42,43,45,46,49]. The equation system 16.11 describes the response of the single-track model to steering inputs and to crosswind excitation. Equations 16.12 through 16.16 show the most important system-related values for this single-track model:

$$\begin{bmatrix} \ddot{\psi} \\ \dot{\beta} \end{bmatrix} = \begin{bmatrix} -\dfrac{c_r \cdot l_r^2 - c_f \cdot l_f^2}{J_z \cdot v} & \dfrac{c_r \cdot l_r - c_f \cdot l_f}{J_z} \\ \dfrac{c_r \cdot l_r - c_f \cdot l_f - m \cdot v^2}{m \cdot v^2} & -\dfrac{c_r + c_f}{m \cdot v} \end{bmatrix} \cdot \begin{bmatrix} \dot{\psi} \\ \beta \end{bmatrix} + \begin{bmatrix} \dfrac{(\rho/2) \cdot A \cdot k_S \cdot e_{CG,x}}{J_z} \\ \dfrac{(\rho/2) \cdot A \cdot k_S}{m \cdot v} \end{bmatrix} \cdot \tau v_{res}^2 + \begin{bmatrix} \dfrac{c_f \cdot l_f}{J_z \cdot i_L} \\ \dfrac{c_f}{m \cdot v \cdot i_L} \end{bmatrix} \cdot \delta_L \tag{16.11}$$

Undamped natural angular frequency:

$$\omega_0 = \sqrt{\frac{m \cdot v^2 \cdot (c_r \cdot l_r - c_f \cdot l_f) + c_r \cdot c_f \cdot (l_r + l_f)^2}{m \cdot v^2 \cdot J_z}} \tag{16.12}$$

Damping time constant:

$$\delta = \frac{m \cdot (c_r \cdot l_r^2 + c_f \cdot l_f^2) + J \cdot (c_f + c_r)}{2 \cdot m \cdot v \cdot J_z} \tag{16.13}$$

Damped natural angular frequency:

$$\omega_d = \sqrt{\omega_0^2 - \delta^2} \tag{16.14}$$

Damping factor:

$$\vartheta = \frac{\delta}{\omega_0} \tag{16.15}$$

Peak response time of yaw rate:

$$T_{\dot{\psi},\max} = \frac{1}{\omega_d} \cdot \arctan \frac{\omega_d}{\delta - (c_r \cdot (l_f + l_r)/m \cdot v \cdot l_f)} \tag{16.16}$$

16.5.2 Vehicle Reactions to Crosswind

Lateral forces may occur in normal travel when a vehicle is met by a diagonal airflow, as is common in windy conditions. They cause the vehicle to deviate from the desired course (such as driving in a straight line) and take the form of lateral and yaw responses. Typical situations consciously registered by the driver are, for example, driving across bridges or overtaking a truck at high speed, as well as—in a sufficiently strong stochastic wind—traveling on open stretches. The driver has to react with steering adjustments to correct for the wind gusts. Depending on the sensitivity of the vehicle to crosswind, this is primarily discomforting but can also become a safety issue.

Due to their stochastic nature, the frequency domain is used to describe crosswind effects on a vehicle. To "normalize" the response of the vehicle to the crosswind excitation, it can be represented by the magnitude ratio [50]. Figure 16.21 shows an example of a magnitude ratio of the yaw velocity with wind excitation at different travel speeds. A constant crosswind produces a constant yaw velocity (magnitude ratio with a frequency $f = 0$ Hz). Due to the decreased damping of the vehicle at high driving speeds, the resonance magnitudes of the yaw velocity increase as the speed increases.

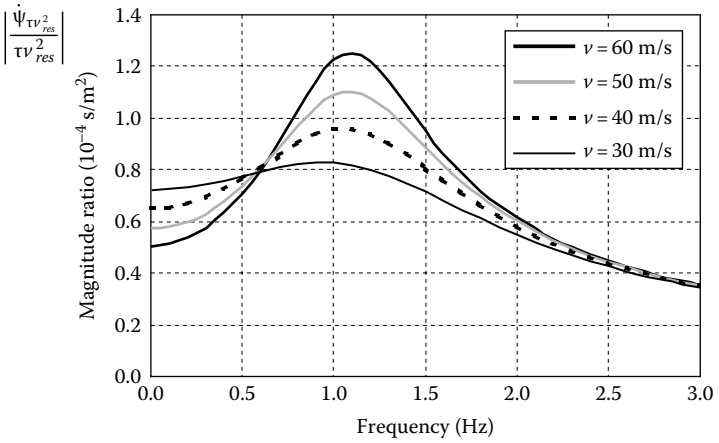

FIGURE 16.21 Magnitude ratio and phase shift of the yaw velocity with crosswind excitation at different travel speeds. (From Wagner, A., Ein Verfahren zur Vorhersage und Bewertung der Fahrerreaktion bei Seitenwind, Dissertation, Universität Stuttgart, Stuttgart, Germany, 2003.)

All other vehicle reactions display a similar response to crosswind excitation as shown in Figure 16.21 for the yaw velocity (see [51]). The crosswind disturbance appears to the driver as a pattern consisting of these reactions. The composition of this pattern depends on the vehicle design and its characteristics and is therefore typical for the vehicle being driven [52]. This vehicle reaction pattern causes a swerve, requiring a steering adjustment by the driver.

Yaw velocity is an important motion quantity in this reaction pattern since it results in a perceptible angular deviation from the course. Crosswind behavior is often considered using the yaw velocity reaction only. When looking at the resonance behavior of the vehicle in a crosswind, however, the vehicle reaction pattern must be considered as a whole, in other words, taking into account all other vehicle reactions.

Figure 16.22 shows the dependency of the damped natural frequency and resonance frequencies on the travel speed with crosswind excitation. The axes were arranged in a way that the abscissa

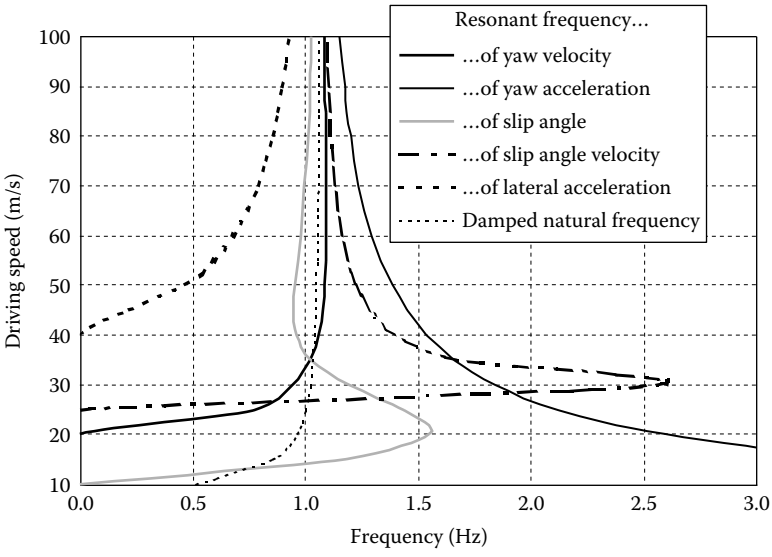

FIGURE 16.22 Dependency of the resonant frequencies of a vehicle on the vehicle's speed with crosswind excitation. (From Wagner, A., Ein Verfahren zur Vorhersage und Bewertung der Fahrerreaktion bei Seitenwind, Dissertation, Universität Stuttgart, Stuttgart, Germany, 2003.)

would represent the frequency as in Figure 16.21. The resonant frequencies are scattered over a wide range within a realistic speed range up to about 50 m/s. At further increases in speed, they approach the damped natural frequency of the vehicle.

If the wind gusts occur with time intervals between each other, the vehicle is allowed to oscillate after excitation. These decaying oscillations occur at a natural frequency determined by the system, in this case the damped natural frequency of the vehicle. When the vehicle is allowed to naturally oscillate, all vehicle reactions vibrate at this frequency. The vehicle's yaw velocity reaction is very important in this case, since the damped natural frequency of the vehicle runs close to the resonant frequency of the yaw velocity. This kind of excitation is typical for passing across bridges or passing trucks. The driver generally understands the interference he or she can expect in these situations and often makes an initial steering adjustment before the interference occurs. These kinds of situations are classed as less critical [51].

If the vehicle is excited by stochastic crosswind, a permanent stochastic vehicle excitation superimposes on the decaying natural oscillations. In contrast to the "sporadic" vehicle excitation by individual wind gusts as described earlier, in this case, the vehicle is excited over the whole range of its resonant frequencies. As a result, the individual vehicle reactions resonate alternately. The yaw velocity reaction, again, is important due to the proximity of its resonant frequency to the undamped natural frequency. Only considering the yaw velocity, however, in this case is not sufficient. All vehicle reactions must be taken into account when stochastic excitation of the vehicle occurs.

16.5.3 Evaluation of Crosswind Behavior

The weaker the excitation by crosswind is, the lower the aerodynamic lateral force and the yaw moment are. It is an obvious objective, therefore, to keep both as low as possible by targeted aerodynamic development. Since crosswind effects mainly involve comfort problems, the subjective perception by the driver is an important factor. It is therefore far more complicated to obtain a clear definition whether a vehicle is sensitive to crosswind using objective criteria (see [53]). This will be explained in more detail in the succeeding text.

To assess the susceptibility of a vehicle to crosswind disturbances, the first step can be to consider the tendency to yaw (Figure 16.23). Due to their rear end shape, squareback vehicles

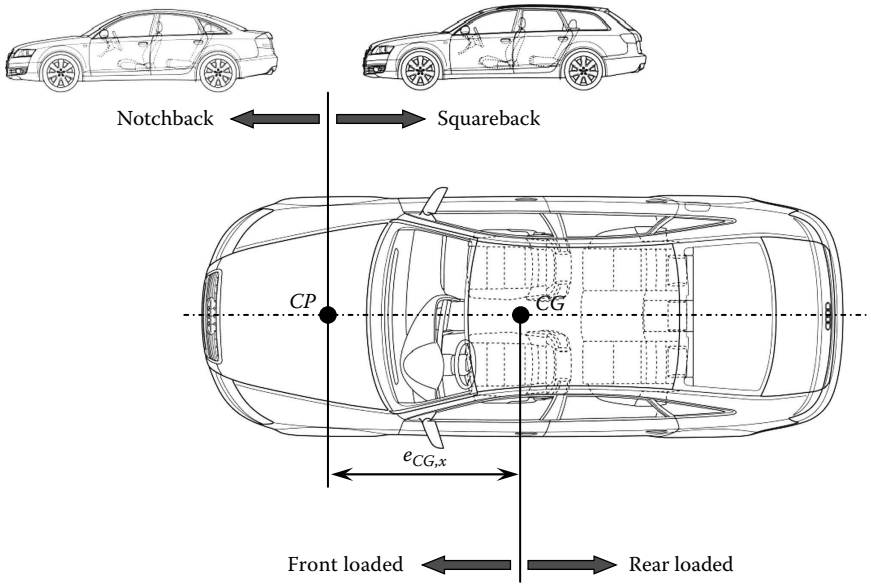

FIGURE 16.23 Estimation of the wind susceptibility using the yaw tendency.

in comparison to notchbacks have more contact surface area at their rear against which a crosswind gust can act. Their *CP* is further back and is therefore closer to the *CG* than it is the case with notchbacks. As a rule, squarebacks therefore experience greater lateral forces but lower yaw moments. In other words, squareback vehicles tend to have less strong yaw reactions to crosswind. The same applies to front-loaded vehicles. If the vehicle's *CG* is further forward, the reactions to crosswind are less intense due to the shortened lever arm $e_{CG,x}$ of the lateral wind-force.

This estimation of yaw reactions enables a first statement to be made with regard to the "crosswind susceptibility" of a vehicle from a stationary point of view. If statements are to be made about a vehicle's time-dependent behavior in crosswinds, other approaches need to be pursued.

One of these approaches is passing a crosswind facility with the vehicle [54,55], which has been used widely up to now. In such a facility, the vehicle is driven through an air jet artificially produced by one or more blowers (Figure 16.24). The measurements can be run in an "open-loop" mode, that is, with locked steering, or in "closed-loop" mode, that is, with compensatory steering inputs by the driver. The assessment takes place in the time domain.

In open-loop maneuvers, the gradient, the maximum value, and the overshoot of the vehicle reactions when passing through the wind facility as well as the diminishing oscillations of the vehicle as it exits are evaluated. The aim is to minimize the vehicle reactions and their overshoots, particularly with regard to yaw reactions. A residual yaw angle and a track deviation remain as the vehicle exits the facility. Similar to Figure 16.23, a statement can be drawn from these quantities whether a vehicle tends more strongly toward yaw or lateral reactions. In closed-loop maneuvers, the driver actions to counter the wind effect as well as the vehicle reactions to both wind gust and steering intervention are evaluated. The evaluation criteria and target functions are specific to each manufacturer.

The evaluation of crosswind behavior by passing through crosswind facilities is disputed [47,51,56]: The flow profile of the artificially produced crosswind differs from natural conditions

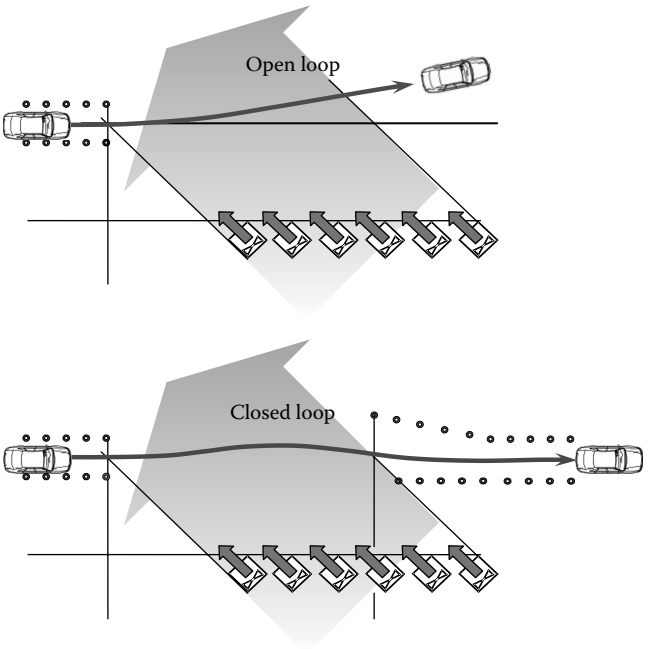

FIGURE 16.24 Illustration of crosswind-facility maneuvers in (a) open loop—fixed/free control—and (b) closed loop. (From Wagner, A., Ein Verfahren zur Vorhersage und Bewertung der Fahrerreaktion bei Seitenwind, Dissertation, Universität Stuttgart, Stuttgart, Germany, 2003.)

that can have a different effect on a vehicle. In closed-loop maneuvers, the driver actions cannot be evaluated realistically since he or she is prepared to react to the wind gust. The driver's subjective perception in natural and artificial wind is often shown to be barely adequate.

The situation simulated in a crosswind facility is analogous to crossing over a bridge or overtaking a truck. The study of a vehicle's behavior in stochastic crosswind has been gaining favor, particularly over the last few years. The vehicle's response has been studied increasingly in the frequency domain to evaluate the crosswind behavior. This should give a better correlation between the objective evaluation and the driver's subjective impression of the vehicle's behavior.

In [47,48], the crosswind behavior was evaluated in natural, stochastic wind by driving on public roads. The magnitude ratio of the yaw velocity to the wind excitation was evaluated (see Figure 16.21). The aim was to minimize the resonant magnitudes of the yaw velocity. In [48], the vehicle reactions to both crosswind and driver's actions, that is, the overall reaction, were observed. In [47], the vehicle reactions exclusive to crosswind, that is, without the driver's actions, were assessed. To eliminate the effect of the driver from the measurements on public roads, the vehicle reactions to steering interventions were determined and "subtracted" from the measured vehicle reactions using single-track models.

Even this method does not produce a complete correlation between objective evaluations and subjective driving impressions [51]. This is due to the fact that the vehicle reactions exclusive to crosswind are considered and minimized. Some vehicles are perceived by the driver to be sensitive to crosswind, although they objectively display low reactions to stochastic wind and vice versa. To reach a complete correlation with the subjective assessment, the driver has to be included in the evaluation.

In [51], a procedure was developed to include the driver in the evaluation as a central member of the driver–vehicle system. The driver was observed in the driver–vehicle control loop during on-road measurements as illustrated in Figure 16.25. The wind disturbance causes vehicle reactions (index τv_{res}^2), which are perceived by the driver and corrected for with steering interventions. The vehicle reactions due to the driver's actions (index δ_L) superimpose on the vehicle reactions due to crosswind (index τv_{res}^2) to form overall vehicle reactions. These overall reactions serve as information to the driver on how effective his or her steering interventions were to compensate for the crosswind gust. Equation 16.18 describes this relationship mathematically.

In Figure 16.25, the driver acts as a "sensor" in terms of his or her perception of vehicle reactions but also as an "actuator" in view of his or her compensatory steering actions. It may occur that steering corrections made by the driver can impair a vehicle's behavior to crosswind (cf. [57]).

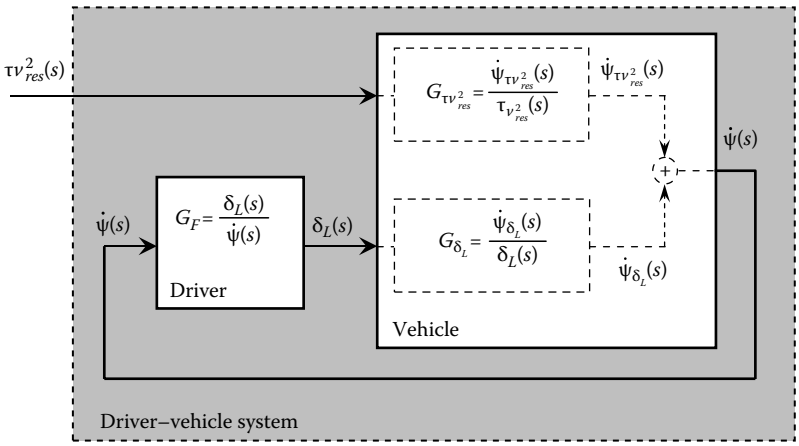

FIGURE 16.25 Signal flow diagram for the driver–vehicle system. (From Wagner, A., Ein Verfahren zur Vorhersage und Bewertung der Fahrerreaktion bei Seitenwind, Dissertation, Universität Stuttgart, Stuttgart, Germany, 2003.)

On the other hand, a vehicle's behavior objectively assessed to be negative can be improved by the steering actions of the driver. For this reason, instead of concentrating exclusively on the direct response of the vehicle to the crosswind excitation, optimizing the interaction between driver and vehicle promises to be more effective.

This is achieved by evaluating the characteristic driver's steering intervention in terms of how he or she processes the information from the vehicle reactions [44]. All vehicle reactions to crosswind appear to the driver as a reaction pattern. During crosswind disturbances, the driver is able, even with different vehicles, to maintain a narrow and similar path. To do this, he or she has to adapt his or her steering interventions to the vehicle's reaction pattern. That is, he or she changes his or her reaction to the information. This change is reflected in the characteristic of his or her compensatory steering input and evaluated by the mentioned approach as illustrated as follows:

$$\frac{\dot{\psi}}{\tau v_{res}^2}(j\omega) = \frac{\dot{\psi}_{\tau v_{res}^2}}{\tau v_{res}^2}(j\omega) + \left[\frac{\dot{\psi}_{\delta_L}}{\delta_L}(j\omega) \cdot \frac{\delta_L}{\tau v_{res}^2}(j\omega) \right] \tag{16.17}$$

Figure 16.26 shows a magnitude ratio of the driver's compensatory steering input related to the wind disturbance and their phase shift from a measurement under stochastic crosswind (driver's actions; Equation 16.17). Using the magnitude ratio, it is possible to analyze how strongly the driver reacts to the individual vehicle reactions [51]. A strong driver reaction to the so-called vestibular information, such as yaw velocity and yaw acceleration, is expressed in high magnitude ratios at frequencies

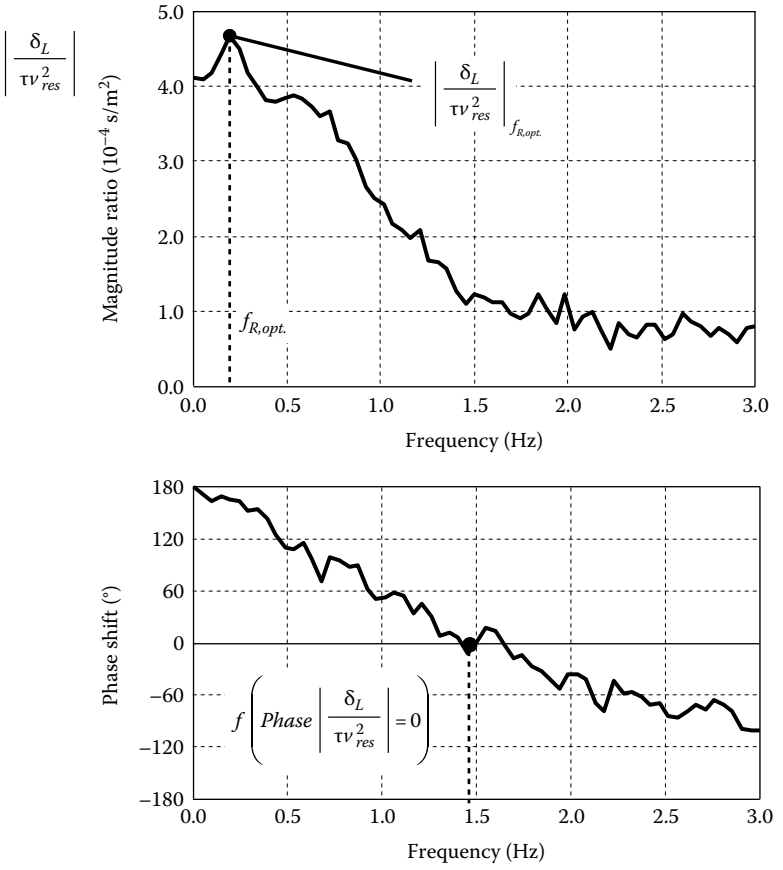

FIGURE 16.26 Magnitude ratio and phase shift of the steering angle to the wind disturbance. (From Wagner, A., Ein Verfahren zur Vorhersage und Bewertung der Fahrerreaktion bei Seitenwind, Dissertation, Universität Stuttgart, Stuttgart, Germany, 2003.)

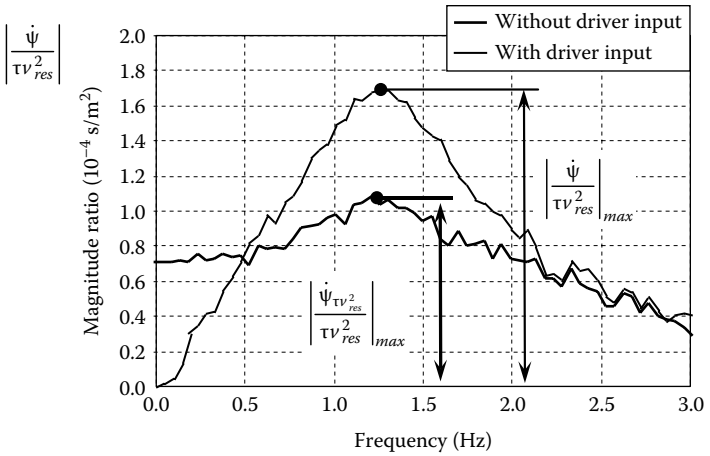

FIGURE 16.27 Magnitude ratio of the yaw velocity with a crosswind disturbance, with and without driver input. (From Wagner, A., Ein Verfahren zur Vorhersage und Bewertung der Fahrerreaktion bei Seitenwind, Dissertation, Universität Stuttgart, Stuttgart, Germany, 2003.)

between 0.8 and 1.5 Hz and in flat phase-shift gradients. The phase shift therefore becomes an indicator of how spontaneously and how fast the driver reacts. Steep gradients of the phase shift result from slow driver reactions and vice versa. Strong driver reactions to visual information such as track deviation or yaw angle are reflected in high magnitude ratios in a frequency range from 0 to about 0.6 Hz.

The effectiveness of this driver action is indicated by the magnitude ratio of the vehicle reactions to the wind disturbance with and without driver input (Figure 16.27). The vehicle reactions without driver input are produced exclusively by the crosswind excitation. The vehicle reaction with driver input is produced by both wind excitation and driver's actions to compensate for the wind excitation (overall vehicle reactions). In a frequency range of about 0.5–2.0 Hz, the driver intensifies the vehicle reactions to the wind by his or her steering interventions. This is typical for all vehicles and results, on the one hand, from the driver's reaction time and, on the other, from the phase shifts of the vehicle reactions [51].

In [51], four criteria expressing the driver's subjective assessment are defined from Figures 16.26 and 16.27:

- If a driver reacts strongly to visual information, a high magnitude ratio is produced in Figure 16.26 in the visual information processing region (0–0.6 Hz). Moreover, the maximum is shifted to higher frequencies. Vehicles in which the driver reacts with this characteristic are felt subjectively to be "indirect" and "requiring steering effort." The evaluation of the amount of steering effort is given by Equation 16.18. High values denote a negative assessment:

$$K_L = \left|\frac{\delta_L}{\tau v_{res}^2}\right|_{f_{R,opt}} \cdot f_{R,opt} \tag{16.18}$$

- Strong reactions to vestibular information result in flat gradients of the phase shift between steering angle and wind excitation in Figure 16.26. These flat gradients reflect fast driver reactions. Vehicles that cause this characteristic driver reaction are felt to be "twitchy" and "unpredictable." This aspect can be evaluated using the frequency at which the phase shift passes through zero (Equation 16.19). High values denote a negative assessment:

$$K_P = f\left(\text{Phase}\left(\frac{\delta_L}{\tau v_{res}^2}\right) = 0\right) \tag{16.19}$$

- The extent to which the driver amplifies the vehicle's reactions by his or her steering interventions (Figure 16.27) can be expressed by the ratio of the resonant magnitudes of the yaw velocity with and without driver input. Equation 16.20 defines a so-called amplification factor. In the case of high amplification factors, the driver perceives the wind disturbance as "difficult to counter":

$$K_V = \frac{\left|\dot{\psi}/\tau v_{res}^2\right|_{\max}}{\left|\dot{\psi}_{\tau v_{res}^2}/\tau v_{res}^2\right|_{\max}} \tag{16.20}$$

- The resonance magnitude of the yaw velocity is defined in Equation 16.21 with driver input (Figure 16.27) as a further criterion. In the case of high resonance magnitudes with driver's actions (overall vehicle reactions), the driver perceives the vehicle reactions as "severe":

$$K_G = \left|\frac{\dot{\psi}}{\tau v_{res}^2}\right|_{\max} \tag{16.21}$$

It must be noted that the perceived intensity of the crosswind excitation is reflected in the vehicle reactions with driver's actions (overall vehicle reactions), which are due to both crosswind and driver's steering actions. It could be shown in [51] that the driver does not directly detect the vehicle reactions exclusively due to crosswind. Earlier procedures, however, aimed at minimizing the vehicle reactions exclusively due to crosswind. This explains why it was not sufficient in earlier procedures to observe the vehicle only.

The individual criteria represented by Equations 16.18 through 16.21 can be combined in one overall evaluation (Equation 16.22), in which different weightings are applied to each of the criteria. High numbers of the overall evaluation denote negative overall assessments. This procedure takes into consideration how the subjective impression during driving occurs: a driver evaluates the crosswind behavior of a vehicle from a number of individual factors and not only based on the reactions of the vehicle:

$$K_{ges} = 2\cdot[K_L] + 5\cdot[K_P] + 3\cdot[K_V] + 1\cdot[K_G] \tag{16.22}$$

Whether the evaluation of the crosswind behavior of a vehicle is positive depends to a large extent on how the driver reacts to the wind disturbance in the vehicle being tested. This procedure optimizes the crosswind behavior of a vehicle by means of improving the interaction between driver and vehicle. In arriving at this definition, both vehicle dynamics and aerodynamics are considered since both affect the vehicle reaction pattern and therefore the characteristics of the driver's actions.

The previously described approach was developed using a wide range of vehicles and the results checked with respect to the influence of several drivers and road speeds. The results corresponded in detail with the subjective perceptions of the drivers. However, performing measurements under natural crosswind is often related with huge time exposures. This was why, in [51], a virtual driver was modeled who is able to adapt the characteristics of his or her steering interventions to different vehicles realistically (for driver models, see Chapter 38). It is possible, utilizing this virtual driver, to use the previously described evaluation procedure also in simulations on the whole virtual driver–vehicle system. Thus, the interaction between driver and vehicle can be studied virtually in an early stage of vehicle development.

16.6 DYNAMICS OF VEHICLE EXCITATION

It is necessary, at this point, to mention one aspect of aerodynamics that occurs in cases of unsteady vehicle excitation. The way a vehicle is excited by crosswind is subject to dynamic processes (cf. [58–62]). This is explained in the following text using a sudden occurrence of a lateral wind gust as an example.

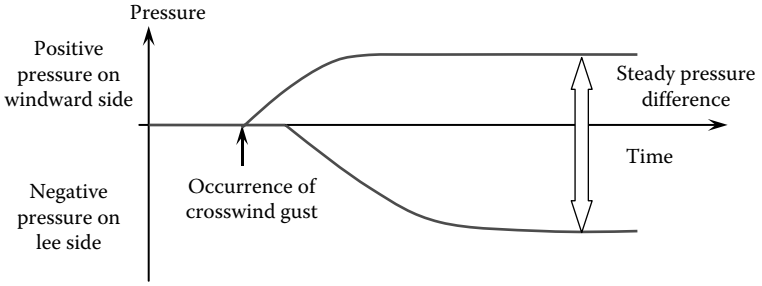

FIGURE 16.28 Principle of pressure buildups on windward and lee sides.

Crosswind forces arise when a vehicle is met by an air jet from the side, in which positive pressure occurs overall on the side facing the wind (windward) and negative pressure occurs overall on the side away from the wind (lee). If the vehicle is hit by a sudden gust, pressure distributions begin to build up gradually along the windward and lee sides of the vehicle [60]. Figure 16.28 illustrates this diagrammatically.

Immediately after a crosswind gust occurs, the pressure starts to increase along the windward side. After a short time, it stabilizes into a steady pressure distribution, applying a positive pressure overall to the windward side. The pressure change along the lee side does not begin until the wind gust has passed across the width of the vehicle. Negative pressures predominate along the lee side where, compared to the windward side, the lee-side pressure distribution starts to develop more slowly. The transition to a steady pressure distribution does not occur until a significantly later point in time. The difference in times, at which the transition to a steady pressure distribution on windward side and lee side has occurred, can amount to up to 0.5 s [60].

Figure 16.29 illustrates the effect of this time difference on the lateral force [51]. Pressures along the sides of a vehicle were measured under natural crosswind conditions. At the same time, the magnitude and direction of the incident air jet on the vehicle were recorded using a multi-hole probe mounted on the roof. Equation 16.9 was used to calculate the lateral wind-forces from the data measured by the multi-hole probe. These lateral wind-forces would arise if the pressure distributions along the windward and lee sides had developed simultaneously. On the other hand, lateral wind-forces were also derived from the measured pressures. These lateral wind-forces actually occur, that is, they involve the windward and lee side effects described earlier. A comparison of both lateral wind-forces (obtained from incident flow data and from measured pressures) indicates differences with regard to their characteristics as well as their magnitude.

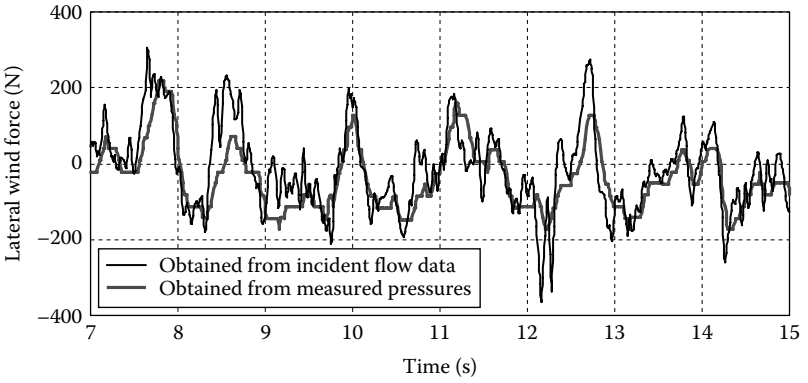

FIGURE 16.29 Derivation of stochastic lateral wind-forces by measuring pressures on the outer skin of the vehicle and measuring the incident airflow. (From Wagner, A., Ein Verfahren zur Vorhersage und Bewertung der Fahrerreaktion bei Seitenwind, Dissertation, Universität Stuttgart, Stuttgart, Germany, 2003.)

The dynamics of the pressure formation along the sides of a vehicle depend on the basic shape of the vehicle. This means that different body shapes can be excited differently by the same crosswind disturbance. The pressure formation in the presence of stochastic crosswind excitation is a central area of research into unsteady aerodynamics [58–61].

In experimental studies of the crosswind behavior, a measurement method can be used that acquires the dynamics of the pressure changes on the windward and lee sides. In simulations, however, the crosswind disturbance has to be modeled, that is, the excitation signal from the crosswind is artificially generated in the form of the product τv_{res}^2 (Section 16.5.1). This offers the benefit of being able to study not only a stochastic crosswind but also specific, selected crosswind phenomena. However, this does not take into consideration the dynamics of the crosswind excitation as described earlier.

If the dynamics of the crosswind excitation are ignored, it is inevitably "assumed" that, on the one hand, there is no time difference between excitations on the windward and lee sides and, on the other hand, different body shapes are excited in the same way. However, this is not the case in the real world. This situation poses a general problem when attempts are made to study crosswind disturbances, particularly of stochastic nature [51,61].

It is possible, in principle, to determine the dynamics of the excitation by computing the airflow and providing the simulation with these data. However, since a time-based phenomenon is involved, a transient airflow calculation has to be made. This must cover a sufficient time span, particularly where stochastic wind disturbances are concerned, so that it is possible to evaluate the results in the frequency domain. This generally results in considerable cost and effort, since it cannot be managed in an acceptable time frame, even with the most up-to-date computer capacity.

One promising possibility is to abandon artificially generated crosswind excitations and, instead, to use measured signals. This ensures, as a first step, that the simulation contains a realistic dynamic representation of the pressure formation on the windward and lee sides. Ideally, measurements can be carried out with the vehicle being tested under stochastic crosswind conditions, and the wind signal excitations recorded in this way can be fed into the simulation as input parameters. If this is not possible, for example, because a prototype is being studied, existing measurements from similar body shapes could be used [51].

16.7 CONCLUSION

Aerodynamics exerts a permanent effect on vehicle dynamics. Low drag reduces fuel consumption and increases performance. The aim of aerodynamic development of a vehicle is therefore to minimize the drag. Lift, pitch moment, and lateral components of the resulting wind-force are decisive parameters in lateral vehicle dynamics and therefore for the interaction between driver and vehicle. In optimizing them, note must be taken of the interactions between lift and drag.

The aerodynamic forces and moments depend on the basic shape of the vehicle and, in particular, on the shape of the rear end. Notchback vehicles have comparatively low drag and tend to have moderate lift, while fastbacks have both high drag and high lift particularly on the rear axle. Compared with notchbacks, squareback vehicles have a higher drag and a tendency to low lift or even negative lift.

One component of drag arises from the formation of longitudinal vortices that occur primarily at the rear end. This component is called vortex drag. It depends quadratically on the lift induced by the longitudinal vortices. Due to the dependency of drag and lift on each other, different rear end shapes must be treated differently for aerodynamic development. Measures to reduce drag applied to a vehicle with positive lift may have the opposite effect to a vehicle with negative lift.

Like all other aerodynamic forces and moments, lift also increases quadratically with road speed and exerts the wheel load. As a result, lateral control capability is reduced. Normally, the loading on front and rear axle is influenced by lift to a different extent. That influences the intrinsic steering behavior of the vehicle. Fluctuations in lift, for example, triggered by instationary flow conditions, have the same effect due to the regressive relationship between normal tire force and lateral tire control force.

In an oblique airstream, as, for example, crosswind, the vehicle experiences a lateral force, a yaw, and a roll moment. This causes the vehicle to veer off course and forces the driver to steer into it.

This process had been observed over a long period of time under quasi-steady conditions. During the last years, however, an instationary consideration of this phenomenon termed "crosswind sensitivity" has been emphasized. From a quasi-steady point of view, lateral force and yaw moment should be as low as possible. Within an instationary consideration, a generalization of this aspect cannot be made.

Thus, the entire system consisting of the driver and vehicle has to be studied. It is not sufficient simply to minimize the vehicle reactions to crosswind by aerodynamic and vehicle dynamics measures. Taking the system as a whole, the driver's influence can negate or reverse the measures taken to optimize the vehicle. Thus, the driver is drawn closer to the center of considerations. By evaluating his or her steering interventions, it is possible to investigate and optimize the interaction between driver and vehicle. A suitable driver model, which can adapt its steering characteristics to the driven vehicle, therefore, has to be incorporated into a virtual study.

A further aspect that should be taken into account is the unsteady character of the aerodynamic excitation of the vehicle. The time-dependent behavior of the pressure formation on the windward and lee sides is a complication in trying to accurately describe the vehicle's excitation. Furthermore, this behavior over time displays a dependency on the basic shape of the vehicle. This is therefore particularly important when different body shapes are being studied using virtual techniques.

This chapter demonstrates clearly that aerodynamic considerations, particularly with regard to unsteady lift and crosswind behavior, must be incorporated into the development process at the earliest possible stage of vehicle design. Furthermore, it is clear from the example of crosswind behavior that a more precise description is needed of the interface between aerodynamics and vehicle motion dynamics.

SYMBOLS

A	Frontal area (m^2)
a_Z	Lateral acceleration (m/s^2)
c_D	Aerodynamic drag coefficient
c_f	Lateral stiffness of front axle (N/rad)
c_L	Aerodynamic lift coefficient
c_{Lf}	Aerodynamic lift coefficient for front axle
c_{Lr}	Aerodynamic lift coefficient for rear axle
c_r	Lateral stiffness of rear axle (N/rad)
c_S	Aerodynamic side force coefficient
c_{Sf}	Aerodynamic side force coefficient for front axle
c_{Sr}	Aerodynamic side force coefficient for rear axle
c_{Mx}	Aerodynamic roll moment coefficient
c_{My}	Aerodynamic pitch moment coefficient
c_{Mz}	Aerodynamic yaw moment coefficient
$e_{CG,x}$	Lever arm of wind-force to *CG* in x direction (m)
F_f	Lateral force on front axle (N)
F_r	Lateral force on rear axle (N)
F_S	Lateral wind-force (N)
f	Frequency (Hz)
f_R	Resonant frequency (Hz)
$f_{R,opt}$	Optical resonant frequency of driver intervention (Hz)
G	Response function
G_F	Response function of the driver to crosswind excitation
G_{δ_L}	Response function of the vehicle to steering inputs
$G_{\tau v_{res}^2}$	Response function of the vehicle to crosswind excitation
g	Gravitational acceleration (m/s^2)
i_L	Steering ratio
J_z	Inertia around the vertical axis (kg m^2)

$j\omega$	Complex component of the frequency domain
K_{ges}	Evaluation criterion for the overall assessment
K_G	Evaluation criterion for the intensity of vehicle reactions
K_L	Evaluation criterion for the steering effort
K_P	Evaluation criterion for the driver's steering response
K_V	Evaluation criterion for the effectiveness of the driver's intervention
k_S	Gradient of the linearized aerodynamic side force coefficient
l_0	Wheelbase (m)
l_f	Distance between *CG* and front axle (m)
l_r	Distance between *CG* and rear axle (m)
M_x	Aerodynamic roll moment (Nm)
M_y	Aerodynamic pitch moment (Nm)
M_z	Aerodynamic yaw moment (Nm)
m	Vehicle mass (kg)
p	Pressure (bar)
r_{CG}	Track radius of the *CG* (m)
$T_{\dot{\psi},\max}$	Peak response time of yaw velocity (s)
t	Time (s)
v	Path speed of the *CG* (m/s)
v_f	Path speed of front axle (m/s)
v_r	Path speed of rear axle (m/s)
v_{res}	Resulting incident flow velocity (m/s)
v_{veh}	Flow velocity due to vehicle motion (m/s)
v_{Wind}	Wind speed (m/s)
α_f	Sideslip angle of front axle (composed of tire slip, elasto-kinematics, and steering elasticity) (rad)
α_r	Sideslip angle of rear axle (composed of tire slip and elasto-kinematics) (rad)
β	Slip angle (rad)
ϑ	Damping factor
δ	Damping time constant (1/s)
δ_L	Steering angle (rad)
ζ	Angular velocity (1/s)
ρ	Air density (kg/m^3)
τ	Resulting incident flow angle (rad)
τv_{res}^2	Factor to express stochastic vehicle excitation (radm^2/s^2)
τ_{Wind}	Wind angle (rad)
ψ	Yaw angle (rad)
$\dot{\psi}$	Yaw velocity (rad/s)
$\dot{\psi}_{\delta_L}$	Driver-induced yaw velocity (rad/s)
$\dot{\psi}_{\tau v_{res}^2}$	Wind-induced yaw velocity (rad/s)
ω	Angular frequency (rad/s)
ω_0	Undamped natural angular frequency (rad/s)
ω_d	Damped natural angular frequency (rad/s)
ω_R	Resonant angular frequency (rad/s)

17.1 INTRODUCTION AND DEFINITIONS

In each of the three perpendicular directions, the tire is capable to generate forces. They are needed to carry the vehicle's weight, to steer, and to brake or accelerate the vehicle. Apart from the forces, that is, the normal load F_z, the lateral force F_y, and the longitudinal driving or braking force F_x, the tire produces moments about the corresponding axes. The aligning torque M_z acting about the vertical axis is the more important one. In Figure 17.1 these forces and moment acting from road to tire have been indicated. Forces and moments are the result of tire deflections that arise due to the mutual interaction between the wheel and road. Obviously, the normal or radial deflection of the tire is a direct result of the vertical motion of the wheel axle and the vertical profile of the road surface. The horizontal deflections of the tire are connected with the horizontal and rotational motions of the wheel that may induce longitudinal and lateral slip of the wheel with respect to the ground.

To become more precise, it is useful to introduce the so-called slip point S. This imaginary point is attached to the wheel rim, and at the instant of observation, the point is located in the lowest position, that is, on the radius passing through the so-called contact center or point of intersection C.

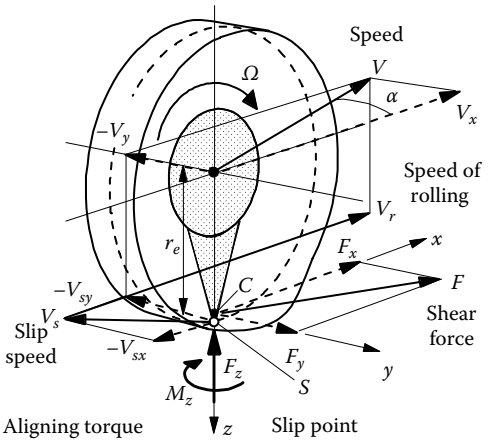

FIGURE 17.1 Tire forces and moment generated through tire deflections and wheel slip velocities.

This latter point forms the intersection of three planes: the road plane, the wheel center plane, and the plane passing through the wheelspin axis and perpendicular to the road plane. The slip point S is normally located slightly below the road surface. Its distance to the wheel center is defined as the slip radius r_s. Here, we take the slip radius equal to the so-called effective free rolling radius r_e. The horizontal velocity of the slip point is the slip speed of the wheel (rim) with respect to the road. Apparently, at free rolling (no driving or braking torque) the longitudinal component of the slip velocity equals zero. Then, the wheel speed of revolution $\Omega = \Omega_o$. When the wheel is being braked ($\Omega < \Omega_o$), point S moves in forward direction with longitudinal slip speed V_{sx}. When the slip point moves sideways, a lateral slip velocity V_{sy} arises. Note that the difference between lateral velocities of points S and C may be neglected. The resulting velocity V_s of point S represents the vector of the slip speed of the wheel. The slip speed components may be used directly to determine the resulting forces and moment. In practice, however, it appears in most cases to be more practical to use the components of the wheel slip vector as input quantities. These slip quantities are obtained by dividing the slip speed components by the forward speed V_x of the wheel center (or better of the contact center C):

$$\kappa = -\frac{V_{sx}}{V_x}\left(= \frac{r_e(\Omega - \Omega_o)}{V_x}\right) \tag{17.1}$$

$$\tan\alpha = -\frac{V_{sy}}{V_x} \tag{17.2}$$

Here, α is the slip angle as indicated in Figure 17.1. Other conventions may use different signs and symbols (cf. the Appendix). Depending on the type of testing equipment, one might define the longitudinal slip κ such that it equals zero at free rolling (as adopted here) or at vanishing longitudinal force $F_x = 0$. As a consequence, in the latter case a slightly shorter value of the slip radius results. The first definition is often used because of traditional testing procedures where the wheel can roll freely. The latter definition is used when the wheel rotational velocity is being controlled. It has the advantage that it can still be used even on very slippery surfaces where free rolling might not occur due to the low friction level not being able to overcome the tire rolling resistance.

The slip components α and κ together with spin slip φ due to wheel camber angle γ and possibly turn slip (path curvature $1/R$) may serve as input quantities in a tire model. With such a mathematical model, the resulting forces and moments can be calculated. The normal load and possibly the speed of travel are used as service parameters.

Tire models are used to calculate the tire forces and moments as responses to the wheel motion that may be expressed in terms of the various slip quantities. We may distinguish theoretical models based on physics of the tire construction and empirical models that are solely based on experimental findings. Also, combinations of both approaches are used in the development of the tire model.

The models that are in use nowadays range from very simple to highly complex descriptions of tire behavior. The model becomes more complex when we need to consider:

- Larger magnitudes of wheel slip, requiring a nonlinear description
- Combined slip as opposed to pure lateral or pure longitudinal slip
- Wheel camber and turn slip
- Wet or icy roads that make the friction coefficient dependency on speed no longer negligible
- Time-varying wheel motion that requires a non-steady-state/transient tire model
- High-frequency inputs and high speed of travel necessitating the inclusion of tire inertial properties
- Short-wavelength wheel oscillations and road irregularities requiring more detailed contact zone deflection considerations
- Simulations starting from or ending at standstill

In the subsequent sections, a brief description of modeling the tire as a vehicle component is given. Most of the material has been taken from the book "Tyre and Vehicle Dynamics" written by the author (cf. Ref. [1]). For further reading and for the study of vehicle dynamics applications, one is referred to that book and to the references listed at the end of this chapter. In the sequel, an overview will be given of some categories of tire modeling and tire dynamic behavior. We will first treat the relatively simple case of steady-state wheel slipping motions over a flat-level road surface by using the well-known physical brush model.

17.2 BRUSH MODEL AT STEADY-STATE SLIP

In the state-of-the-art paper by Pacejka and Sharp [2], a description is given of some recent tire models. The discussion was restricted to those models that were developed for use in vehicle dynamics studies at or close to steady-state conditions. To gain insight, let us consider a very simple physical model that can nicely explain how the forces and the moment are generated through the action of wheel slip in pure lateral or longitudinal directions or at a combination of these slip components (e.g., braking in a curve).

The model is the so-called brush tire model. The elastic bristles (similar to tread elements) are attached to the rim or to the assumedly rigid carcass that can only deflect vertically to accommodate the flat contact area. In the contact zone, the other ends of the bristles touch the road surface. Figure 17.2a depicts the deflected brush model. Three different cases of slip are considered. For each case the wheel slip speed vector (i.e., the speed of point S attached to the wheel rim) has been indicated. The base points of the elastic elements move parallel with respect to the road with that slip speed V_s (turn slip and camber not considered). As soon as the foremost element (at the right-hand side of the diagram) touches the road, the deformation starts to develop. The end point of the element that touches the surface remains in contact without sliding up to a point along the contact line where the frictional force that is maximally available is not enough to further deflect the element. At that transition point, the sliding zone is entered. In that zone, the element will continue to slide until it is lifted from the ground at the trailing edge. It may be noted that in the adhesion zone, where sliding does not occur, the contact line is straight and parallel to the speed vector of the wheel center (or better of the contact center C).

The model is simplified in that the friction coefficient is assumed to be constant (Coulomb friction) and that the stiffness of the elements is assumed to be the same in all horizontal directions. Further, a symmetric parabolic pressure distribution is considered. For the case of pure lateral slip,

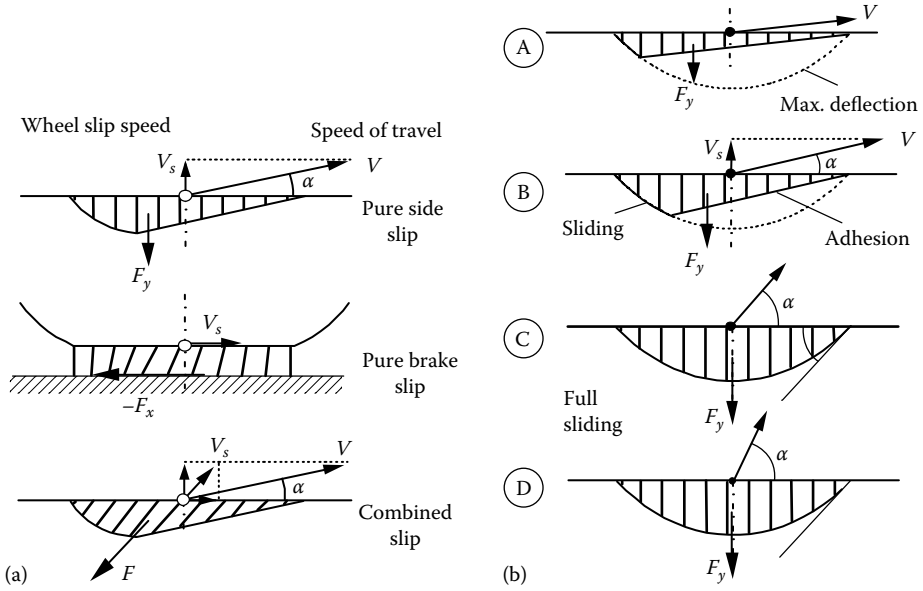

FIGURE 17.2 (a) Three modes of slip of the brush tire model. (b) Brush model at different levels of side slip.

Figure 17.2b shows how the deflection changes in magnitude and in distribution when the slip angle increases from very small to large. The initially approximately triangular shape (due to almost vanishing sliding) changes into a symmetric distribution when complete sliding is reached (case C).

We observe that the side force increases and that at the same time the pneumatic trail (the moment arm of the side force) decreases with increasing side slip. The resulting characteristics for the side force F_y and the aligning torque M_z are presented in Figure 17.3a. From the slip angle where complete sliding starts (case C), the side force is saturated and attains its maximum value equal to the friction coefficient μ times the vertical load F_z, while the moment becomes equal to zero. The curves appear to be very similar in nature to those established from measured data.

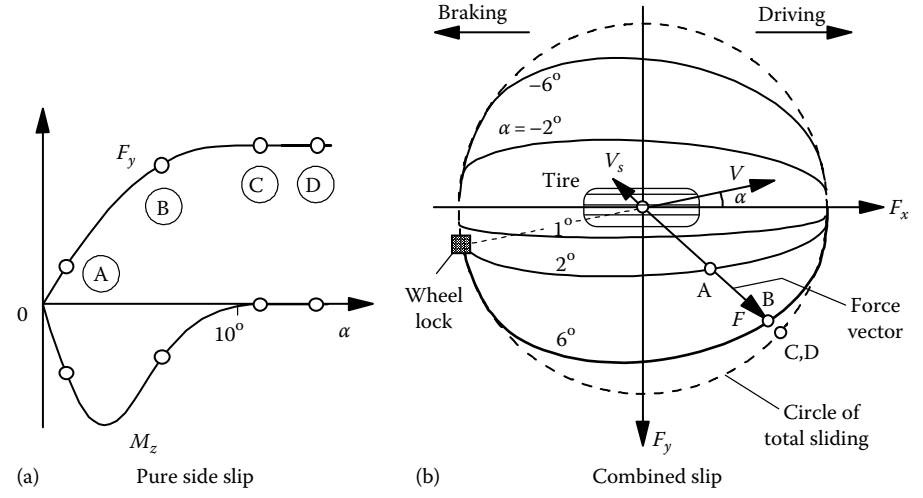

FIGURE 17.3 (a) The resulting side force and aligning torque characteristics of the model of Figure 17.2b with the corresponding cases A, B, C, and D indicated. (b) Combined slip characteristics for the side force versus fore and aft force at constant values of the slip angle. Cases A, B, C, and D of this isotropic tire model correspond in level of total slip with those indicated in Figure 17.2b.

The case of combined slip is analogous to the cases of pure lateral or longitudinal slip. Figure 17.3b shows the resulting F_y versus F_x diagram. Along the curves for constant slip angle α, the longitudinal slip κ varies. For a given ratio of tanα and κ, that is, for a given direction of the slip speed vector $\boldsymbol{V}_s$ (and the horizontal force vector $\boldsymbol{F}$ directed opposite to that slip speed), the four cases of increasing resulting slip A, B, C, and D have been indicated again.

17.2.1 Theory of the General Case of Combined Slip

To save space, we will not begin the theoretical analysis with one of the pure slip cases (cf. [1]), but start out with the general combined slip situation. For the analysis of the influence of longitudinal slip on the lateral force and moment generation, we will, for the sake of mathematical simplicity, restrict ourselves to the case of equal longitudinal and lateral stiffnesses of the tread elements (isotropic model), that is,

$$c_p = c_{px} = c_{py} \tag{17.3}$$

and equal and constant friction coefficients

$$\mu = \mu_x = \mu_y \tag{17.4}$$

Again a parabolic pressure distribution is considered.

Figure 17.4 depicts the deformations that arise when the tire model that runs at a given slip angle α is driven or braked. Due to the isotropic properties, the deflections are directed opposite to the slip

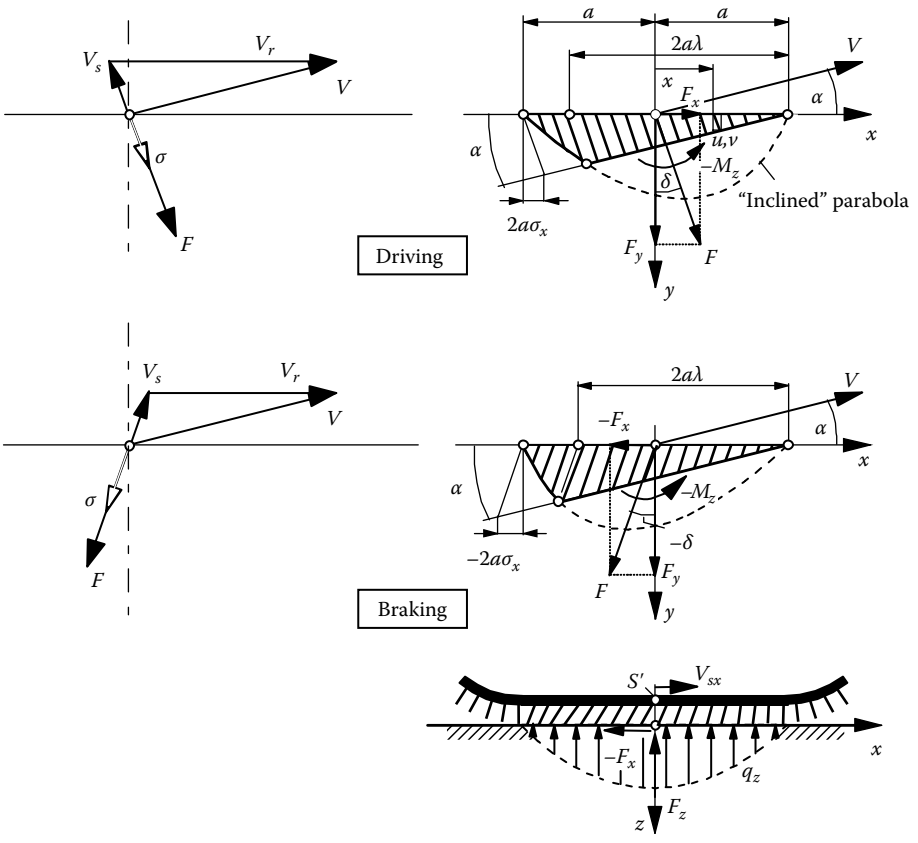

FIGURE 17.4 Vector diagram and deformation of the brush model running at a given slip angle for the cases of driving and braking.

speed vector $\boldsymbol{V}_s$, also in the sliding region. In this latter region, the tips of the elements slide over the road with sliding speed $\boldsymbol{V}_g$ directed opposite to the local friction force $\boldsymbol{q}$ (per unit contact length). The whole deformation history of a tread element while running through the contact area is a one-dimensional process along the direction of $\boldsymbol{V}_s$.

The velocity of progression of a base point through the contact length is the rolling speed V_r. The deflection rate of an element in the adhesion region is equal to the slip speed V_s. The time that elapses from the point of entrance to the point of a distance x in front of the contact center equals

$$\Delta t = \frac{a - x}{V_r} \tag{17.5}$$

with a denoting half the contact length. In this position, the deflection of an element that is still in adhesion becomes in vectorial form:

$$e = \begin{pmatrix} u \\ v \end{pmatrix} = \boldsymbol{V}_s \, \Delta t = -\frac{\boldsymbol{V}_s}{V_r}(a - x) \tag{17.6}$$

It seems natural at this stage to introduce the alternative (theoretical) slip quantity that reads in vectorial form:

$$\boldsymbol{\sigma} = \begin{pmatrix} \sigma_x \\ \sigma_y \end{pmatrix} = -\frac{\boldsymbol{V}_s}{V_r} = -\frac{1}{V_r}\begin{pmatrix} V_{sx} \\ V_{sy} \end{pmatrix} \tag{17.7}$$

with the linear speed of rolling

$$V_r = V_x - V_{sx} \tag{17.8}$$

The relations of these theoretical slip quantities with the practical slip quantities κ (= $- V_{sx}/V_x$) and $\tan\alpha$ (= $- V_{sy}/V_x$) are

$$\begin{aligned} \sigma_x &= \frac{\kappa}{1+\kappa} \\ \sigma_y &= \frac{\tan\alpha}{1+\kappa} \end{aligned} \tag{17.9}$$

The deflection of an element in the adhesion region now reads

$$e = (a - x)\,\boldsymbol{\sigma} \tag{17.10}$$

from which it is apparent that longitudinal and lateral deflections are governed by σ_x and σ_y, respectively, and independent of each other. This would not be the case if the deflection is expressed in terms of the practical quantities κ and α.

The local horizontal contact force acting on the tips of the elements (per unit contact length) reads

$$\boldsymbol{q} = c_p(a - x)\,\boldsymbol{\sigma} \text{ (adhesion region)} \tag{17.11}$$

As soon as

$$q = |\boldsymbol{q}| = \sqrt{q_x^2 + q_y^2} > \mu q_z \tag{17.12}$$

the sliding region is entered. Then the friction force vector becomes

$$\boldsymbol{q} = -\frac{\boldsymbol{V}_s}{V_s}\mu q_z = \frac{\boldsymbol{\sigma}}{\sigma}\mu q_z \text{ (sliding region)} \tag{17.13}$$

where

$$V_s = \sqrt{V_{sx}^2 + V_{sy}^2} \tag{17.14}$$

and

$$\sigma = \sqrt{\sigma_x^2 + \sigma_y^2} \tag{17.15}$$

Similarly, the magnitude of the deflection of an element becomes

$$e = |\boldsymbol{e}| = \sqrt{u^2 + v^2} \tag{17.16}$$

The location of the point of transition from adhesion to sliding region at $x = x_t$ is obtained from the condition:

$$c_p e = \mu q_z \tag{17.17}$$

or

$$c_p \sigma (a - x_t) = \frac{3}{4}\mu F_z \frac{a^2 - x_t^2}{a^3} \tag{17.18}$$

which yields

$$x_t = \frac{4}{3}\frac{c_p a^3 \sigma}{\mu F_z} - a = a(2\theta\sigma - 1) \tag{17.19}$$

or with $\lambda = (a - x_t)/2a$ denoting the fraction of the contact length where sliding starts

$$\lambda = 1 - \theta\sigma \tag{17.20}$$

where the composite parameter θ reads

$$\theta = \frac{2}{3}\frac{c_p a^2}{\mu F_z} \tag{17.21}$$

From Equation 17.20 the slip σ_{sl} at which total sliding starts can be calculated. We get with $\lambda = 0$:

$$\sigma_{sl} = \frac{1}{\theta} \tag{17.22}$$

The magnitude of the total force $F = |\boldsymbol{F}|$ can now be obtained by integrating $c_p e$ over the contact length. We find

$$F = \mu F_z(1-\lambda^3) = \mu F_z\left\{3\theta\sigma - 3(\theta\sigma)^2 + \left(\theta\sigma\right)^3\right\} \quad \text{for } \sigma \le \sigma_{sl}$$
$$F = \mu F_z \quad \text{for } \sigma \ge \sigma_{sl} \tag{17.23}$$

that obviously follows the same course as the characteristic for F_y shown in Figure 17.3a. The force vector $\boldsymbol{F}$ acts in a direction opposite to $\boldsymbol{V}_s$ or $-\sigma$. Hence

$$\boldsymbol{F} = F\frac{\sigma}{\sigma} \tag{17.24}$$

from which the components F_x and F_y may be obtained.

The moment $-M_z$ is obtained by integration of $xc_p e_y$ over the contact length. If expressed in terms of multiplication of F_y with the pneumatic trail t, we have

$$M_z = -t(\sigma)\cdot F_y \tag{17.25}$$

The pneumatic trail t that indicates the distance behind the contact center C where the resultant side force F_y is acting appears to become

if $|\sigma| \le \sigma_{sl}$

$$t = -\frac{M_z}{F_y} = \frac{1}{3}a\frac{1-3\theta\sigma+3(\theta\sigma)^2-\theta\sigma^3}{1-\theta\sigma+(1/3)(\theta\sigma)^2} \tag{17.26}$$

and if $|\sigma| \ge \sigma_{sl}$

$$t = 0 \tag{17.27}$$

In Figures 17.5 and 17.6, the dramatic reduction of the pure slip forces (the side force and the longitudinal force, respectively) that occurs as a result of the simultaneous introduction of the other slip component (the longitudinal slip and the side slip, respectively) has been indicated. We observe a (almost) symmetric shape of these interaction curves. The peak of the side force versus

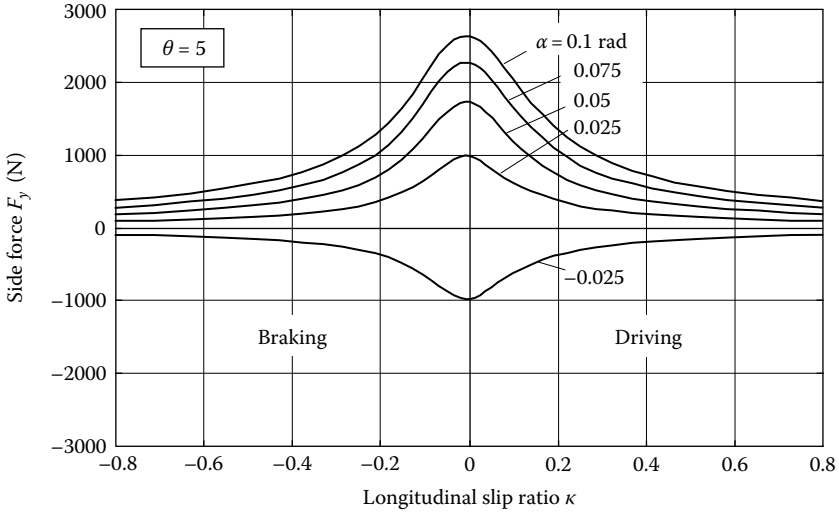

FIGURE 17.5 Reduction of side force due to the presence of longitudinal slip.

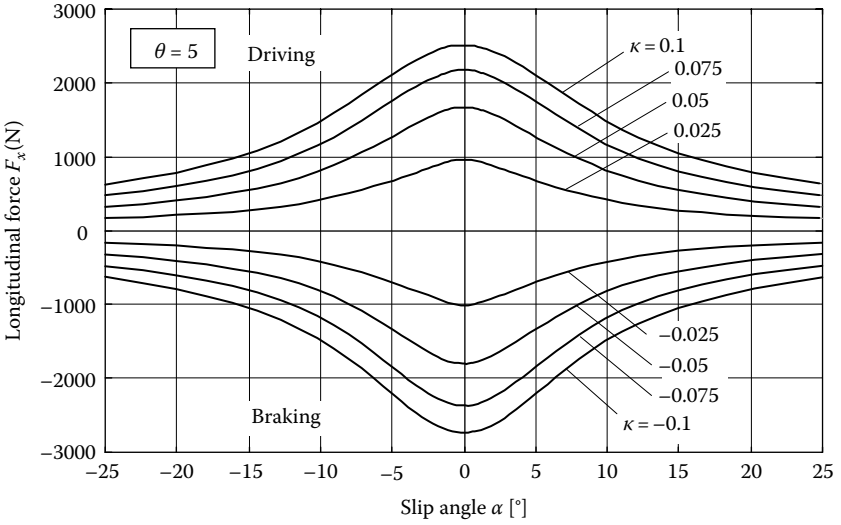

FIGURE 17.6 Reduction of longitudinal force due to the presence of side slip.

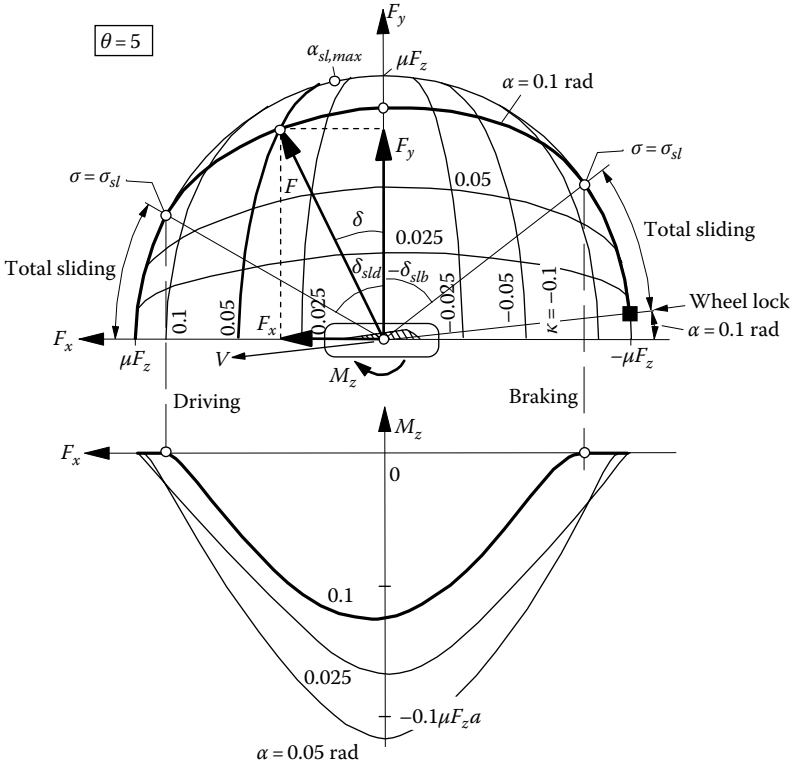

FIGURE 17.7 Cornering force and aligning torque as functions of longitudinal force at constant slip angle α or longitudinal slip κ.

longitudinal slip curves at constant values of the slip angle appears to be slightly shifted toward the braking side. This phenomenon will be further discussed in connection with the alternative representation of the same results according to Figure 17.7. At very large longitudinal slip, that is, when $|V_{sx}|/V_x \to \infty$, the side force approaches zero and the same occurs for the longitudinal force when the lateral slip tanα goes to infinity ($\alpha \to 90°$) at a given value of the longitudinal slip because

obviously in that case with $V_x \to 0$, also the longitudinal slip speed must vanish. For a wheel that is locked ($\Omega = 0$) with $V_{sx} = V_x$ and $\kappa = -1$, we have $F_y = \mu F_z \sin\alpha$ and $F_x = -\mu F_z \cos\alpha$.

In Figure 17.7, the calculated variations of F_y and M_z with F_x have been plotted for several fixed values of α. Also the curves for constant κ have been indicated. At braking, F_y appears to be a little larger than at driving. This would at least be true for those pairs of driving and braking conditions that show the same side slip angle and the same magnitude of the deviation angle δ of the slip velocity vector and thus of the force vector with respect to the y-axis. Then, the slip speeds V_s are equal in magnitude, but at braking the speed of rolling V_r is obviously smaller. When considering the definition of the theoretical slip σ (17.7) and the functional relationship (17.23) with the force F, it becomes clear that F must be larger in the case of braking because of the then larger magnitude of σ. Finally, the case of wheel lock is pointed at. Then, the force vector $\boldsymbol{F}$ that in magnitude is equal to μF_z is directed opposite to the speed vector of the wheel $\boldsymbol{V}$ that then coincides with the slip speed vector $\boldsymbol{V}_s$.

Experimental evidence supports the nature of the theoretical curves for the forces as shown in Figure 17.7. Often, the shape appears to be more asymmetric than predicted by the simple brush model. This may be due to a slight increase in the contact length while braking (making the tire stiffer) and by the brake force-induced slip angle of the contact patch at side slip. This is accomplished through the torsion of the carcass caused by the moment about the vertical axis that is exerted by the braking force that has shifted its line of action due to the lateral deflection that is associated with the side force.

The moment curves presented in the lower diagram of Figure 17.7 show a more or less symmetric bell shape. As expected, the aligning torque becomes equal to zero when total sliding occurs ($\sigma \geq \sigma_{sl}$). In cases observed in practice, these computed moment characteristics may appreciably deviate from the experimental ones. The model may be improved by introducing a lateral shift of the base line where the tread elements are attached. This shift corresponds to the lateral carcass deflection occurring at side slip under the action of the lateral force and may give rise to a sign change of the moment in the braking range of the characteristic (cf. [1]).

Although the force diagrams appear quite realistic, this simple brush model is in general not suitable to produce quantitatively correct and thus acceptable results. Considerable deviations may occur and the following important features that are not included in the simple brush model may be responsible for these (cf. Figure 17.8): unequal stiffnesses in x and y directions, nonconstant friction coefficient, lateral and bending compliance of the carcass and belt, nonsymmetric and nonconstant

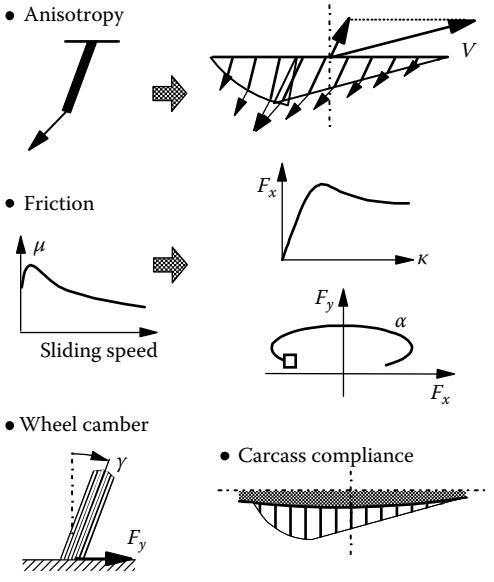

FIGURE 17.8 Physical factors that complicate modeling of the tire.

pressure distribution, and tread width. Introducing these factors in a tire model would considerably increase its complexity. Also, the introduction of wheel camber and turn slip would complicate the matter. To be able to handle these complicating features, computer models using discrete elements, the deflections of which are calculated during the simulation process, may be employed (cf. Pacejka et al. [1–3]). Some of these physical models may become highly advanced and can be used to simulate complex dynamic conditions (cf., e.g., Gipser [4,5] and Oertel [6,7]).

An alternative way to achieve a better mathematical description is the use of empirical models. For modeling steady-state conditions, two approaches will be discussed in the subsequent two sections: First, the similarity method and subsequently the more advanced Magic Formula tire model will be treated.

17.3 SIMILARITY METHOD

The method to be discussed in this section is based on the observation that the pure slip curves remain approximately similar in shape when the tire runs at conditions that are different from the reference condition. The reference condition is defined here as the state where the tire runs at its rated (nominal) load (F_{zo}), at camber equal to zero ($\gamma = 0$), at either free rolling ($\kappa = 0$) or side slip equal to zero ($\alpha = 0$), and on a given road surface (μ_o). A similar shape means that the characteristic that belongs to the reference condition is regained by vertical and horizontal multiplications and shifting of the curve. A demonstration that in practice similarity indeed approximately occurs is given by Radt and Milliken [8]. Figure 17.9 presents the results when the side force and the slip angle are normalized resulting in the nondimensional quantities shown along the axes. The raw data have been processed to make the characteristics pass through the origin of the graph. The curve results from a Magic Formula fit. The parameters B', C', D', and E' for the nondimensional side force (subscript y) have been used in the nondimensional version of the Magic Formula given further on. Also for the aligning torque, it can be shown that normalized curves appear to become very much the same.

The resulting model is through its simplicity relatively fast. It is capable to represent pure slip conditions rather well including the influence of a camber angle. The description of the situation at combined lateral and longitudinal slip is qualitatively satisfactory. Quantitatively, however, deviations may occur at higher levels of the combined two slip values.

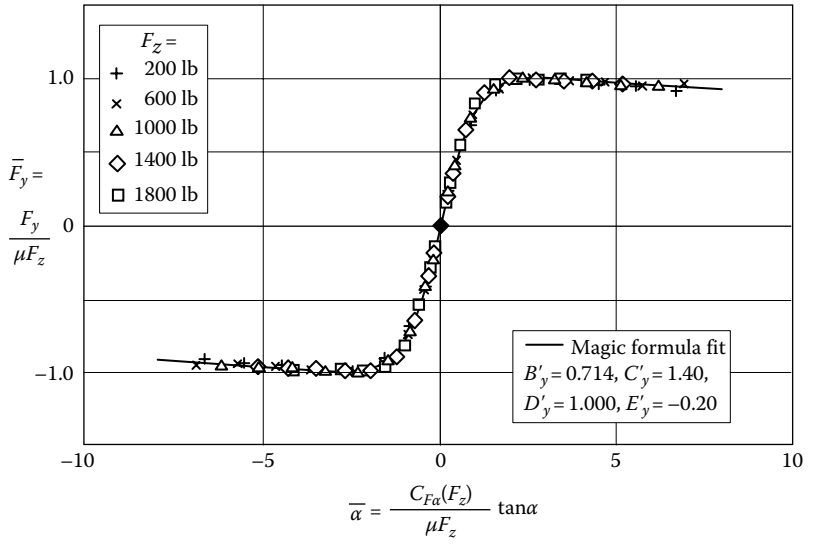

FIGURE 17.9 Result of Radt's nondimensionalization of tire characteristics showing that the tire side force characteristics measured at different loads reduce to virtually the same curve when the force and the slip angle are normalized as indicated.

17.3.1 Pure Slip Conditions

The functions representing the reference curves that are found at pure slip conditions are designated with the subscript *o*. We have, for instance, the reference function $F_y = F_{yo}(\alpha)$ that represents the side force versus slip angle relationship at nominal load F_{zo}, with longitudinal slip and camber equal to zero and the friction level represented by μ_o. We may now try to change the condition to a situation at a different wheel load F_z. Two basic changes will occur with the characteristic: (1) a change in level of the curve where saturation of the side force takes place (peak level) and (2) a change in slope at vanishing side slip ($\alpha = 0$). The first modification can be created by multiplying the characteristic both in vertical and in horizontal directions with the ratio F_z/F_{zo}. The horizontal multiplication is needed to not disturb the original slope. We obtain for the new function

$$F_y = \frac{F_z}{F_{zo}} F_{yo}(\alpha_{eq}) \tag{17.28}$$

with the equivalent slip angle:

$$\alpha_{eq} = \frac{F_{zo}}{F_z}\alpha \tag{17.29}$$

Because, obviously, the derivative of F_{yo} with respect to its argument α_{eq} at $\alpha_{eq} = 0$ is equal to the original cornering stiffness $C_{F\alpha o}$, we find for the derivative of F_y with respect to α the same value for the slope at $\alpha = 0$:

$$\frac{\partial F_y}{\partial \alpha} = \frac{F_z}{F_{zo}} \frac{dF_{yo}}{d\alpha_{eq}} \frac{\partial \alpha_{eq}}{\partial \alpha} = \frac{dF_{yo}}{d\alpha_{eq}} = C_{F\alpha o} \tag{17.30}$$

which proves that the slope at the origin of the characteristic is not affected by the successive multiplications. The second step in the manipulation of the original curve is the adaptation of the slope. This is accomplished by a horizontal multiplication of the newly obtained characteristic. This is done by multiplying the argument with the ratio of the new and the original cornering stiffness. Consequently, the new argument reads

$$\alpha_{eq} = \frac{C_{F\alpha}(F_z)}{C_{F\alpha o}} \frac{F_{zo}}{F_z}\alpha \tag{17.31}$$

Together with Equation 17.28 we have the new formulation for the side force versus slip angle relationship at the new load F_z. In Figure 17.10a the two steps taken to obtain the new curve have been illustrated. Here, the nominal load $F_{zo} = 3000$ N and the new load $F_z = 1500$ N.

In the same figure the characteristic of the aligning torque has been adapted to the new condition. For this, we use the knowledge gained when working with the brush model (cf. Figure 17.3a). More specifically, we will obey the rule that according to the theory, obviously, the point where the M_z curve reaches the α-axis lies below the peak of the F_y curve. According to Equation 17.22 this occurs at $\tan\alpha = 1/\theta$. This requirement means that the same equivalent slip angle (17.31) must be used as for the argument of the F_y function (17.28). Secondly, we will use information on the new value of the aligning stiffness $C_{M\alpha}(F_z)$. The reference curve for M_{zo} that is used is more realistic than the theoretical curve of Figure 17.3a. Typically, the moment changes its sign in the larger slip angle range approximately where F_y reaches its peak.

With the same equivalent slip angle and the new aligning stiffness, we obtain the expression for the new value of the aligning torque according to the similarity concept:

$$M_z = \frac{F_z}{F_{zo}} \frac{C_{M\alpha}(F_z)}{C_{M\alpha o}} \frac{C_{F\alpha o}}{C_{F\alpha}(F_z)} M_{zo}(\alpha_{eq}) \tag{17.32}$$

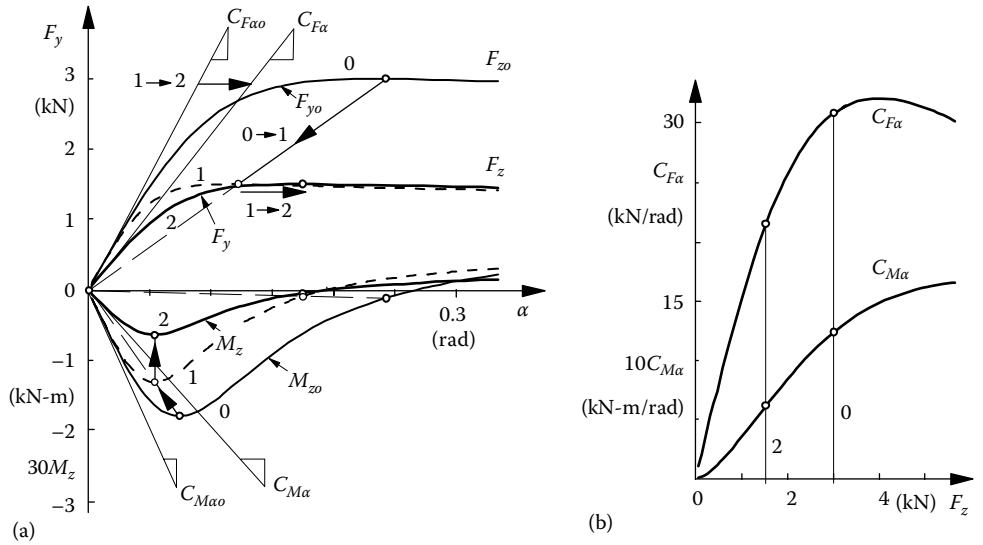

FIGURE 17.10 (a) Using the similarity method to adapt F_y and M_z curves to a new level of load. (b) Cornering and aligning stiffness versus wheel load.

The first and third factors being the inverse of the multiplication factor used in (17.31) are needed to maintain the original slope. The second factor multiplies the intermediate M_z curve (1 in Figure 17.10a) in vertical direction to adapt the slope to its new value (2) while not disturbing the α scale. It may be noted that the combined second and third factor equals the ratio of the new and the original values of the pneumatic trail t/t_o.

For the calculations connected with Figure 17.10a, the reference characteristics for F_{yo}, M_{zo}, and $C_{F\alpha}$ have been described by means of the Magic Formula-type functions. For this occasion, the aligning stiffness is modeled as the product of a certain fraction of the contact length $2a$ and the cornering stiffness. The resulting characteristics for these four quantities as shown in Figure 17.10a and b are realistic. The following formulae have been used:

The side force at nominal load F_{zo}

$$F_{yo} = D_{yo} \sin[C_y \arctan \{B_{yo}\alpha - E_y(B_{yo}\,\alpha - \arctan(B_{yo}\alpha))\}] \tag{17.33}$$

with stiffness factor

$$B_{yo} = \frac{C_{F\alpha o}}{C_y D_{yo}} \tag{17.34}$$

the peak factor for the side force that, in general, is different from the one for the longitudinal force (as a consequence, we introduce μ_{yo} beside μ_{xo} in the peak factor)

$$D_{yo} = \mu_{yo} F_{zo} \tag{17.35}$$

and the cornering stiffness as function of wheel load F_z

$$C_{F\alpha} = c_1 c_2 F_{zo} \sin\left\{2 \arctan\left(\frac{F_z}{c_2 F_{zo}}\right)\right\} \tag{17.36}$$

The aligning torque at nominal wheel load

$$M_{zo} = D_{zo} \sin[C_z \arctan \{B_{zo}\alpha - E_z(B_{zo}\alpha - \arctan(B_{zo}\alpha))\}] \tag{17.37}$$

with stiffness factor

$$B_{zo} = \frac{-C_{M\alpha o}}{C_z D_{zo}} \tag{17.38}$$

the peak factor (a_o representing half the contact length at nominal load)

$$D_{zo} = c_3 a_o D_{yo} \tag{17.39}$$

and the aligning stiffness as function of wheel load F_z

$$C_{M\alpha} = tC_{F\alpha} = c_4 a C_{F\alpha} \tag{17.40}$$

where apparently the pneumatic trail $t = c_4 a$. Half the contact length a is assumed to be proportional with the square root of the wheel load:

$$a = a_o \sqrt{\frac{F_z}{F_{zo}}} \tag{17.41}$$

The resulting approximation of the pneumatic trail turns out to be quite adequate and might be considered to be used in the set of Magic Formula tire model in Equation 17.128 to be dealt with later on.

The values of parameters used for the calculations to be conducted have been listed in Table 17.1.

The next two items we will deal with are a change in friction coefficient from μ_{yo} to μ_y and the introduction of a camber angle γ. The first change can be handled by multiplying the curves in radial direction with factor μ_y/μ_{yo}. Together with the change in load, we find

$$F_y = \frac{\mu_y F_z}{\mu_{yo} F_{zo}} F_{yo}(\alpha_{eq}) \tag{17.42}$$

with

$$\alpha_{eq} = \frac{C_{F\alpha}(F_z)}{C_{F\alpha o}} \frac{\mu_{yo} F_{zo}}{\mu_y F_z} \alpha \tag{17.43}$$

The friction coefficient may be assumed to depend on (decay with) the slip velocity V_s. To model the situation on wet roads, a decaying function $\mu(V_s)$ may be employed (cf., e.g., ([1], Equations 17.110 and 17.95)).

TABLE 17.1
Parameter Values

F_{zo}	3000 N	C_y	1.3	C_x	1.5	c_1	8	c_5	1
a_o	0.08 m	E_y	−1	E_x	−1	c_2	1.33	c_6	0.3
b	0.07 m	C_z	2.3	μ_{yo}	1	c_3	0.25	c_7	100
r_e	0.30 m	E_z	−2	μ_{xo}	1.26	c_4	0.5	c_8	15

When considering experimental $F_y - \alpha$ characteristics at small camber angles, a reasonable result is expected when the F_y curve is shifted horizontally. Then, the peak side force remains unchanged, which is a reasonable assumption but not always supported by experimental evidence (where often but not always a slight increase in maximum side force is manifested) or by computations with a physical model with constant friction and finite contact width that show a slight decrease. For small angles, the camber thrust is approximated by the product of the camber stiffness and the camber angle: $F_{y\gamma} = C_{F\gamma}\gamma$. Consequently, the α shift should amount to

$$S_{Hy} = \frac{C_{F\gamma}(F_z)}{C_{F\alpha}(F_z)}\gamma \tag{17.44}$$

so that

$$\alpha^* = \alpha + S_{Hy} \tag{17.45}$$

which gives rise to α_{eq} (17.43) with α replaced by α^*.

For the representation of the aligning moment at the new conditions, the situation is more complex. From test results and more advanced calculations, it is observed that for not too large slip angles, the original curve M_{zo} tends to shift both sideways and upward. If the same equivalent slip angle and thus the same horizontal shift (17.44) as for the force are employed, the moment would become zero where also the side force curve crosses the α-axis. A moment equal to $-C_{M\alpha}\, S_{Hy}$ would arise at $\alpha = 0$. However, the moment should become equal to $C_{M\gamma}\gamma$, with a positive camber moment stiffness $C_{M\gamma}$. This implies that an additional vertical shift is required equal to

$$S_{Vz} = C_{M\gamma}(F_z)\gamma + C_{M\alpha}(F_z)S_{Hy} \tag{17.46}$$

This additional moment corresponds to the so-called residual torque M_{zr}, which is the moment that remains when the side force becomes equal to zero. For larger values of the slip angle, the additional moment should tend to zero. This may be easily accomplished by dividing (17.46) by a term like $1 + c_7\alpha^2$.

The dependencies of the camber stiffnesses on the vertical load may be assumed linear. We have

$$C_{F\gamma} = c_5 F_z, \quad C_{M\gamma} = c_6 \frac{b^2}{r_e} C_{F\kappa} \tag{17.47}$$

where

b denotes half the (assumedly constant) width of the contact patch

r_e is the effective rolling radius

$C_{F\kappa}$ is the longitudinal slip stiffness, which is considered to be linearly increasing with load

$$C_{F\kappa} = c_8 F_z \tag{17.48}$$

The camber moment stiffness $C_{M\gamma}$ mainly results from left and right opposite longitudinal slip in the contact area. In Figure 17.11, the different steps leading to the condition with a (small) camber angle have been demonstrated. First, the original curve (0) is moved to the left over a distance equal to the horizontal shift (17.44) yielding the intermediate curve (1). Then the residual torque is added: vertical shift (17.46) possibly made a function of slip angle by multiplying the shift with a decaying weighting function as suggested earlier. The load F_z and the friction coefficient μ_y have been kept equal to their reference values 3000 N and 1, respectively.

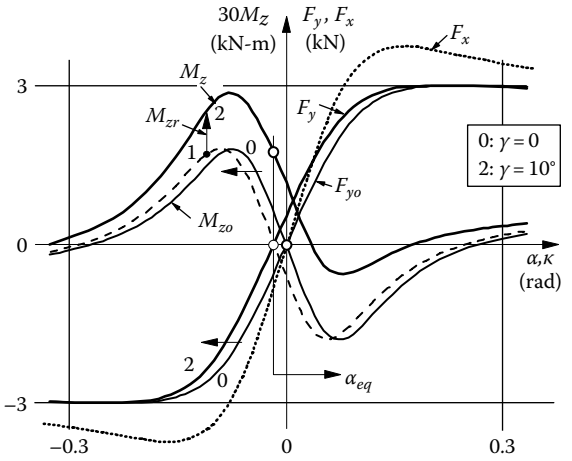

FIGURE 17.11 Introduction of a camber angle in the side force and the aligning torque pure slip characteristics according to the similarity method. The longitudinal force pure slip characteristic. ($F_z = F_{zo} = 3000$ N, $\mu_y = \mu_{yo} = 1$, $\mu_x = \mu_{xo} = 1.26$).

The longitudinal force at pure longitudinal slip may be modeled in the same way as we did for the side force. Equations similar to (17.33) through (17.35) hold for the reference function. An influence of camber on the longitudinal force, however, is assumed not to occur. In the same Figure 17.11, the characteristic for F_x versus κ has been drawn. The values of the relevant additional parameters for the longitudinal force and the moment have been listed in Table 17.1.

We finally have the following similarity formulae for pure slip conditions (either at longitudinal or at lateral slip) for the longitudinal force:

$$F_x = \frac{\mu_x F_z}{\mu_{xo} F_{zo}} F_{xo}(\kappa_{eq}) \tag{17.49}$$

with the equivalent longitudinal slip

$$\kappa_{eq} = \frac{C_{F\kappa}(F_z)}{C_{F\kappa o}} \frac{\mu_{xo} F_{zo}}{\mu_x F_z} \kappa \tag{17.50}$$

and for the side force

$$F_y = \frac{\mu_y F_z}{\mu_{yo} F_{zo}} F_{yo}(\alpha_{eq}) \tag{17.51}$$

with the equivalent slip angle, containing the horizontal shift (17.44),

$$\alpha_{eq} = \frac{C_{F\alpha}(F_z)}{C_{F\alpha o}} \frac{\mu_{yo} F_{zo}}{\mu_y F_z} \left(\alpha + \frac{C_{F\gamma}(F_z)}{C_{F\alpha}(F_z)} \gamma \right) \tag{17.52}$$

and for the aligning torque

$$M_z = \frac{\mu_y F_z}{\mu_{yo} F_{zo}} \frac{C_{M\alpha}(F_z)}{C_{M\alpha o}} \frac{C_{F\alpha o}}{C_{F\alpha}(F_z)} M_{zo}(\alpha_{eq}) + M_{zr} \tag{17.53}$$

with the residual torque corresponding to the vertical shift (17.46) provided with the reduction factor

$$M_{zr} = \frac{C_{M\gamma}(F_z) + t(F_z)C_{F\gamma}(F_z)}{1 + c_7\alpha^2}\gamma \tag{17.54}$$

17.3.2 Combined Slip Conditions

We will now address the problem of describing the situation at combined slip. The analysis of the brush model has gained considerable insight into the mechanisms that play a role and we will use the theoretical slip quantities $\sigma_{x,y}$ (17.9) and the magnitude σ (17.15) and we will adopt the concept similar to that of assessing the components of the resulting horizontal force according to (17.24) and use the pneumatic trail t as in (17.25). We have for the theoretical slip quantities with the α shift due to camber included

$$\sigma_x = \frac{\kappa}{1+\kappa} \tag{17.55}$$

$$\sigma_y^* = \frac{\tan\alpha^*}{1+\kappa} \tag{17.56}$$

and

$$\sigma^* = \sqrt{\sigma_x^2 + \sigma_y^{*2}} \tag{17.57}$$

with

$$\sigma^* = \alpha + \frac{C_{F\gamma}(F_z)}{C_{F\alpha}(F_z)}\gamma \tag{17.58}$$

In the ensuing theory, we will make use of the theoretical slip quantities (17.55, 17.56), which does produce the slope in the constant α curves in the F_y versus F_x diagram at $F_x = 0$. It should be noted, however, that experience has shown that the use of practical slip quantities s_x and s_y^* (i.e., κ and $\tan\alpha^*$ that may be obtained again by omitting the denominators in (17.55, 17.56) may already give very good results (cf. [1]). Note that when approaching wheel lock, $\sigma_x \to \infty$. This calls for an artificial limitation by adding a small positive quantity to the denominator of expression (17.55).

Because we are dealing with an in general non-isotropic tire, we have pure longitudinal and lateral slip characteristics that are not identical (cf. Figure 17.11). Still, we will take the lateral and longitudinal components but then of the respective pure slip characteristics F_{yo} and F_{xo}. If we want to use the theoretical slip quantities σ, we must have available pure slip characteristics with σ_x and σ_y as abscissa.

Next, we should realize that through (17.45) camber has been accounted for and that, as a consequence, σ_y is to be replaced by σ_y^* defined by Equation 17.56. The resulting force and moment functions are denoted by $F_{xo}(\sigma_x)$, $F_{yo}(\sigma_y^*)$, and $M_{zo}(\sigma_y^*)$. As illustrated in Figure 17.12, the "components" now become with σ^* denoting the magnitude of the theoretical slip vector (17.57):

$$F_x = \frac{\sigma_x}{\sigma^*}F_{xo}(\sigma^*), \quad F_y = \frac{\sigma_y^*}{\sigma^*}F_{yo}(\sigma^*) \tag{17.59}$$

The figure shows how the force vector arises from the individual pure slip characteristics. At small slip, in general, the vector does not run opposite with respect to the slip speed vector $\boldsymbol{V}_s$.

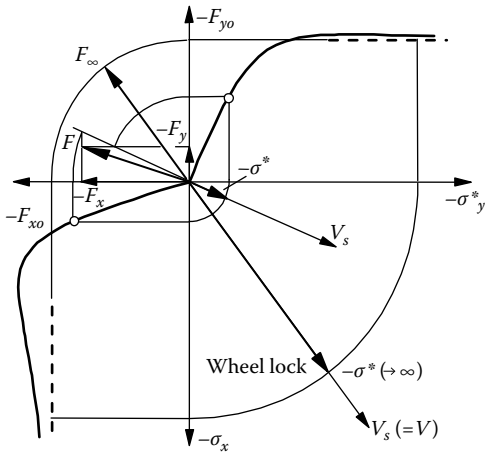

FIGURE 17.12 Construction of the resulting combined slip force from the pure slip characteristics according to Equation 17.59.

At wheel lock, however, the force vector does run opposite with respect to the slip speed vector because it is assumed here that the levels of the individual characteristics (asymptotes) are the same for the slip approaching infinity (in the Magic Formula we should have $\mu_{yo}\sin(\tfrac{1}{2}\pi C_y) = \mu_{xo}\sin(\tfrac{1}{2}\pi C_x)$). At large slip the theory apparently fails to properly account for the contribution of the camber angle. At wheel lock one would expect the side force to become zero at vanishing slip angle. This will not exactly be the case in the model due to the equivalent theoretical side slip defined according to Equation 17.56 with α^* given by (17.45).

For the aligning torque, the formulae have not been reproduced. We may refer to the original text [1].

With the similarity expressions for the pure slip forces $F_{x,yo}$, we finally obtain the following formulae for combined slip conditions. For the longitudinal force

$$F_x = \frac{\sigma_x}{\sigma^*}\frac{\mu_x F_z}{\mu_{xo} F_{zo}} F_{xo}(\sigma^x_{eq}) \tag{17.60}$$

with the equivalent slip

$$\sigma^x_{eq} = \frac{C_{F\kappa}(F_z)}{C_{F\kappa o}}\frac{\mu_{xo} F_{zo}}{\mu_x F_z}\sigma^* \tag{17.61}$$

and for the side force

$$F_y = \frac{\sigma^*_y}{\sigma^*}\frac{\mu_y F_z}{\mu_{yo} F_{zo}} F_{yo}(\sigma^y_{eq}) \tag{17.62}$$

with the equivalent slip

$$\sigma^y_{eq} = \frac{C_{F\alpha}(F_z)}{C_{F\alpha o}}\frac{\mu_{yo} F_{zo}}{\mu_y F_z}\sigma^* \tag{17.63}$$

For the case of a load different from the reference value and the presence of a camber angle, the combined slip characteristics for the tire side force have been assessed by using the preceding equations.

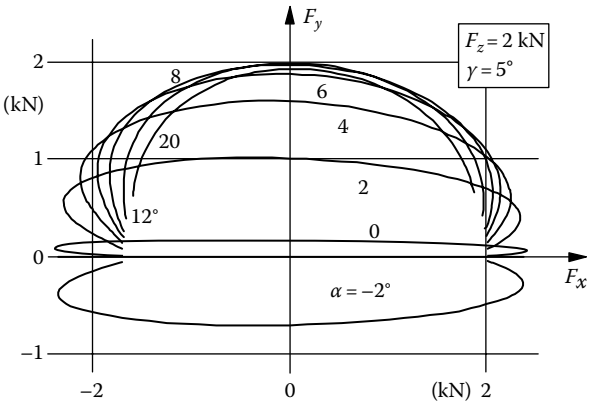

FIGURE 17.13 Cornering force versus longitudinal force at a new load and camber angle as computed with the similarity method.

The resulting diagrams with slip angle α used as parameter have been presented in Figure 17.13. Due to the use of the theoretical slip quantities (17.55, 17.56), we find that the curves of F_y show the slight slope near $F_x = 0$ also observed to occur with the physical brush model and sometimes more pronounced in experimentally assessed characteristics. The additional slope that arises when a camber angle is introduced for which the torsional compliance is responsible does not appear. A special formulation would be needed to represent this effect. In the next section, we will take care of this in connection with the Magic Formula tire model.

It may be further remarked that the similarity model given by Equations 17.60 through 17.63 together with (17.55) and (17.56) and the reference pure slip functions does represent the actual tire steady-state behavior correctly in the following extreme cases: (1) in pure slip situations, (2) in the linearized combined slip situation (small α and κ), and (3) in the case of a locked wheel ($\gamma = 0$). As illustrated in Figure 17.12, the model correctly shows that when the wheel is locked, the resulting force acts in a direction opposite to the slip speed vector $\boldsymbol{V}_s$ if in the original reference pure slip curves, the level of F_{xo} and of F_{yo} tends to the same level when both slip components approach infinity (governed by parameters μ and C in the Magic Formula). Other combinations of slip may give rise to deviations with respect to measured characteristics. It is noted that the approximate combined slip performance of the side and fore and aft forces can be represented without the necessity to have combined slip measurement data. In [1] the computed results have been compared with experimental data showing good agreement.

17.4 MAGIC FORMULA TIRE MODEL

A widely used semiempirical tire model to calculate steady-state tire force and moment characteristics for use in vehicle dynamics studies is based on the so-called Magic Formula. The development of the model was started in the mid-1980s. In a cooperative effort, TU Delft and Volvo developed several versions (Bakker et al. [9], Pacejka et al. [10]). In these models the combined slip situation was modeled from a physical view point. In 1993 Michelin (cf. Bayle et al. [11]) introduced a purely empirical method using Magic Formula-based functions to describe the tire horizontal force generation at combined slip. This approach was adopted in Delft Tire [12]. In the newer versions of "Delft Tire," the original description of the aligning torque is altered to accommodate a relatively simple physically based combined slip extension. The pneumatic trail is introduced as a basis to calculate this moment about the vertical axis (cf. Pacejka [12]). A complete listing of the model is given in the sequel.

17.4.1 Model Description

The general form of the formula that holds for given values of vertical load and camber angle reads

$$y = D\sin[C\arctan\{Bx - E(Bx - \arctan Bx)\}] \tag{17.64}$$

with

$$Y(X) = y(x) + S_V \tag{17.65}$$

$$x = X + S_H \tag{17.66}$$

where

Y is the output variable F_x, F_y, or possibly M_z
X is the input variable $\tan\alpha$ or κ
B is the stiffness factor
C is the shape factor
D is the peak value
E is the curvature factor
S_H is the horizontal shift
S_V is the vertical shift

The Magic Formula $y(x)$ typically produces a curve that passes through the origin $x = y = 0$, reaches a maximum, and subsequently tends to a horizontal asymptote. For given values of the coefficients B, C, D, and E, the curve shows an antisymmetric shape with respect to the origin. To allow the curve to have an offset with respect to the origin, two shifts S_H and S_V have been introduced. A new set of coordinates $Y(X)$ arises as shown in Figure 17.14. The formula is capable of producing characteristics that closely match measured curves for the side force F_y (and if desired also for the aligning torque M_z, cf. Equation 17.37) and for the fore and aft force F_x as functions of their respective slip quantities: the slip angle α and the longitudinal slip κ with the effect of load F_z and camber angle γ included in the parameters.

Figure 17.14 illustrates the meaning of some of the factors by means of a typical side force characteristic. Obviously, coefficient D represents the peak value (with respect to the central x-axis and for $C \geq 1$) and the product BCD corresponds to the slope at the origin ($x = y = 0$). The shape factor C controls the limits of the range of the sine function appearing in formula (17.64) and thereby determines the shape of the resulting curve. The factor B is left to determine the slope at the origin and is called the stiffness factor. The factor E is introduced to control the curvature at the peak and at the same time the horizontal position of the peak.

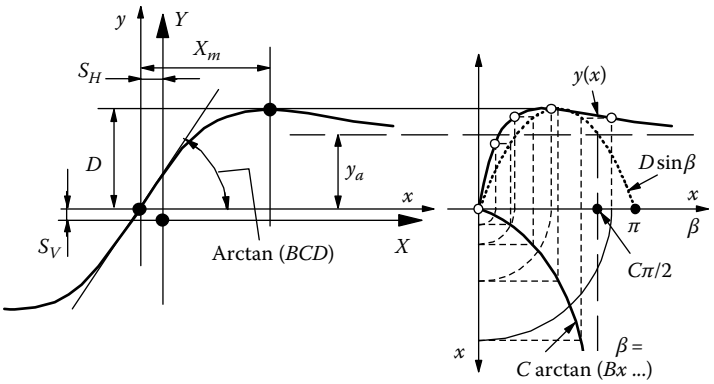

FIGURE 17.14 Curve produced by the original sine version of the Magic Formula, Equation 17.136. The meaning of curve parameters has been indicated.

From the heights of the peak and of the horizontal asymptote, the shape factor C may be computed:

$$C = 1 \pm \left(1 - \frac{2}{\pi} \arcsin \frac{y_a}{D} \right) \tag{17.67}$$

From B and C and location x_m of the peak, the value of E may be assessed:

$$E = \frac{Bx_m - \tan\{\pi/(2C)\}}{Bx_m - \arctan(Bx_m)} \quad (\text{if } C > 1) \tag{17.68}$$

The offsets S_H and S_V appear to occur when ply-steer and conicity effects and possibly the rolling resistance cause the F_y and F_x curves not to pass through the origin. Wheel camber may give rise to a considerable offset of the F_y versus α curves. Such a shift may be accompanied by a significant deviation from the pure antisymmetric shape of the original curve. To accommodate such an asymmetry, the curvature factor E is made dependent of the sign of the abscissa (x):

$$E = E_o + \Delta E \cdot \operatorname{sgn}(x) \tag{17.69}$$

Also the difference in shape that is expected to occur in the F_x versus κ characteristic between the driving and braking ranges can be taken care of. In Figure 17.15, the influence of the two shape factors C and E on the appearance of the curves has been demonstrated. The diagrams have been normalized by dividing y by D and multiplying x with CB making the curve peak level and initial slope independent of the parameters.

In rather extreme cases, the sharpness that can be reached by means of the function given by Equation 17.64 may not be sufficient. It turns out to be possible to considerably increase the sharpness of the curves by introducing an extra term in the argument of the arctan function. For this we may refer to the original text [1].

The various factors are functions of normal load and wheel camber angle. Several parameters appear in these functions. A suitable regression technique is used to determine their values from measured data according to a quadratic algorithm for the best fit (cf. Oosten and Bakker [13]). One of the important functional relationships is the variation of the cornering stiffness (almost exactly given by the product of the coefficients B_y, C_y, and D_y of the side force function: $BCD_y = K_{y\alpha} = C_{F\alpha} = \partial F_y/\partial\alpha$ at $\tan\alpha = -S_H$) with F_z and γ.

$$BCD_y = p_1 \sin \frac{2 \arctan(F_z/p_2)}{1 + p_3\gamma^2} \tag{17.70}$$

For zero camber, the cornering stiffness attains its maximum p_1 at $F_z = P_2$. In Figure 17.16, the basic relationship has been depicted. Apparently, for a cambered wheel the cornering stiffness decreases with increasing $|\gamma|$. Note the difference in curvature left and right of the characteristics at larger values of the camber angle. To accomplish this, a split-E according to Equation 17.69 has been employed. In the complete listing of the formulae, shown later on, nondimensional parameters have been introduced. For example, the parameters in (17.70) will become $p_1 = F_{zo}p_{Ky1}$, $p_2 = F_{zo}p_{Ky2}$, and $p_3 = p_{Ky3}$, with F_{zo} denoting the nominal wheel load.

The aligning torque M_z can now be obtained by multiplying the side force F_y with the pneumatic trail t and adding the usually small (except with camber) residual torque M_{zr} (cf. Figure 17.17). We have

$$M_z = -t \cdot F_y + M_{zr} \tag{17.71}$$

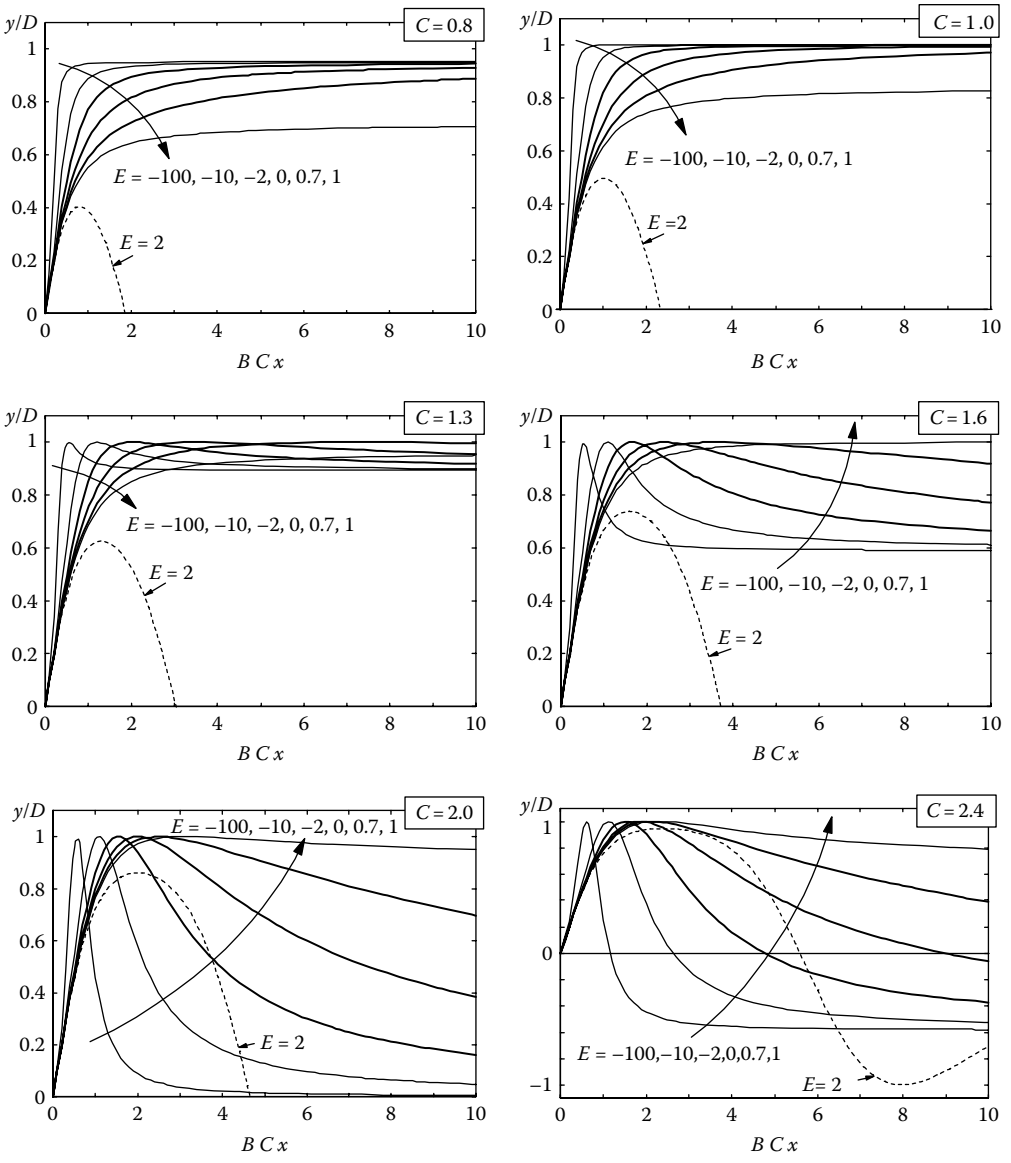

FIGURE 17.15 The influence of the shape factors C and E on the appearance of the curve according to Equation 17.64. Note that a value of $E > 1$ does not produce realistic curves.

The pneumatic trail decays with increasing side slip and is described with the aid of the cosine version of the Magic Formula as follows:

$$t(\alpha_t) = D_t \cos[C_t \arctan\{B_t\alpha_t - E_t(B_t\alpha_t - \arctan(B_t\alpha_t))\}] \tag{17.72}$$

where

$$\alpha_t = \tan\underline{\alpha} + S_{Ht} \tag{17.73}$$

The residual torque showing a similar decay

$$M_{zr}(\alpha_r) = D_r \cos\left[\arctan\left(B_r\alpha_r\right)\right] \tag{17.74}$$

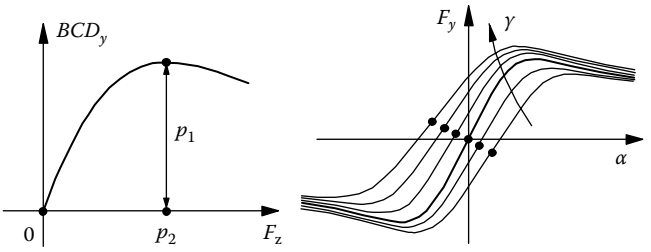

FIGURE 17.16 Cornering stiffness versus vertical load and the influence of wheel camber, Equation 17.70.

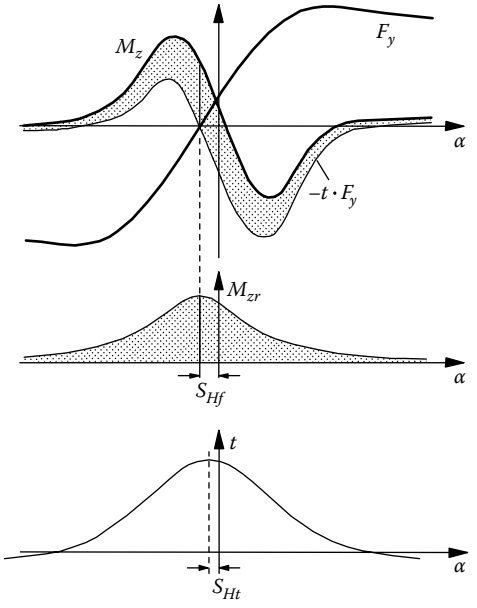

FIGURE 17.17 The aligning torque characteristic composed of a part directly attributed to the side force and a part due to the so-called residual torque (due to tire conicity and camber).

with

$$\alpha_r = \tan\alpha + S_{Hf} \tag{17.75}$$

It is seen that both parts of the moment are modeled using the Magic Formula, but instead of the sine function, the cosine function is employed. In that way, a hill-shaped curve is produced. The peaks are shifted sideways.

The residual torque is assumed to attain its maximum D_r at the slip angle where the side force becomes equal to zero. This is accomplished through the horizontal shift S_{Hf}. The peak of the pneumatic trail occurs at $\tan\alpha = -S_{Ht}$. This formulation has proven to give very good agreement with measured curves. The advantage with respect to the earlier versions, where formula (17.64) is used for the aligning torque as well, is that we have now directly assessed the function for the pneumatic trail, which is needed to handle the combined slip situation.

In Figure 17.18, the basic properties of the cosine-based curve have been indicated (subscripts of factors have been deleted again). Again, D is the peak value, C is a shape factor determining the level y_a of the horizontal asymptote, and now B influences the curvature at the peak (illustrated with

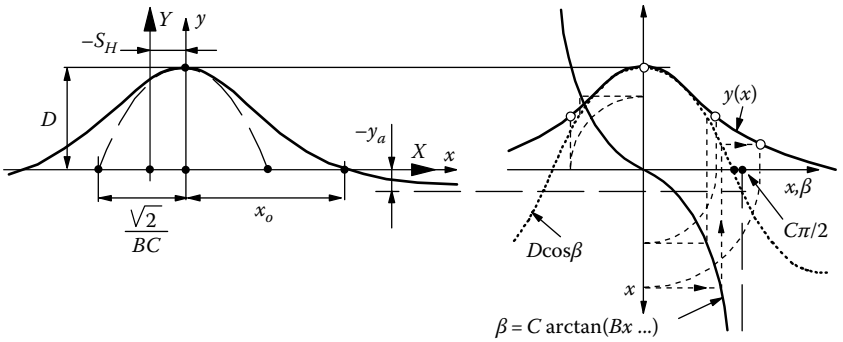

FIGURE 17.18 Curve produced by the cosine version of the Magic Formula, Equations 17.72 and 17.78). The meaning of curve parameters has been indicated.

the inserted parabola). The factor E modifies the shape at larger values of slip and governs the location x_o of the point where the curve intersects the x-axis. The following formulae hold

$$C = \frac{2}{\pi}\arccos\frac{y_a}{D} \tag{17.76}$$

$$E = \frac{Bx_o - \tan\{\pi/(2C)\}}{Bx_o - \arctan(Bx_o)} \quad (\text{if } C > 1) \tag{17.77}$$

In case of the possible presence of large camber angles (motorcycles), it may be better to use in (17.71) the side force F_y that would arise at $\gamma = 0$. Also, the side force function (17.64) and the cornering stiffness function (17.70) may be modified to better approximate large camber response for motorcycle tires (cf. De Vries [14] and [edn. 1 or 2] for a full listing of equations). We refer to [1] for the discussion of the model extension for turn slip (path curvature) also applicable in case of combined slip with braking or driving forces.

In the paper of Pacejka and Bakker [10], the tire's response to combined slip was modeled by using physically based formulae. A newer more efficient way is purely empirical. This method was developed by Michelin and published by Bayle et al. [11]. It describes the effect of combined slip on the lateral force and on the longitudinal force characteristics. Weighting functions G have been introduced that when multiplied with the original pure slip functions (17.64) produce the interaction effects of κ on F_y and of α on F_x. The weighting functions have a hill shape. They take the value one in the special case of pure slip (κ or α equal to zero). When, for example, at a given slip angle α from zero increasing brake slip is introduced, the relevant weighting function for F_y may first show a slight increase in magnitude (becoming larger than one) but will soon reach its peak after which a continuous decrease follows. The cosine version of the Magic Formula is used to represent the hill-shaped function:

$$G = D\cos[C\arctan(Bx)] \tag{17.78}$$

Here, G is the resulting weighting factor and x is either κ or $\tan\alpha$ (possibly shifted). The coefficient D represents the peak value (slightly deviating from one if a horizontal shift of the hill occurs), C determines the height of the hill's base, and B influences the sharpness of the hill. Coefficient B constitutes the main factor responsible for the shape of the weighting functions.

As an extension to the original function published by Bayle et al., the part with shape factor E will be added later on. This extension appears to improve the approximation, in particular at large levels of slip, especially in view of the strict condition that the weighting function G must remain positive for all slip conditions.

For the side force we get the following formulae:

$$F_y = G_{y\kappa} \cdot F_{yo} + S_{Vy\kappa} \tag{17.79}$$

with the weighting function now expressed such that it equals unity at $\kappa = 0$

$$G_{y\kappa} = \frac{\cos[C_{y\kappa} \arctan(B_{y\kappa}\kappa_s)]}{\cos[C_{y\kappa} \arctan(B_{y\kappa}S_{Hy\kappa})]} (>0) \tag{17.80}$$

where

$$\kappa_s = \kappa + S_{Hy\kappa} \tag{17.81}$$

and further the coefficients

$$B_{y\kappa} = r_{By1} \cos\left[\arctan\left\{r_{By2}\left(\tan\alpha - r_{By3}\right)\right\}\right] \tag{17.82}$$

$$C_{y\kappa} = r_{Cy1} \tag{17.83}$$

$$S_{Hy\kappa} = r_{Hy1} + r_{Hy2} df_z \tag{17.84}$$

$$S_{Vy\kappa} = D_{Vy\kappa} \sin[r_{Vy5} \arctan\left(r_{Vy6}\kappa\right)] \tag{17.85}$$

$$D_{Vy\kappa} = \mu_y F_z \cdot (r_{Vy1} + r_{Vy2} df_z + r_{Vy3}\gamma) \cdot \cos\left[\arctan(r_{Vy4} \tan\alpha)\right] \tag{17.86}$$

with df_z the notation for the nondimensional increment of the vertical load with respect to the (adapted) nominal load (cf. Equation 17.90 shown later on). Figure 17.19 depicts the two weighting functions displayed both as functions of α and of κ and the resulting force characteristics. In the following text, an explanation is given.

In Equation 17.79, F_{yo} denotes the side force at pure side slip obtained from Equation 17.64. The denominator of the weighting function (17.80) makes $G_{y\kappa} = 1$ at $k = 0$. The horizontal shift $S_{Hy\kappa}$ of the weighting function accomplishes the slight increase that the side force experiences at moderate braking before the peak of $G_{y\kappa}$ is reached and the decay of F_y commences. This horizontal shift may be made dependent on the vertical load. $C_{y\kappa}$ controls the level of the horizontal asymptote. If $C_{y\kappa} = 1$, the weighting function (17.80) will approach zero when $\kappa \to \pm\infty$. This would be the correct value for $C_{y\kappa}$ if κ is expected to be used in the entire range from plus to minus infinity. If this is not intended, then $C_{y\kappa}$ may be chosen different from one if $G_{y\kappa}$ is optimized with the restriction to remain positive. The factor $B_{y\kappa}$ influences the sharpness of the hill-shaped weighting function. As indicated, the hill becomes more flat (wider) at larger slip angles. Then $B_{y\kappa}$ decreases according to (17.82). When in an extreme situation α approaches 90°, that is, when $V_{cx} \to 0$, $B_{y\kappa}$ will go to zero and, consequently, $G_{y\kappa}$ will remain equal to one unless κ goes to infinity, which may easily be the case when at $V_{cx} \to 0$ the wheel speed of revolution Ω and thus the longitudinal slip velocity V_{sx} remain unequal to zero. The quantity $S_{Vy\kappa}$ is the vertical "shift," which sometimes is referred to as the κ-induced ply steer. At camber, due to the added asymmetry, the longitudinal force clearly produces a torque that creates a torsion angle comparable with a possibly already present ply-steer angle. This shift function varies with slip k as indicated in (17.49).

As illustrated in Figure 17.19, its peak value $D_{Vy\kappa}$ depends on the camber angle γ and decays with increasing magnitude of the slip angle α. Figure 17.20 presents measured data together with the fitted curves as published by Bayle et al.

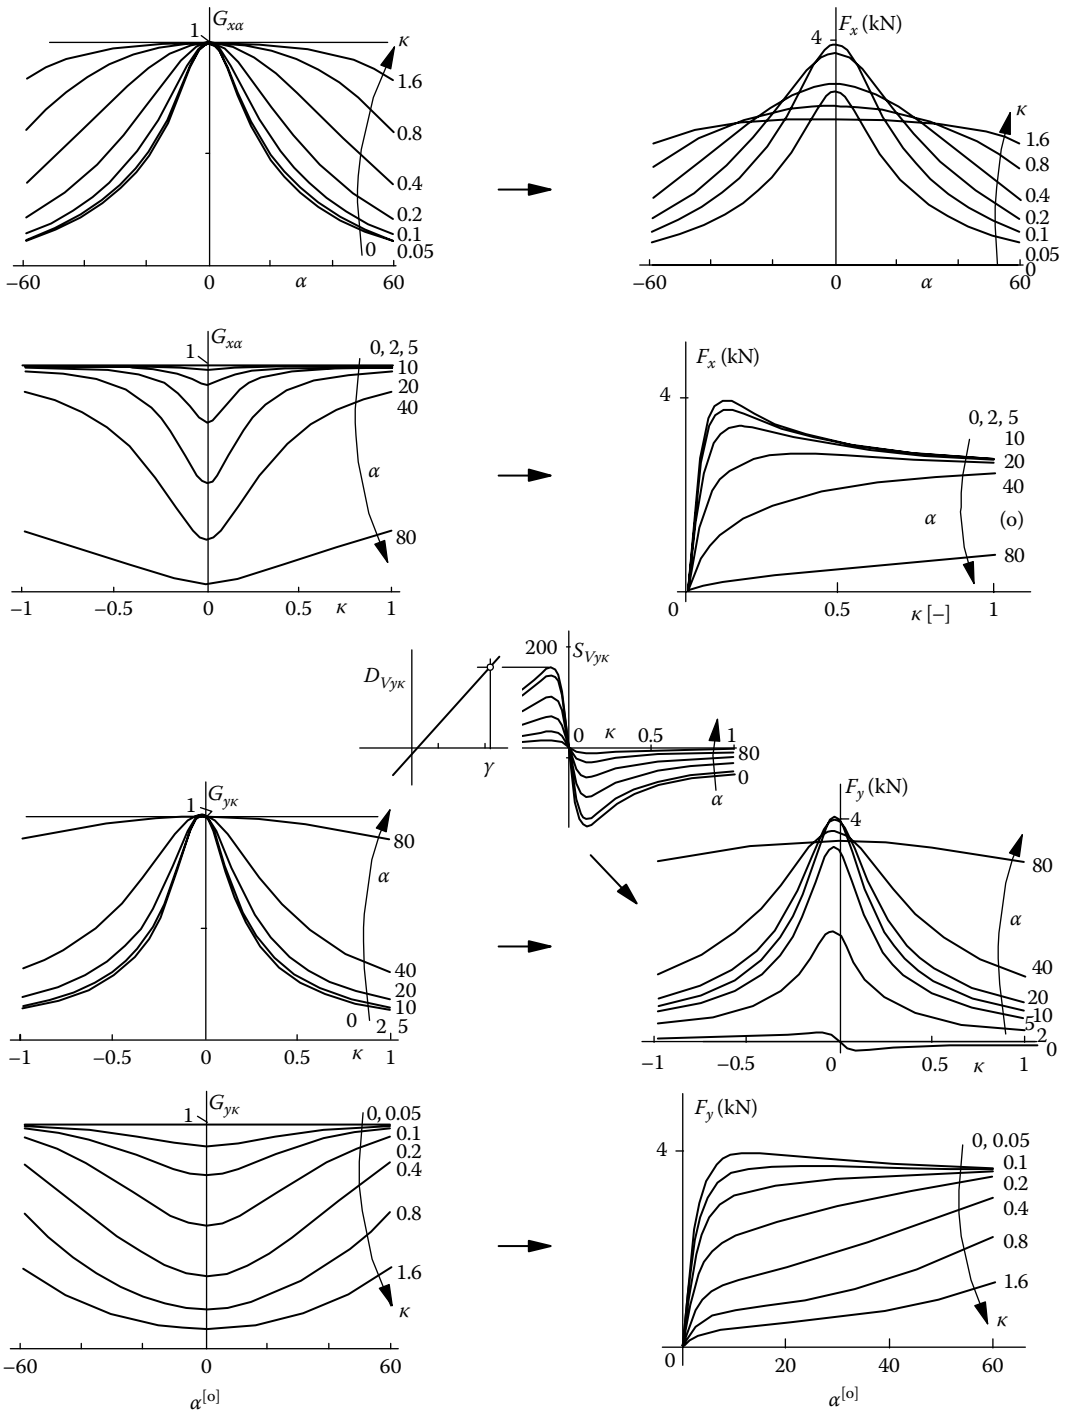

FIGURE 17.19 Nature of weighting functions and the resulting combined slip longitudinal and lateral forces, the latter also affected by the κ-induced ply-steer "vertical shift" $S_{Vy\kappa}$.

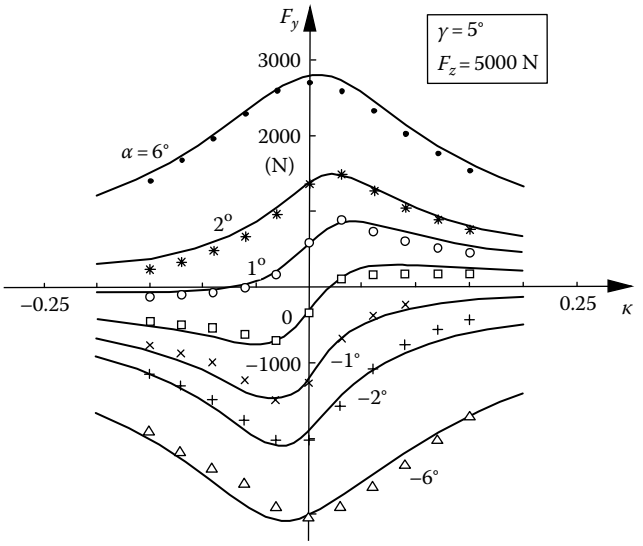

FIGURE 17.20 The combined slip side force characteristics in the presence of a camber angle. (From Bayle, P. et al., A new tyre model for vehicle dynamics simulation, *Proceedings of the Automotive Technology International*, Aachen, Germany, pp. 193–198, 1993.)

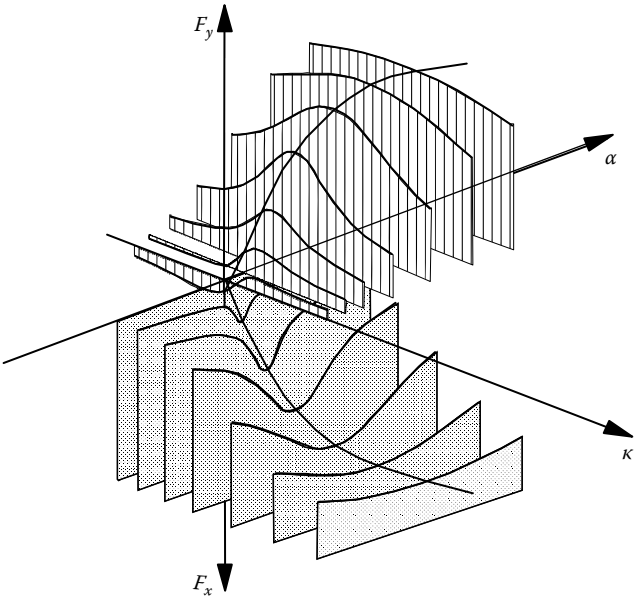

FIGURE 17.21 A 3-D graph of combined slip force characteristics.

The combined slip relations for F_x are similar to what we have seen for the side force. However, a vertical shift function was not needed to be included. In Figure 17.21, a three dimensional (3-D) graph is shown indicating the variation of F_x and F_y with both α and κ. The initial "*S*" shape of the F_y versus κ curves (at small α) due to the vertical shift function is clearly visible.

Regarding the aligning torque, physical insight is used to model the situation at combined slip. We write

$$M_z = -t(\alpha_{t,eq}) \cdot F_y + M_{zr}(\alpha_{r,eq}) + s(F_y, \gamma) \cdot F_x \tag{17.87}$$

The arguments α_t and α_r (including a shift) appearing in the functions (17.73, 17.75) for the pneumatic trail and residual torque at pure side slip are replaced by equivalent slip angles, as indicated by Equation 17.88, incorporating the effect of κ on the composite slip:

$$\alpha_{t,eq} = \sqrt{\alpha_t^2 + \left(\frac{K_{x\kappa}}{K_{y\alpha}}\right)^2 \kappa^2} \cdot \mathrm{sgn}(\alpha_t) \tag{17.88}$$

and similar for $\alpha_{r,eq}$. To approximate the same effect on the degree of sliding in the contact patch as would occur with side slip, the longitudinal slip κ is multiplied with the ratio of the longitudinal and lateral slip stiffnesses.

Besides, an extra term is introduced in (17.87) to account for the fact that a moment arm s arises for F_x as a result of camber γ and lateral tire deflection associated with F_y. This extra term may give rise to a sign change of the aligning torque in the range of braking as is observed to occur in practice.

17.4.2 Full Set of Equations

The Magic Formula model equations contain the nondimensional model parameters p, q, r, and s and, in addition, a set of scaling factors λ and spin factors ζ (camber plus turn slip, both not shown here, cf. [1]). Other parameters and variable quantities used in the equations are:

g	acceleration due to gravity
V_c	magnitude of the velocity of the wheel contact center C
$V_{cx,y}$	components of the velocity of the wheel contact center C
$V_{sx,y}$	components of slip velocity V_s (of point S)
V_r	$(= R_e\,\Omega = V_{cx} - V_{sx})$ forward speed of rolling
V_o	reference velocity $(= \sqrt{(gR_o)}$ or other specified value)
R_o	unloaded tire radius $(= r_o)$
R_e	effective rolling radius $(= r_e)$
Ω	wheel speed of revolution
ρ_z	tire normal deflection (> 0 if compression)
F_{zo}	nominal (rated) load (≥ 0)
F'_{zo}	adapted nominal load

The effect of having a tire with a different nominal load may be roughly approximated by using the scaling factor λ_{Fzo}. cf. [1], 3d ed. for influence of inflation pressure.

$$F'_{zo} = \lambda_{Fzo} F_{zo} \tag{17.89}$$

Further, we introduce the normalized change in vertical load

$$df_z = \frac{F_z - F'_{zo}}{F'_{zo}} \tag{17.90}$$

Instead of taking the slip angle α itself (in radians, from Equation 17.2) as input quantity, one may in case of very large slip angles and possibly backward running of the wheel better use the tangent of the slip angle defined as the lateral slip:

$$\alpha^* = \tan\alpha \cdot \mathrm{sgn}\, V_{cx} = -\frac{V_{cy}}{|V_{cx}|} \tag{17.91}$$

For the camber angle we introduce

$$\gamma^* = \sin\gamma \tag{17.92}$$

The longitudinal slip ratio is defined as follows:

$$\kappa = -\frac{V_{sx}}{|V_{cx}|} \tag{17.93}$$

If the forward speed V_{cx} becomes or is equal to zero, one might add a small quantity ε in the denominator of (17.91, 17.93) to avoid singularity, or, when transient slip situations occur, one should use the transient slip quantities (or deformation gradients) $\tan\alpha'$ and κ' as defined and used in the next section.

To avoid the occurrence of similar singularities in the ensuing equations due to, for example, zero velocity or zero vertical load, a small additional quantity ε (with same sign as its neighboring main quantity) will be introduced in relevant denominators like in the next equation.

For the factor cosα appearing in the equations for the aligning torque to properly handle the case of large slip angles and possibly backward running ($V_{cx} < 0$), we have defined

$$\cos'\alpha = \frac{V_{cx}}{V_c'} \tag{17.94}$$

with

$$V_c' = V_c + \varepsilon_V \tag{17.95}$$

where we may choose $\varepsilon_V = 0.1$ m/s.

For the three forces and three moments acting from road to tire and defined according to the diagram of Figure 17.1 (along and around the x-, y-, z-axes, $F_z > 0$), the equations, first those for the condition of pure slip (including camber, note that the formulation for the camber stiffness (cf. (17.114) through (17.117)) has been changed with respect to earlier publications) and subsequently those for the condition of combined slip, read: (for more details cf. [1], 3d edition).

Longitudinal force (*pure longitudinal slip*)

$$F_{xo} = D_x \sin[C_x \arctan\{B_x\kappa_x - E_x(B_x\kappa_x - \arctan(B_x\kappa_x))\}] + S_{Vx} \tag{17.96}$$

$$\kappa_x = \kappa + S_{Hx} \tag{17.97}$$

$$C_x = p_{Cx1}\ (>0) \tag{17.98}$$

$$D_x = \mu_x \cdot F_z\ (>0) \tag{17.99}$$

$$\mu_x = p_{Dx1} + p_{Dx2} df_z\ (>0) \tag{17.100}$$

$$E_x = (p_{Ex1} + p_{Ex2} df_z + p_{Ex3} df_z^2) \cdot \{1 - p_{Ex4}\,\mathrm{sgn}(\kappa_x)\} \quad (\le 1) \tag{17.101}$$

$$K_{x\kappa} = F_z \cdot (p_{Kx1} + p_{Kx2} df_z) \cdot \exp(p_{Kx3} df_z)$$

$$\left(= B_x C_x D_x = \frac{\partial F_{xo}}{\partial \kappa_x} \text{ at } \kappa_x = 0 \right) \quad \left(= C_{F\kappa} \right) \tag{17.102}$$

$$B_x = \frac{K_{x\kappa}}{C_x D_x + \varepsilon_x} \tag{17.103}$$

$$S_{Hx} = (p_{Hx1} + p_{Hx2} df_z) \tag{17.104}$$

$$S_{Vx} = F_z (p_{Vx1} + p_{Vx2} df_z) \left\{ \frac{V_{cx}}{\varepsilon_{Vx} + V_{cx}} \right\} \tag{17.105}$$

Lateral force (*pure side slip*)

$$F_{yo} = D_y \sin[C_y \arctan \{B_y \alpha_y - E_y (B_y \alpha_y - \arctan (B_y \alpha_y))\}] + S_{Vy} \tag{17.106}$$

$$\alpha_y = \alpha^* + S_{Hy} \tag{17.107}$$

$$\alpha_{t,eq} = \sqrt{\alpha_t^2 + \left(\frac{K_{xk}}{K'_{ya}} \right)^2 k^2} \cdot \operatorname{sgn}(\alpha_t) \tag{17.164}$$

$$\alpha_{r,eq} = \sqrt{\alpha_r^2 + \left(\frac{K_{xk}}{K'_{ya}} \right)^2 k^2} \cdot \operatorname{sgn}(\alpha_r) \tag{17.165}$$

In the textbook [1], a set of parameter values have been listed for a specific tire. Examples of computed characteristics compared with experimentally assessed curves for both pure slip and combined slip conditions have been presented. The formulae appear to produce very good agreement. The effect of having turn slip is modeled and some calculated characteristics have been presented for a set of hypothetical model parameters. Also, the possibility to define the effects of conicity and ply steer as responses to equivalent camber and equivalent slip angles has been discussed. A possibly better description than (17.156) for the overturning couple of truck, car, and motorcycle tires due to side slip and camber has been introduced.

17.5 FIRST-ORDER TIRE LAG

For relatively low-frequency and large-wavelength transient and oscillatory vehicle motions, tire inertia and the effect of the finite length of the contact patch may be neglected or taken care of in an approximative manner. In [1], a thorough treatment has been given of the out-of-plane stretched string tire model (based on the early work of von Schlippe [15]) together with a number of extended and approximated models. In one of these approximate models, the effect of the finite length of the contact patch has been ignored. For the aligning torque, the model includes the effects of tread width and gyroscopic couple.

The present section deals with the further development of this type of single-contact-point model that in its simplest form is very popular in vehicle dynamics studies. Both in-plane and out-of-plane models will be discussed for small slip, linear and for large slip, nonlinear conditions. The concept of the relaxation length is central in the model structure. The development of the single-contact-point models follows an essentially different and much simpler line compared with the theoretical approach on which the string model is based. Because of its simplicity, it is possible to enhance the model to cover the full nonlinear combined slip range including rolling from standstill or even change direction from forward to backward rolling. Camber and turn slip may be included.

With the linear and nonlinear models, various vehicle dynamics problems may be approximately analyzed such as the shimmy phenomenon, transient vehicle motions with oscillatory steer inputs, motion over undulated road surfaces at side slip and camber and at controlled braking, steering vibrations induced by wheel imbalance, and tire out-of-roundness. In [1] a number of applications addressing these problems have been studied.

17.5.1 Model Development

The model consists of a contact patch (point) that is suspended with respect to the wheel rim by a longitudinal (circumferential) and a lateral spring. These springs represent the compliance of the tire carcass. The contact point may move (slip) with respect to the ground in lateral and longitudinal directions. Through this relative motion the side force, longitudinal force, and aligning torque are generated. To determine these forces and moments, contact patch lateral slip (possibly including ply steer) and longitudinal slip are defined. In addition, contact line curvature, due to camber possibly including conicity and due to turn slip, is thought to occur. These contact patch slip quantities may then be used as input in the steady-state tire slip model, for example, the Magic Formula, to calculate the transient force and moment variation that act upon the contact patch.

17.5.2 Linear Model

Figure 17.22 depicts the model in top view. At the instant considered, the wheel slip point S (attached to the wheel rim at a level near the road surface) and the contact point S' are defined to

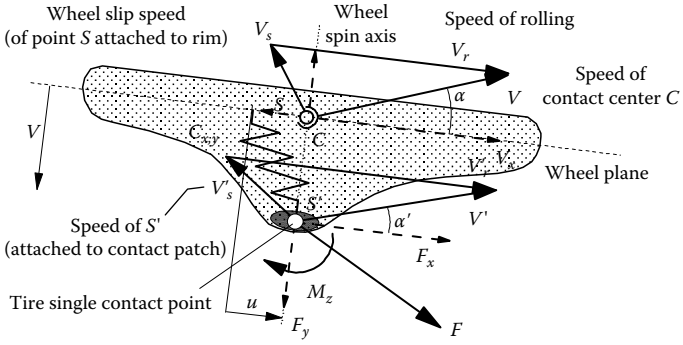

FIGURE 17.22 Single-contact-point tire model showing lateral and longitudinal carcass deflections, u and v (top view).

be located in the plane through the wheel axis and normal to the road. These points (which may be thought to lie on two parallel slip circles) move over the road surface with the wheel and contact patch slip velocities, respectively. In the figure, the x and y components of the slip velocities have been shown as negative quantities. The difference of the velocities of the two points causes the carcass springs to deflect. Consequently, the time rates of change of the longitudinal and lateral deflections u and v read

$$\frac{du}{dt} = -(V_{sx} - V'_{sx}) \tag{17.166}$$

and

$$\frac{dv}{dt} = -(V_{sy} - V'_{sy}) \tag{17.167}$$

If we assume small values of slip, we may write for the side force acting from road to contact patch with $C_{F\alpha}$ denoting the cornering or side slip stiffness:

$$F_y = C_{F\alpha}\alpha' = -C_{F\alpha}\frac{V'_{sy}}{|V_x|} \tag{17.168}$$

It is assumed here that the difference between the wheel center longitudinal velocity V_x and the longitudinal velocity V_{cx} of the contact center is negligible:

$$V_{cx} \approx V_x \tag{17.169}$$

Consequently, we may employ here V_x in the denominator. With the lateral tire stiffness at road level C_{Fy}, we have for the elastic internal force that balances the side slip force

$$F_y = C_{Fy}v \tag{17.170}$$

and we can write for Equation 17.167 with Equations 17.168 and 17.170 after having introduced the relaxation length for side slip σ_a:

$$\sigma_\alpha = \frac{C_{F\alpha}}{C_{Fy}} \tag{17.171}$$

The differential equation for the lateral deflection due to side slip v_α (later on we will also have a lateral deflection due to camber γ) is

$$\frac{dv_\alpha}{dt} + \frac{1}{\sigma_\alpha}|V_x|v_\alpha = |V_x|\alpha = -V_{sy} \tag{17.172}$$

where α is the wheel slip angle: $\alpha \approx -V_{sy}/|V_x|$. The side force is obtained by multiplying v_α with C_{Fy}.

In a similar way we can deal with the longitudinal force response. With the longitudinal tire stiffness C_{Fx} at road level and the longitudinal slip stiffness C_{Fk}, we obtain for the relaxation length σ_k

$$\sigma_k = \frac{C_{Fk}}{C_{Fx}} \tag{17.173}$$

and we can derive with Equation 17.166 the differential equation for the fore and aft deflection u:

$$\frac{du}{dt} + \frac{1}{\sigma_k}|V_x|u = |V_x|K = -V_{sx} \tag{17.174}$$

with k the longitudinal wheel slip ratio: $k \approx -V_{sx}/|V_x|$. The longitudinal force may be obtained by multiplying u with the stiffness C_{Fx}.

Next, we consider the wheel camber as input. For a suddenly applied camber angle γ (about the line of intersection at ground level), we assume that a contact line curvature and thus the camber thrust $C_{F\gamma}\gamma$ are immediately felt at the contact patch. As a reaction, a contact patch side slip angle α' is developed that builds up the lateral carcass deflection $v = v_\gamma$. Again Equation 17.170 applies. The side force that acts on the wheel now becomes

$$F_y = C_{FY}V_\gamma = C_{F\gamma}\gamma + C_F\alpha' \tag{17.175}$$

With wheel side slip kept equal to zero, $V_{sy} = 0$, and $V'_{sy} = -|V_x|\alpha'$, Equation 17.167 can be written in the form:

$$\frac{dv_\gamma}{dt} + \frac{1}{\sigma_\alpha}|V_x|v_\gamma = \frac{C_{F\gamma}}{C_{F\alpha}}|V_x|\gamma \tag{17.176}$$

This equation shows that according to this simple model, the camber force relaxation length σ_γ is equal to the relaxation length for side slip σ_α. This theoretical result is substantiated by careful camber step response experiments, performed by Higuchi [16] on a flat plank test rig. A similar equation results for the total spin φ including turn slip and camber, [1].

The forces and moment may be obtained from the deflections u and v by first assessing the transient slip quantities α', k', and γ' and from these with the slip stiffnesses the forces and moment.

According to the adopted steady-state model, Equation 17.158, the moment response to camber is the sum of the residual torque, M_{zr}, assumedly mainly due to finite tread width, and $-t_\alpha F_y$, assumedly caused by camber-induced side slip. A first-order approximation for the response of M_{zr} with the short relaxation length equal to half the contact length a may be employed. Here, however, we suffice with the assumption that the moment due to tread width responds instantaneously to camber.

For the linear, small slip condition we find

$$\alpha' \approx \tan\alpha' = \frac{v_\alpha}{\sigma_\alpha}, \quad F_{y\alpha} = C_{F\alpha}\alpha' \quad M_{Z\alpha} = -C_{M\alpha}\alpha' = -t_\alpha F_{y\alpha} \tag{17.177}$$

$$k' = \frac{u}{\sigma_k}, \quad F_x = C_{Fk}k' \tag{17.178}$$

$$\gamma' = \frac{C_{F\alpha}}{C_{F\gamma}}\frac{v_\gamma}{\sigma_\alpha}, \quad F_{y\gamma} = C_{F\gamma}\gamma', \quad M_{zry} = (C_{M\gamma} + t_\alpha C_{F\gamma})\gamma \tag{17.179}$$

The pneumatic trail due to side slip is denoted here with t_α. The total aligning torque becomes

$$M_z = -t_\alpha(F_{y\alpha} + F_{y\gamma}) + M_{zr\gamma} \tag{17.180}$$

In an alternative model, used for motorcycle dynamic studies, the terms with $t_\alpha C_{Fy}$ or $t_\alpha F_{y\gamma}$ in (17.179, 17.180) are omitted (cf. discussion in [1] following Equation 7.40).

The Equations (17.172, 17.174, 17.176) may be written in terms of the transient slip quantities. For example, we may express v_α in terms of α' by using the first equation of (17.177). Insertion in (17.172) gives

$$\sigma_\alpha \frac{d\alpha'}{dt} + |V_x|\alpha' = |V_x|\alpha = -V_{sy} \tag{17.181}$$

If we recognize the fact that the relaxation length is a function of the vertical load and if the average slip angle is unequal to zero, an additional term shows up in the linearized equation (variations of α' and of $F_z(t)$ are small) that results from the differentiation of $v_\alpha = \sigma_\alpha \alpha'$ with respect to time. Then, Equation 17.172 becomes

$$\alpha' \frac{d\alpha'}{dF_z} + \left(|V_x| + \frac{d\alpha'}{dF_z}\frac{dF_z}{dt} \right) \alpha' = |V_x|\alpha = -V_{sy} \tag{17.182}$$

Obviously, when using Equation 17.181, a response to a variation of the vertical load cannot be expected. If the load varies, Equation 17.181 is inadequate and the original Equation 17.172 or the corresponding Equation 17.182 should be used.

With (17.170) Equation 17.172 may be written directly in terms of F_y. If we may consider the carcass lateral stiffness C_{Fy} virtually independent of the wheel load F_z, we obtain by using Equation 17.171:

$$\sigma_\alpha \frac{dF_y}{dt} + |V_x| F_y = |V_x| F_{yss} \tag{17.183}$$

Since we have the same relaxation length for both the responses to side slip and camber, this equation appears to hold for the combined linear response to the inputs α and γ or φ. In the right-hand member, F_{yss} denotes the steady-state (instantaneous) response to these inputs and possibly a changing vertical load at a given slip condition. Multiplication with the pneumatic trail produces the moment $-M'_z$ (if $\gamma = \varphi = 0$). A similar differential equation may be written for the F_x response to k.

Equations 17.172 and 17.174 have been written in the form (V_x not in denominator and $V_{sx,y}$ used as right-hand member) that makes them suitable for simulations of stopping and starting from zero speed occurrences. At speed $V_x = 0$, Equation 17.174 turns into an integrator: $u = -\int V_{sx} dt$. With Equation 17.178 the longitudinal force becomes $F_x = C_{Fk} k' = C_{Fk} u/\sigma_k$, which with (17.175) is equal to $C_{Fx} u$. This is the correct expression for the tire that at standstill acts like a longitudinal or tangential spring. When the wheel starts rolling, the tire gradually changes into a damper with rate $C_{Fk}/|V_x|$. Figure 17.23 depicts a corresponding mechanical model with spring and damper in series. It shows that at low speed the damper becomes very stiff and the spring dominates. At higher forward

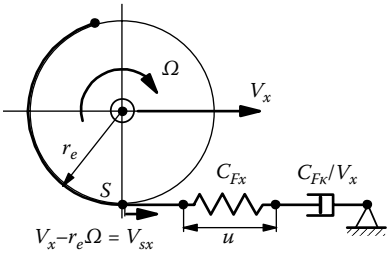

FIGURE 17.23 Mechanical model of transient tangential tire behavior.

velocities the spring becomes relatively stiff and the damper part dominates the behavior of the tire. A similar model may be drawn for the transient lateral behavior. It may be noted that Equation 17.183 is not suited for moving near or at $V_x = 0$. In [1] the use of the transient models for the response to lateral and longitudinal wheel slip speed at and near zero speed is demonstrated.

17.5.3 Semi-Nonlinear Model

For the extension of the linear theory to cover the nonlinear range of the slip characteristics, it may be tempting to employ Equation 17.183 and use the instantaneous nonlinear force response as input in the differential equation. The input steady-state side force is calculated, for example, with the Magic Formula, using the current wheel slip angle α. This method, however, may lead to incorrect results as due to the phase lag in side force response; the current (varying) wheel load may not correspond to the calculated magnitude attained by the side force. In limit conditions, the tire may then be predicted to be still in adhesion, while in reality full sliding occurs. A better approach is the utilization of the original Equation 17.172 and the calculation of the side force afterward by using the resulting transient slip angle α' (17.177) as input in the Magic Formula.

In general, we have the three Equations 17.172, 17.174, 17.176 and the first equations of (17.177) through (17.179) producing α', κ', and γ' or φ' that are used as input in the nonlinear force and moment functions (γ or φ directly in the expressions for M_r), for example, the equations of the Magic Formula tire model (Section 17.4):

$$F_x = F_x(k', \alpha', F_z) \tag{17.184}$$

$$F_y = F_y(\alpha', \gamma', K', F_z) \tag{17.185}$$

$$M_z' = -t_\alpha F_y \tag{17.186}$$

$$M_{zr} = M_{zr}(\gamma, \alpha', K', F_z) \tag{17.187}$$

$$M_z = M_z' + M_{zr} + s \cdot F_x \tag{17.188}$$

where if required, γ may be replaced by φ as the spin argument, cf. [1], edn.3.

This nonlinear model is straightforward and is often used in transient or low-frequency vehicle motion simulation applications. Starting from zero speed or stopping to standstill is possible. However, as has been mentioned before, at V_x equal or close to zero, Equations 17.172 and 17.174 act as integrators of the slip speed components $V_{sx,y}$, which may give rise to possibly very large deflections. The limitation of these deflections may be accomplished by making the derivatives of the deflections u and v equal to zero, if (1) the forward wheel velocity has become very small ($<V_{low}$) and (2) the deflections take values larger than physically possible (cf. [1]).

Another extreme situation is the condition at wheel lock. At steady state, Equation 17.174 reduces to

$$\frac{1}{\sigma_k}|V_x|u = -V_x \tag{17.189}$$

which indicates that the deflection u according to the semi-linear theory becomes as large as the relaxation length σ_k. Avoiding the deflections from becoming too large, which is of importance at, for example, repetitive braking, calls for an enhanced nonlinear model. Another shortcoming of the model that is to be tackled concerns the experimentally observed property of the tire that its relaxation length depends on the level of slip. At higher levels of side slip, the tire shows a quicker response to additional changes in side slip. This indicates that the relaxation lengths decrease with increasing slip.

17.5.4 Fully Nonlinear Model

With the first equation of (17.177), we may write the original Equation 17.172 as follows:

$$\frac{dv_\alpha}{dt} + |V_x| \tan\alpha' = |V_x| \tan\alpha = -V_{sy} \tag{17.190}$$

Writing this equation entirely in terms of the transient slip angle by using (17.170) with $v = v_\alpha$ and remembering that $F_y = F_y(\alpha', F_z)$ directly yields

$$\frac{1}{C_{Fy}} \frac{\partial F_y}{\partial \tan\alpha'} \frac{d\tan\alpha'}{dt} + |V_x| \tan\alpha' = -V_{sy} - \frac{1}{C_{Fy}} \frac{\partial F_y}{\partial F_z} \frac{dFz}{dt} \tag{17.191}$$

The additional input dF_z/dt requires information of the slope $\partial F_y/\partial F_z$ at given values of the slip angle. If the vertical load remains constant, the last term vanishes and we have the often used equation of the *restricted fully nonlinear model*:

$$\sigma_\alpha \frac{d\tan\alpha'}{dt} + |V_x| \tan\alpha' = -V_{sy} \tag{17.192}$$

with

$$\sigma_\alpha = \frac{1}{C_{Fy}} \frac{\partial F_y}{\partial \tan\alpha'} \tag{17.193}$$

If we consider an average slip angle α_o and a small variation $\tilde{\alpha}$ of tanα and the corresponding lateral slip velocities, Equation 17.192 becomes after having subtracted the average part:

$$\sigma_\alpha \frac{d\tilde{\alpha}'}{dt} + |V_x| \tilde{\alpha}' = -\tilde{V}_{sy} \tag{17.194}$$

which indicates that the structure of (17.192) is retained and that σ_α (17.193) represents the actual relaxation length of the linearized system at a given load and slip angle. Obviously, the relaxation length is associated with the slope of the side force characteristic. It also shows that the relaxation length becomes negative beyond the peak of the side force characteristic that makes the solution of (17.194) but also of the original Equation 17.190 unstable if the point of operation lies in that range of side slip. We may, however, limit σ_α downward to avoid both instability and excessive computation time: $\sigma_\alpha = \max(\sigma_\alpha, \sigma_{min})$. The transient response of the variation of the force proceeds in proportion with the variation of $\tilde{\alpha}'$ as $\tilde{F}_y = (\partial F_y/\partial \tan\alpha)\tilde{\alpha}'$.

When Equation 17.192 is used, an algebraic loop does not occur as would be the case when a general equation, the nonlinear version of Equation 17.172, for the lateral deflection v is employed (cf. [1]). The relaxation length σ_α can be directly determined from the already available tanα'. However, since the last term of (17.191) has been omitted, Equation 17.192 has become insensitive to F_z variations.

A similar function and differential equation can be derived for the transient response to longitudinal slip. We obtain for the relaxation length

$$\sigma_k = \frac{1}{C_{Fx}} \frac{\partial F_x}{\partial k'} \tag{17.195}$$

It is of interest to note that the extreme case of wheel lock can now be handled correctly with $u = F_x/C_{Fx}$ (cf. [1]).

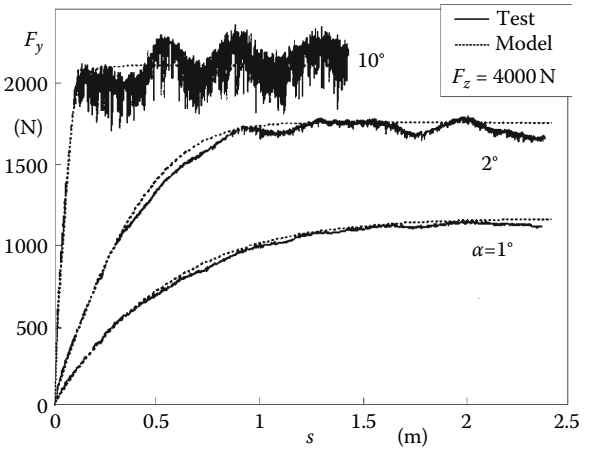

FIGURE 17.24 Side force response to small and large step change in slip angle as assessed by flat plank experiments and computed with the model defined by Equation 17.190.

Figures 17.24 through 17.26 present results obtained by Higuchi [16] for a passenger car 205/60R15 tire tested on a flat plank machine (TU Delft). Figure 17.24 shows the response of the side force to step changes in slip angle at the nominal load of 4000 N. The diagram clearly indicates the difference in behavior at the different levels of side slip with a very rapid response occurring at $\alpha = 10°$. The fully nonlinear model according to Equation 17.190, in conjunction with Equation 17.185, gives satisfactory agreement. The measured response curves have been corrected for the side force variation that for the not fully symmetric and regular tire arises already at zero slip angle. The test is performed by loading the tire after the slip angle (steer angle) has been applied. Subsequently, the plank is moved. The aligning torque behaves in a similar manner (not shown) although a little initial delay in response occurs as correctly predicted by the string model (cf. [1]). At larger slip angles (beyond the level where the M_z peak occurs), the aligning torque first shows a peak in the response after which the moment decays to its steady-state value. This behavior is nicely followed by the model [1]. Figure 17.25 shows the side force response to small increments in slip angle. The experiment is conducted by, after having stopped the plank motion, steering the wheel half a degree further and continuing the forward motion. It was first ascertained that the response of the side force to a step steer input was hardly influenced by having first lifted the tire from the road surface or not. Of course, the aligning moment response, in the latter case, is quite different because of initial torsion about the vertical axis. The resulting side

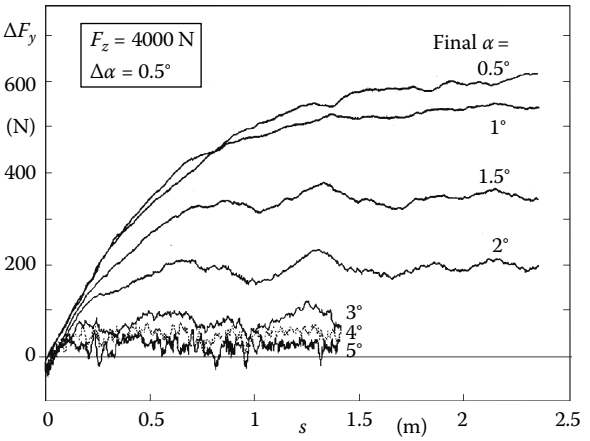

FIGURE 17.25 Side force response to small increment of slip angle $\Delta\alpha$ at different levels of slip angle indicating the decrease of relaxation length at increasing side slip level that is in agreement with Equation 17.193.

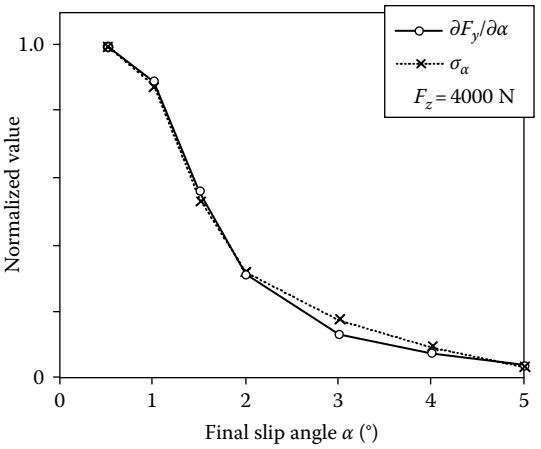

FIGURE 17.26 Correspondence between F_y versus α slope and relaxation length σ_α as assessed by experiments.

force responses as depicted in Figure 17.25 have been compared with the exponential response of the side force increment as predicted by the solution of Equation 17.194 with (17.193). Fitting with a least square procedure gave the relaxation length σ_α as presented in Figure 17.26. The resulting variation of σ_α with slip angle level is compared with the slope of the steady-state side force characteristic, both normalized making their values equal to unity at vanishing slip angle.

The excellent agreement supports the theoretical findings. Higuchi also investigated the responses to changes in camber angle and to a limited extent also to the related turn slip. The force response to a change in camber exhibits a peculiar feature. It turns out that directly after the wheel is cambered (about the line of intersection), a side force is developed instantaneously. This, obviously, is caused by the nonsymmetric distortion of the cross section of the lower part of the tire. This initial "non-lagging" part of the side force has been discussed elaborately in Ref. [1].

17.5.5 Gyroscopic Couple

In [1] the gyroscopic couple about the vertical axis that arises as a result of the time rate of change of the average tire tilt deflection angle has been introduced. This angle is considered to be proportional with the lateral tire deflection v or the side force F_y. The moment may be written in terms of the deflection rate:

$$M_{z,gyr} = c_{gyr} m_t r_e \Omega \frac{dv}{dt} \tag{17.196}$$

where at free rolling the wheel speed of revolution equals the forward velocity divided by the effective rolling radius of the tire. In general, we have

$$\Omega = \frac{V_x - V_{sx}}{r_e} \tag{17.197}$$

For a radial ply steel-belted car tire, the nondimensional coefficient c_{gyr} has been estimated to take the value 0.5. The quantity m_t represents the mass of the tire. Extending the expression (17.188) or Equation 17.158 yields for the total aligning moment:

$$M_z = M'_z + M_{zr} + sF_x + M_{z,gyr} \tag{17.198}$$

The gyroscopic couple has a large damping effect on steering vibrations of front wheels, notably on unstable shimmy oscillations (cf. [1]).

17.5.6 Enhanced Nonlinear Transient Tire Model

A totally different approach to model the transient rolling properties of the tire is based on the separation of contact patch slip properties and carcass compliance not through the use of relaxation lengths but by incorporating the carcass springs in the model explicitly. The contact patch may be given some inertia to facilitate the computational process (computational causality). This has the drawback that a relatively high natural frequency is introduced, possibly making the computation slower. We may, however, employ alternative methods to avoid the inclusion of the small mass. The model to be discussed automatically accounts for the property that the lag in the response to wheel slip and load changes diminishes at higher levels of slip that in the previous section was realized by decreasing the relaxation length. This latter approach, however, appeared to possibly suffer from computational difficulties if the model has to also account for the transient response to wheel load variations. Also, the response to combined slip was less easy to model. In developing the enhanced model, we should, however, try to maintain the nice feature of the relaxation length model to adequately handle the simulation at speeds near or equal to zero.

Figure 17.27 depicts the structure of the enhanced transient model. The contact patch can deflect in circumferential and lateral direction with respect to the lower part of the wheel rim. Only translations are allowed to ensure that the slip angle seen by the contact patch at steady state is equal to that of the wheel plane. As mentioned before, a mass point is thought to be attached to the contact patch. That mass point coincides with point S^*, the velocity of which constitutes the slip speed of the contact point. This slip velocity is used, together with the (assumedly at the contact patch detected) path curvature due to turn slip and wheel camber, to compute the forces F_x, F_y and the moment M_z that act from road to contact patch. We may add a simple relaxation length model to enable computations near zero speed. The model was first employed by Van der Jagt et al. [17] and later generalized by Pacejka and Besselink [18].

With mass m_c and carcass stiffnesses $c_{cx,y}$ and damping ratios $k_{cx,y}$ introduced, the equations of motion for the contact patch mass point with longitudinal and lateral speed components $V^*_{sx,y}$ read (yaw rate term in accelerations disregarded):

$$m_c\dot{V}^*_{sx} + k_{cx}\dot{u} + c_{cx}u = F_x(\kappa',\alpha',F_z) \tag{17.199}$$

$$m_c\dot{V}^*_{sy} + k_{cy}\dot{v} + c_{cy}v = F_y(\alpha',\kappa',\gamma,F_z) - F_{y,NL} \tag{17.200}$$

The forces acting from ground to contact patch shown at the right-hand sides are computed from the steady-state formulae. The non-lagging camber force part $F_{y,NL}$ is assumed to act directly on the wheel rim. We may approximate the non-lagging force part by a linear relation with γ using the camber thrust stiffness $C_{F\gamma}$, the non-lagging fraction ε_{NL}, and the weighting function $G_{y\kappa}$ to take care of the presence of a fore and aft force F_x:

$$F_{y,NL} = G_{yk}\varepsilon_{NL}C_{Fy}y \tag{17.201}$$

It should be noted that ε_{NL} changes with wheel load. We may refer to [1] for a more suitable and general approach to account for the non-lagging part.

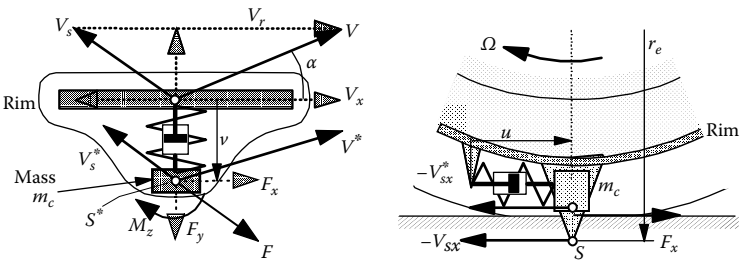

FIGURE 17.27 Enhanced transient tire model in top and side view showing carcass compliances and contact patch mass.

To enable calculations near or at standstill, we may add additional first-order differential equations with relaxation length σ_c. From these equations, the transient slip quantities result that act as input in the steady-state slip force formulae. We have

$$\sigma_c \frac{d\alpha'}{dt} + |V_x|\alpha' = -V_{sy}^* \tag{17.202}$$

$$\sigma_c \frac{d\kappa'}{dt} + |V_x|\kappa' = -V_{sx}^* \tag{17.203}$$

The contact relaxation length σ_c may be given a small but finite value, for instance, equal to half the contact length, a_o, at nominal load. This corresponds to theoretical findings of Section 17.6. Equations 17.202 and 17.203 do not respond to load changes. For this, we rely on the effect of the carcass compliance (in conjunction with the load-dependent cornering stiffness) that gives adequate results. Effectively, the resulting lateral compliance of the standing tire is

$$\frac{1}{C_{Fy}} = \frac{1}{c_{cy}} + \frac{\sigma_c}{C_{F\alpha}} \tag{17.204}$$

and the effective resulting tire relaxation length (for side slip response) is

$$\sigma_\alpha = \frac{C_{F\alpha}}{C_{Fy}} = \frac{C_{F\alpha}}{c_{cy}} + \sigma_c \tag{17.205}$$

This equation may, in fact, be employed to assess the lateral carcass stiffness at ground level c_{cy}. From the measured tire relaxation length σ_α and cornering stiffness $C_{F\alpha}$, the lateral stiffness of the standing tire C_{Fy} follows. By taking σ_c equal to half the contact length a, the carcass lateral stiffness c_{cy} can be determined. The relaxation length for load variations remains equal to

$$\sigma_{\alpha,Fz} = \frac{C_{F\alpha}}{c_{cy}} \tag{17.206}$$

which is a little smaller than σ_α. Although this results from practical modeling considerations, we may in fact come close to the measurement results (cf. ([1], Figure 7.10)).

If one is not interested to include the ability to simulate near or at zero forward speed, the contact relaxation length σ_c may be disregarded and taken equal to zero. In Section 17.6, the contact relaxation length σ_c forms an essential element in the model developed for short-wavelength behavior.

The deflection rates needed in Equations 17.199 and 17.200 are equal to the difference in slip velocities:

$$\dot{u} = V_{sx}^* - V_{sx} \tag{17.207}$$

$$\dot{v} = V_{sy}^* - V_{sy} \tag{17.208}$$

As has been mentioned before, the wheel slip velocity V_s with components $V_{sx,y}$ is defined as the horizontal velocity of the slip point S that is thought to be attached to the wheel rim at a distance r_e, the effective rolling radius, below the wheel center in the wheel center plane:

$$V_{sx} = V_x - r_e\Omega \tag{17.209}$$

$$V_{sy} = V_y - r\dot{\gamma} \tag{17.210}$$

where $V_{x,y}$ denote the horizontal (parallel to road plane) components of the wheel center velocity. In Equation 17.210, the camber angle is assumed to be small and r_e is replaced by the loaded radius r.

The forces acting on the wheel rim, finally, become

$$F_{xa} = k_{cx}\dot{u} + c_{cx}u \tag{17.211}$$

$$F_{ya} = k_{cy}\dot{v} + c_{cy}v + F_{y,NL} \tag{17.212}$$

The aligning torque becomes

$$M'_z = -t_\alpha F_y \tag{17.213}$$

$$M_{zr} = M_{zr}(\gamma, \alpha', \kappa', F_z) \tag{17.214}$$

$$M_z = M'_z + M_{zr} + s \cdot F_x + M_{z,gyr} \tag{17.215}$$

The last equation forms an extension of Equation 17.158 through the introduction of the gyroscopic couple that follows from Equation 17.196.

To illustrate the performance of the model, the calculated side force response to successive step changes in camber angle, slip angle, and brake slip has been presented in Figure 17.28. The contact patch relaxation length σ_c has not been used in this example. In [1], the model is applied in the problems of controlled braking on an uneven road and on starting from standstill where in the latter case σ_c is employed. The less demanding case of the response of side force and aligning torque to successive steps in pure side slip, shown in Figure 17.29, was calculated with the restricted fully

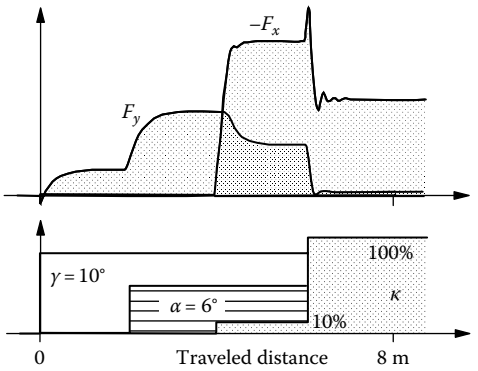

FIGURE 17.28 Side force and brake force response to step changes in combined slip, computed with the enhanced transient tire model of the present section.

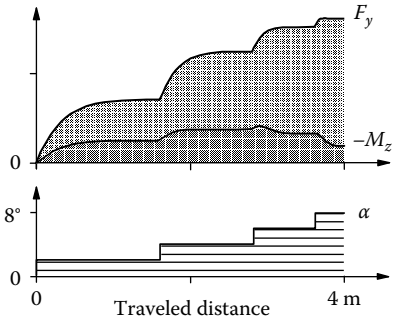

FIGURE 17.29 Side force and aligning torque response to successive steps in side slip as computed with the restricted transient fully nonlinear model, Equation 17.192.

nonlinear model according to Equation 17.192. Very similar results are found when the enhanced model is used, that is, with the inclusion of the contact mass m_c.

17.6 SHORT-WAVELENGTH INTERMEDIATE FREQUENCY TIRE MODEL

The present section briefly describes a model that is able to cover situations where the wavelength is relatively short (>20 cm and possibly even shorter for modeling road obstacle enveloping properties) and the frequency is relatively high (ca. <60–80 Hz) while the level of slip may be high. Situations in which combined slip occurs can be handled, and the Magic Formula model can be used as the basis for the nonlinear force and moment description. As a result, a continuous transition from time-varying slip situations to steady-state conditions is realized. The original model development was restricted to the more important responses to variations of longitudinal and side slip. Also, the possibility to traverse distinct road irregularities (cleats) was included in the tire model. The model is based on the work of Zegelaar [19] and Maurice [20] conducted at the Delft University of Technology and supported by TNO Automotive and a consortium of industries. The model is referred to as the *SWIFT* model (corresponding to the title of the present section) or in the context of Delft tire: *MF-Swift*. Subsequent developments of the model made it possible to also include variations of wheel camber and turn slip. Moreover, more general road surfaces with 3-D unevennesses can be handled. The reader is referred to [1,21] for detailed information.

The crucial step that was taken to reach further than one can by using the string model is the separation of modeling the carcass and the contact patch. In this way, a much more versatile model can be established that correctly describes slip properties at short wavelengths and at high levels of slip. The model achieved can be seen as a further development of the enhanced single-contact-point model of the preceding section, Figure 17.27. In Figure 17.30, the model structure has been depicted. Five elements of the model structure can be distinguished: (1) The inertia of the belt that has been taken into account to properly describe the dynamics of the tire. The restriction to frequencies of about 60–80 Hz allows the belt to be considered as a rigid circular ring. (2) The so-called residual stiffnesses that have been introduced between contact patch and ring to ensure that the total static tire stiffnesses in vertical, longitudinal, lateral, and yaw directions are correct. The total tire model compliance is made up of the carcass compliance, the residual compliance (in reality a part of the total carcass compliance), and the tread compliance. (3) The brush model that represents the contact patch featuring horizontal tread element compliance and partial sliding. On the basis of this model, the effects of the finite length and width of the footprint are approximately included. This element of

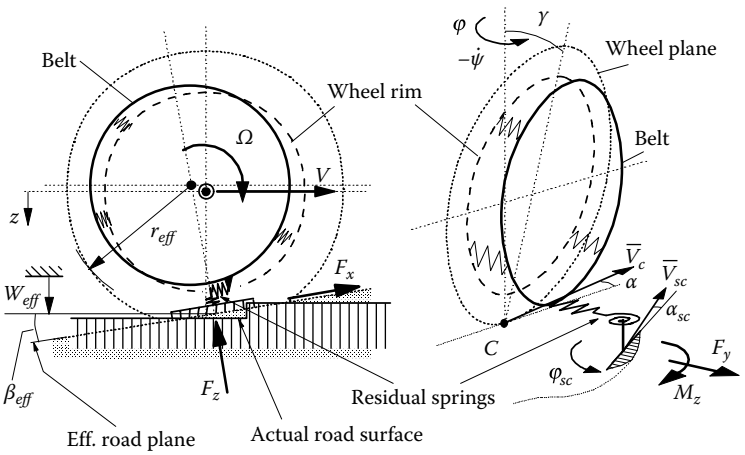

FIGURE 17.30 General configuration of the Swift model featuring rigid belt ring, residual stiffnesses, contact patch slip model, and effective road inputs.

the model is the most complex part and accomplishes the reduction of the allowed input wavelength to ca. 10 cm. (4) Effective road inputs to enable the simulation of the tire moving over an uneven road surface with the enveloping behavior of the tire properly represented. The actual 3-D profile of the road is replaced by a set of four effective inputs: the effective height, the effective forward and transverse slopes of the road plane, and the effective forward road curvature that is largely responsible for the variation of the tire's effective rolling radius. (5) The Magic Formula tire model to describe the nonlinear slip force and moment properties.

Similar but more physically oriented models have been developed. A notable example is the *BRIT* model of Gipser. He employs a brush-ring model featuring tread elements distributed over a finite contact patch with realistic pressure distributions and demonstrates the use of the model with simulations of the tire traversing a sinusoidal road surface also at a slip angle and at braking (cf. Gipser et al. [4]). Other models using discrete and finite elements, *Ftire* and *RMod-K*, have been developed by Gipser [5] and Oertel and Fandre [7], respectively. In [22] Lugner et al. give a comprehensive comparative discussion on the three dynamic models *MF-Swift*, *Ftire*, and *RMod-K*.

In the ensuing discussion, firstly, the slip model of the contact patch covering small wavelengths and large slip will be dealt with. Secondly, the model for the description of the dynamic behavior of the rigid belt ring with residual compliance will be added. Thirdly, the feature of the model that takes care of running over uneven roads will be addressed. Full-scale tire test results will demonstrate the validity of the model.

17.6.1 Contact Model Non-Steady-State Behavior

Theoretical analysis (cf. [1]) shows that the transient slip behavior of the brush model can be approximated by three first-order differential equations. They read for the transient longitudinal slip k'

$$\sigma_c \frac{d\kappa'}{dt} + |V_x|\kappa' = -V_{sxc} \tag{17.216}$$

the transient side slip α'

$$\sigma_c \frac{d\alpha'}{dt} + |V_x|\alpha' = -V_{syc} - |V_x|\psi'^{r}_{st} \tag{17.217}$$

and the transient side slip for the pneumatic trail α'_t

$$\sigma_2 \frac{d\alpha'_t}{dt} + |V_x|\alpha'_t = |V_x|\alpha' \tag{17.218}$$

Additional four first-order differential equations take care of the response to varying turn slip and camber. The forward speed is denoted by V_x. The inputs are the slip velocities of the contact patch, V_{sxc}, V_{syc}, and $d\psi_{sc}/dt$. The outputs are the transient slip quantities. The last term in (17.217) (static carcass yaw distortion in feedback loop) is needed to enable the use of actual tire side slip characteristics (17.220).

The relaxation lengths decrease with the magnitude of total slip, due to decreasing zone of adhesion in the contact patch. At vanishing slip we have $\sigma_c = a$ (half the contact length) and $\sigma_2 = t$ (the pneumatic trail). To assess the forces and moment, the transient slip quantities are subsequently used as input into the steady-state force and pneumatic trail formulae. At pure slip conditions we would have

$$F_x = F_x(\kappa', \alpha', \ldots) \tag{17.219}$$

$$F_y = F_y(\kappa', \alpha', \ldots.) \tag{17.220}$$

$$M_z = -t(\kappa', \alpha'_t \ldots) \cdot F_y + M_{zr}(\kappa', \alpha', \ldots) + (s + y^r_{st}) \cdot F_x + C_{\Delta M} \cdot (\alpha' - \alpha'_t) \tag{17.221}$$

The last term with $C_{\Delta M}$ in (17.221) represents the small extra moment, which is kept in linear form. This term is needed to model the situation where due to the differences in phase, the side force may become zero while the moment is still nonzero. The coefficient $C_{\Delta M}$ also decreases gradually to zero with increasing magnitude of the total slip. At vanishing slip this quantity is equal to the aligning stiffness of the contact patch model (the brush model). M_{zr} represents the moment due to spin (turning and camber). The term with F_x reflects the influence of the lateral shift of the line of action of F_x (cf. original Magic Formula model formulations).

At three different levels of side slip, α_o = 0, 0.08 and 0.16 rad, a comparison of the earlier approximate simulation model (for the brush model with (17.219) through (17.221) replaced by its analytically established steady-state characteristics and the last term of (17.217) removed) with the analytical solution of the brush physical model has been conducted in terms of the path frequency response functions. Figure 17.31 shows the results for the case that the contact patch model is attached to a flexible carcass. The general conclusion is that at least for wavelengths larger than ca.10 cm, the correspondence can be judged to be very good. The upper pair of diagrams that refer to the side force response shows the sideways "shift" of the phase lag curves that is caused by the drop in relaxation length with increasing average slip angle. The diagram for the aligning torque response clearly shows the transition from second- to first-order behavior when the average slip angle changes from zero to larger values.

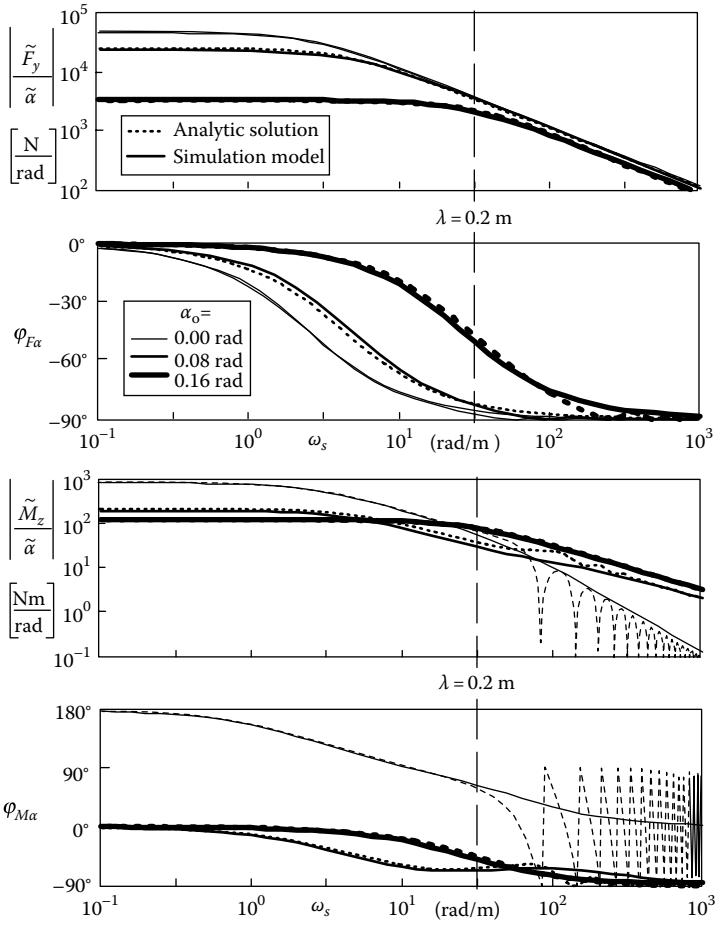

FIGURE 17.31 Frequency response functions of linearized system including carcass flexibility at different average slip angle levels according to the analytical solution and to the approximate simulation model. The path frequency at a wavelength of the input wheel plane motion equal to 20 cm has been indicated.

The model may be expanded also to cover the responses to changes in camber and turn slip. The latter is important especially for the simulation of parking maneuvers. We refer to the original text [1] for detailed information.

The first problem that was encountered is the fact that in the model described earlier where the contact patch is represented by the brush model, the steady-state characteristics employed (17.220, 17.221) belong to the brush model and not to the total model including yaw torsional compliance of the carcass. It is preferred to use functions in terms of the slip values of the wheel, since these functions (possibly Magic Formulae) are directly available from full-scale experiments performed on the road or on flat track or drum test rigs.

An obvious solution is to model the contact patch characteristics with the Magic Formulae. These deviate from those assessed for the complete tire because the contact patch "sees" a slip angle that differs (is smaller) from that of the wheel plane. A set of adapted *MF* parameters may be established off-line for the contact patch, or an iteration loop may be included to achieve the correct steady-state behavior of the total model. A simpler, more practical way has been found, however, which allows the use of the Magic Formula characteristics as obtained from tire slip tests. This is accomplished by adding the last term of Equation 17.217 (the static yaw distortion of the carcass) (cf. [1]).

17.6.2 Residual Stiffnesses and Belt Dynamics

In the preceding part, the contact patch model has been used in connection with a flexible carcass. In the present section, the inertia of the belt is introduced. Since we restrict the application of the model to frequencies lower than ca. 60–80 Hz, the belt may be approximated as a rigid ring that is attached to the wheel rim through flexible sidewalls. To ensure that the total static tire stiffness remains unchanged, residual springs have been introduced between contact patch and belt. The residual springs defined in the model have been indicated in Figure 17.32.

The horizontal dynamics of the contact patch are handled with a set of six first-order differential equations, while the six degrees of freedom belt motion are modeled with two sets of three second-order differential equations.

In the study of Zegelaar [19], also reported in [1], important experimental observations have been made regarding constitutive relationships of the tire such as contact area dimensions, static and dynamic vertical stiffness and characteristics at different speeds of rolling, static longitudinal stiffness of the standing tire, tire radius growth with speed, rolling resistance, effective rolling radius, and rolling resistance couple. Model parameter values are assessed through full-scale tire dynamic experiments carried out on different types of test facilities. Many of the parameters are obtained by minimizing the difference between measured and calculated (complex) response functions.

The calculated vibrational rigid body modes at zero speed using the parameters as established from experiments carried out on the rotating drum have been depicted in Figures 17.33 and 17.34.

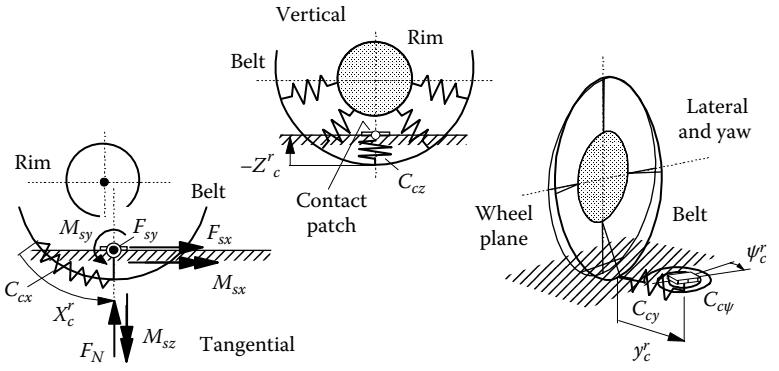

FIGURE 17.32 Deflections of the residual springs attaching contact patch to belt.

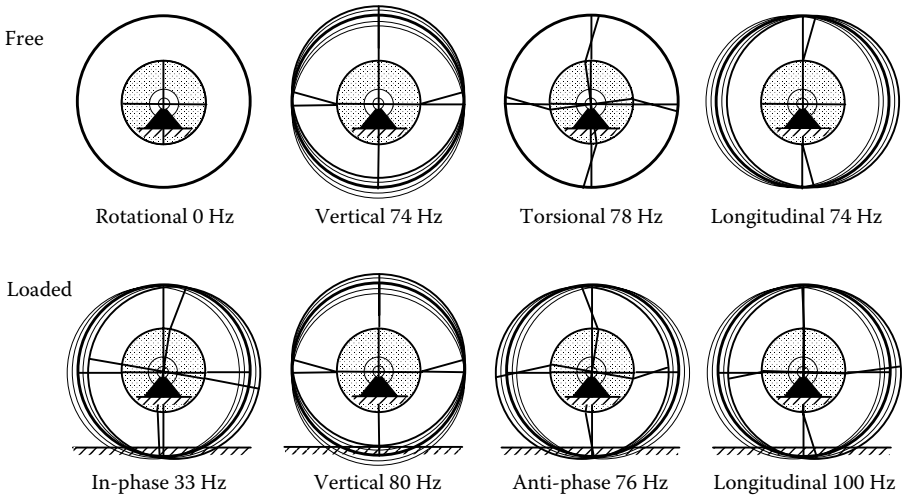

FIGURE 17.33 Calculated in-plane vibrational modes of tire/wheel system with axle fixed and tire free or loaded on the drum surface with vertical load F_N = 4000 N and at zero speed.

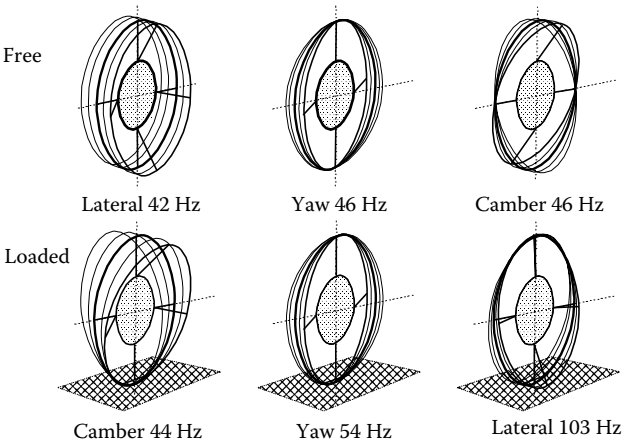

FIGURE 17.34 Calculated out-of-plane vibrational modes of tire/wheel system with axle fixed and tire free or loaded on the drum surface with vertical load F_N = 4000 N and zero speed.

We have four in-plane degrees of freedom of belt ring and wheel rim (two translational and two rotational) and three out-of-plane degrees of freedom (lateral, yaw, and camber). As a consequence, we can distinguish four in-plane rigid body modes and three out-of-plane rigid body modes. The mode shapes may change considerably when the tire is making contact to the drum surface. The free rotation (0 Hz) mode changes into a mode with the belt and rim rotating in phase with respect to each other. The lateral and camber modes form combinations: one low-frequency mode with a low axis of camber oscillations and one high-frequency mode with a rotation axis closer to the top of the tire and relatively large lateral deflections in the contact zone.

As an example, Figure 17.35 presents the out-of-plane frequency response functions of the side force and the aligning torque amplitudes to yaw oscillations compared with test results as obtained on the yaw oscillation test stand up to ca. 60 Hz. To demonstrate the in-plane performance of the model, simulations and experiments conducted on the dynamic brake/cleat drum

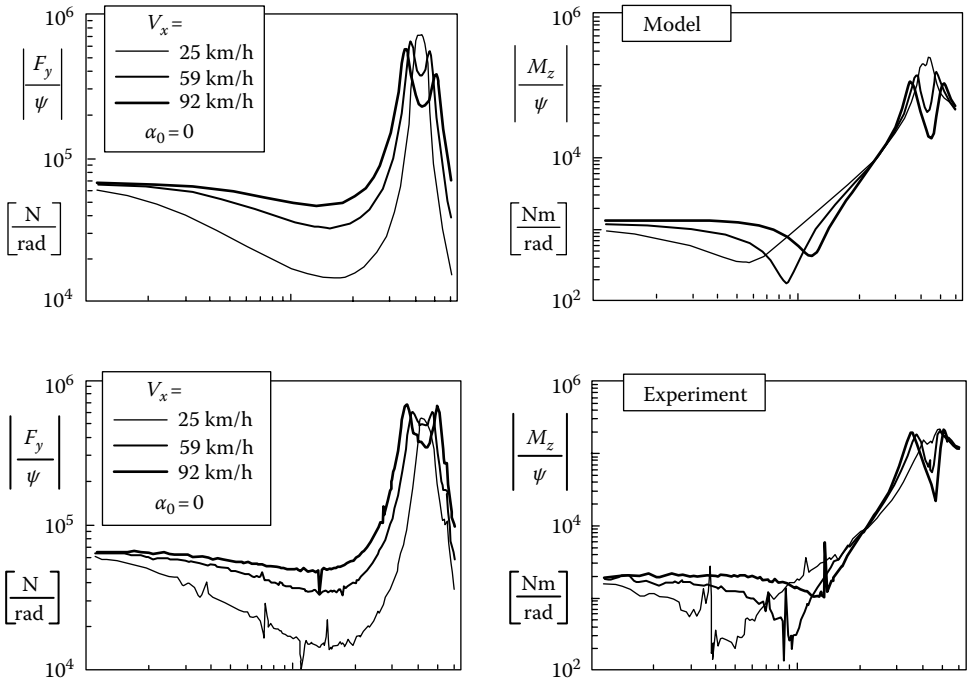

FIGURE 17.35 Calculated (top) and measured out-of-plane frequency response functions of the side force and aligning torque amplitude to steer angle variations at zero average slip angle for three values of forward speed and normal load $F_N = 4000$ N. (From Maurice, J.P., Short wavelength and dynamic tire behaviour under lateral and combined slip conditions, Dissertation, TU Delft, Delft, the Netherlands, 2000.)

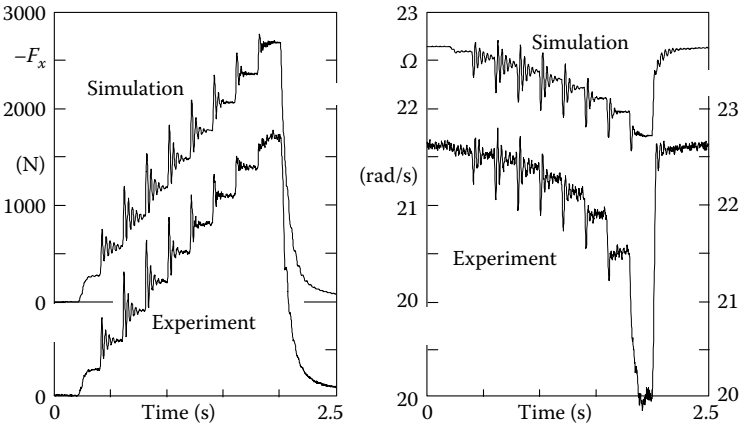

FIGURE 17.36 Brake force response to successive step increments of brake pressure. The diagrams depict the variation of force and wheel speed of revolution with time. Apparently, the actual friction coefficient is lower than assumed in the model. (From Zegelaar, P.W.A., The dynamic response of tires to brake torque variations and road unevennesses, Dissertation, TU Delft, Delft, the Netherlands, 1998.)

test facility have been carried out pertaining to successive stepwise increases in brake pressure. The response of the longitudinal force and the associated wheel speed has been presented in Figure 17.36. Apparently, the rigid ring model provided with the short-wavelength transient slip model and residual compliances is very well capable of describing the dynamic tire behavior in the frequency range up to about 60 Hz.

17.6.3 Dynamic Tire Response to Short Road Unevennesses

The actual road surface profile over which the tire rolls may contain spectral components showing relatively short wavelengths. If the wavelength is smaller than two to three times the contact length, a geometric filtering of the profile becomes necessary if the tire model employed is assumed to contact the road in a single point. For the *SWIFT* model, a special filter has been developed that takes care of the envelopment properties of the tire and the variation in effective rolling radius that occurs when the tire rolls over a short obstacle. The envelopment of an obstacle takes place in the contact zone. It is assumed that local dynamic effects can be neglected. The changing conditions that arise for the tire when quasi-statically traversing an obstacle are measured and modeled and subsequently used as effective road plane inputs for the tire model at higher speeds. The belt inertia takes care of the dynamic effects. To arrive at a geometrically filtered road profile description, Bandel [23] introduces the effective road plane. The effective plane height and forward slope variation may be established by conducting an experiment where the wheel is rolled at a very low velocity over an uneven road surface at constant vertical load and the forces and vertical displacement are measured. According to the definition, the resulting force (with the rolling resistance force subtracted) that acts upon the wheel axle is directed perpendicularly to the effective road plane. The effective height variation, w, is taken equal to the vertical axle displacement. The effective forward slope $\tan\beta_y$ is found by dividing the longitudinal horizontal force (after having subtracted the relatively small rolling resistance force) by the vertical force. In the model, the effective road height and slope can be assessed by using basic curves in connection with a two-point follower with shift length l_s (Zegelaar [19]) or by moving two cams with an oval shape (Schmeitz, cf. [1 (3d ed.), 21,24]) over the actual road surface following each other at a distance equal to the length l_s (slightly smaller than the contact length). The height of the midpoint of the connecting line of the lowest points of the cams and the inclination of this line represent the effective road height and effective forward slope. Figure 17.37 illustrates this "tandem cam" configuration. Fitting the tandem cam parameters is accomplished by assessing the best approximation of very low-speed responses of a tire running over steps or strips of different heights at a number of constant vertical loads. Once the parameters have been established, the cam dimensions can be kept fixed and independent of step height, obstacle shape, or vertical load. Inspection shows that the shape of the lower part of the ellipse turns out to be practically identical to the contour of the tire in side view just in front of the contact zone up to the height of the highest step considered in the fitting process. The tandem base length l_s does depend on the vertical load. The tandem cam configuration can be employed to simulate rolling over single cleats or arbitrary irregular, normally encountered, road surfaces.

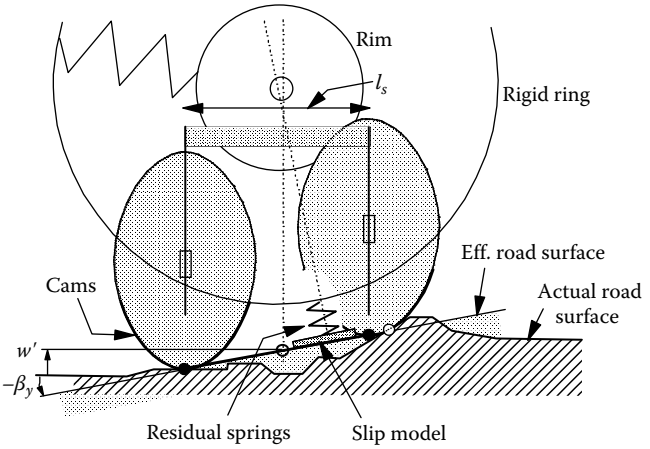

FIGURE 17.37 The "tandem cam" configuration of Schmeitz, generating the effective road height and slope, attached to the ring and slip model.

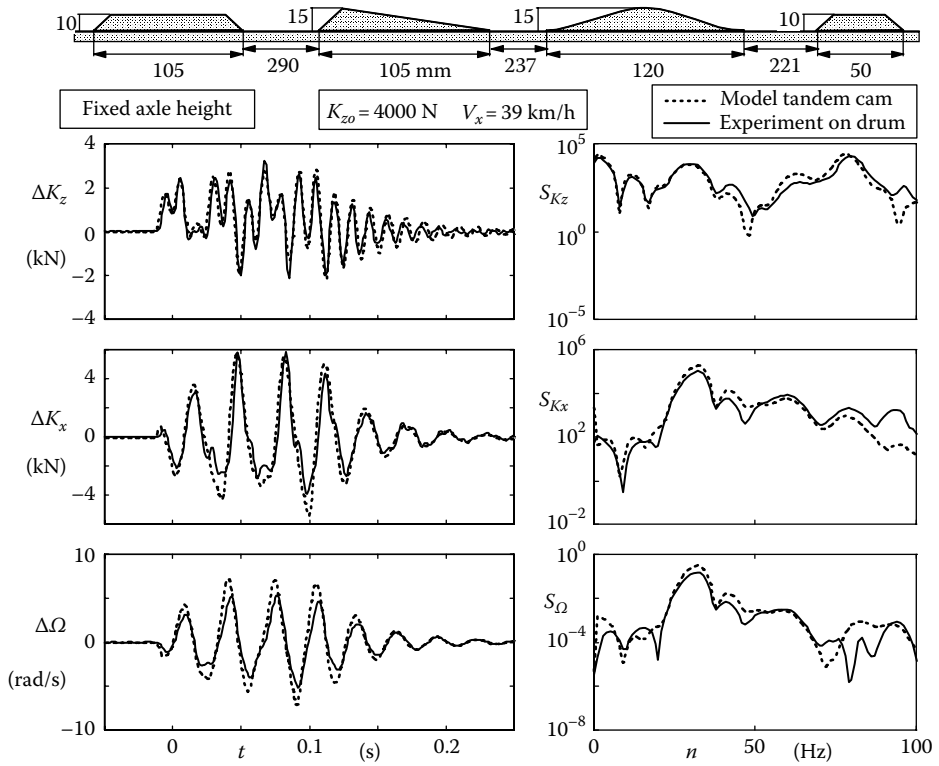

FIGURE 17.38 Running over a series of cleats mounted on the drum surface, at constant axle height. Measured and computed variations of vertical and longitudinal wheel spindle forces K_z and K_y and wheel angular speed Ω versus time and as power spectral densities S. The center of the first (left-hand) cleat passes under the wheel center at $t = 0$. After t = ca. 0.12 s the surface is undisturbed.

Analysis shows that the variation of the effective rolling radius with respect to the initial condition, where the effective slope β_y and slope rate of change (curvature) $d\beta_y/ds$ are zero and the radial tire deflection $\rho_z = \rho_{zo}$, becomes

$$\tilde{r}_e = -\eta\tilde{\rho}_z - r_{eo}(1-\cos\beta_y) + \rho_z r_{eo}\frac{d\beta_y}{ds} \tag{17.222}$$

On uneven road surfaces, the last term constitutes by far the most important contribution to the effective rolling radius variation and thus to the wheel rotational acceleration that can only be brought about by a variation in the longitudinal contact force F_x. This force also often outweighs the part of the horizontal longitudinal force that directly results from the forward slope itself.

In Figure 17.38, an example is presented where a 205/60 R15 tire rolls at constant axle height over a drum surface provided with a number of differently shaped obstacles. Comparison of measured and computed vertical and horizontal (longitudinal) wheel spindle forces K_z and K_x and wheel speed of revolution Ω varying with time and as power spectra S shows satisfactory agreement.

Road camber variations that occur, for example, when the tire rolls over an oblique cleat, can be handled by taking two parallel tandems (track width taken equal to the width of the contact patch) and assessing the average transverse effective slope tan β_x (cf. Figure 17.39 showing the double-track "road feeler" moving over a step-shaped road unevenness with angle θ). For short-wavelength (<0.2 m) road camber variations that, for example, occur with obstacles like oblique steps or strips, additional intermediate cams (say three additional cams along each of the four edges of the "road feeler") are to be inserted with slopes averaged to get sufficiently accurate results (cf. [21,24]).

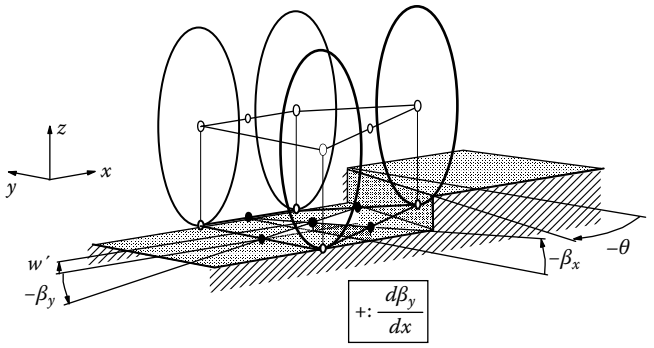

FIGURE 17.39 The double-track tandem cam road feeler for 3-D road unevennesses, moving over oblique step. Four effective road inputs.

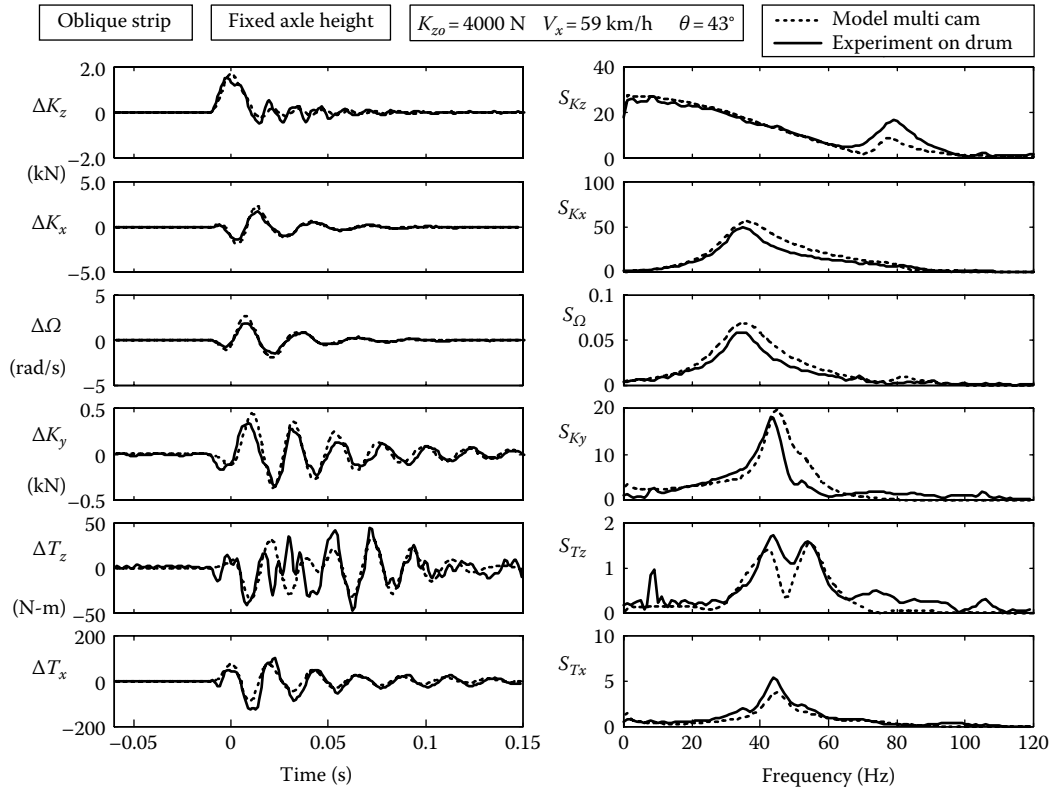

FIGURE 17.40 Running over an oblique cleat (10 × 50 mm strip) mounted on the drum surface at an angle of 43°, at constant axle height. Measured and computed variations of wheel spindle forces K and moments T and wheel angular speed Ω versus time and as power spectral densities S.

In total we have now four effective road input quantities: (1) the effective height w, (2) the effective forward road slope angle β_y, (3) the effective transverse road slope angle β_x, and (4) the effective forward road curvature $d\beta_y/dx$.

In Figure 17.40, example results are shown of experimental and model simulation results of the tire moving at constant axle height at a speed of 59 km/h over an oblique strip (height 10 mm, width 50 mm) mounted at an angle of 43° with respect to the drum axis (wheel slip angle and camber angle are zero). The variations of the wheel spindle forces $K_{x,y,z}$ and moments $T_{x,z}$ and the wheel angular velocity Ω are presented as functions of time and as power spectral densities versus frequency.

Again, it is seen that a reasonable or good correspondence can be achieved. The various tire/wheel resonance frequencies can be observed to show up vertical mode at 78 Hz (K_z), rotational mode at 35 Hz (K_x and Ω), camber mode at 46 Hz (K_y, T_z, and T_x), and yaw mode at 54 Hz (T_z).

17.7 TIRE STEADY-STATE AND DYNAMIC TEST FACILITIES

At various automotive and tire industrial companies and at a number of universities and institutes, test facilities are available for performing full-scale tire measurements to assess the tire force and moment generation properties. The test installation may be built on a truck or trailer that is equipped with a special wheel suspension and guidance system to which a measuring hub is attached. Typically, with such an over the road testing equipment, moderate speeds up to ca. 120 km/h can be reached. The frequencies with which the steer angle can be varied are relatively low. The camber angle is changed mechanically or through a hydraulic cylinder. The vertical load may be set at a desired average level; the load variations caused by road unevennesses are filtered out. Commonly, the longitudinal slip results from the controlled application of the brake pressure. In very few cases, the wheel angular velocity is controlled through a hydraulic motor that acts relative to the vehicle's road wheel speed of revolution. In such a way, the test wheel drive and brake slip can be varied in a controlled manner. In some devices, water can be sprayed in front of the test wheel to create wet road conditions. The measuring hub contains strain gauge or piezoelectric force measuring elements. With these test facilities usually measurements are conducted at quasi-steady-state conditions. Typically, a side slip or brake slip sweep may be imposed at a low rate. After processing, correcting, and averaging the signals, the steady-state force and moment slip characteristics are obtained.

The large indoor test stands usually operate along similar lines. These rigs are based on an imitated road surface provided by the surface of a drum or by that of a flat track (endless belt). Somewhat higher frequencies of changing vertical axle position and yaw angle can usually be achieved (up to ca. 2–8 Hz). Drum test stands have been built with diameters ranging from 2 to ca. 4–5 m. With the larger drums the tire usually runs or can also be run on the inner surface. This configuration makes it possible to mount realistic road surface segments and to maintain a layer of water on the inner surface, thereby enabling testing at wet or icy (and even snowy) conditions. External drums of 2.5–3 m diameter are more often encountered. Also, flat bed and flat plank test rigs are used. Typically, but not always, these machines operate at very low speed of travel of either the plank or the wheel axle. Also, turn table or swing arm devices exist that are constructed to measure turn slip properties.

On the drum test stand, a measuring tower or a special wheel guidance system with a force measurement platform or hub can be positioned. For dynamic higher-frequency tire tests, very stiff rigs are required (or very soft seismic systems). Special equipment is used that is often limited to a specific application to allow the system to become light and sufficiently rigid, that is, high first natural frequency. Devices exist dedicated to specific tasks such as systems with axle fixed (but adjustable in height) to assess tire nonuniformity, cleat response, or response to brake pressure variations; axle forced to perform only vertical axle oscillations to assess the vertical dynamic stiffness and the response of the longitudinal force; and only yaw angle variation of the axle to assess the tire dynamic steer response.

In Figure 17.41, a picture is shown of the Delft tire test trailer (cf. [25] cf. [1] 3d edn.) now owned by TNO, Helmond. The trailer has two measuring stations: one for passenger car-size tires limited to not so large camber angles (<30°) and, on the other side, a system specially designed for motorcycle tires that can handle also large camber angles (up to 55°). The test wheel can be subjected to a (varying) steer and camber angle and can be braked up to wheel lock. Water can be sprayed at a controlled rate in front of the test tire. The three forces and two moments (i.e., except the brake torque) are measured with the aid of measuring hubs: a large strain gauge-based and a compact piezoelectric-based system, respectively.

Figure 17.42 depicts the flat track machine of MTS. The upper structure, in which the steering axis is located, can be tilted about a line that forms the line of intersection of the wheel center plane and the belt that imitates the road surface. Through this configuration a pure camber or wheel inclination angle variation can be created (at zero steer angle). A very early

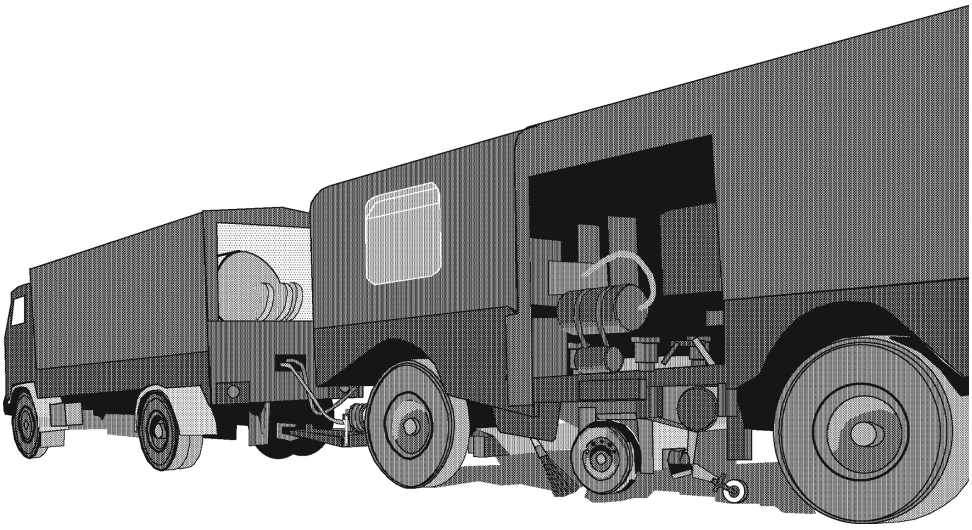

FIGURE 17.41 The Delft tire test trailer.

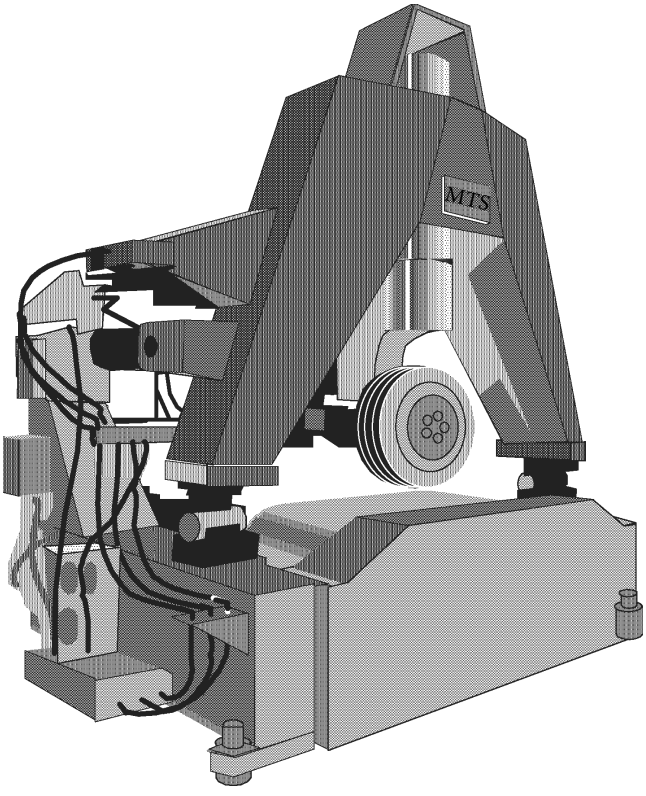

FIGURE 17.42 The MTS flat track test machine.

example of such a system is the large "Tread Mill" of (formerly) Calspan, Buffalo, that can also handle larger truck tires. The belt is supported by two drums and underneath the tire by a flat air or water-bearing surface. The lateral stabilization of the belt is accomplished by varying the yaw or the tilt angle of one of the drums. The test wheel can be driven and braked in a slip-controlled manner.

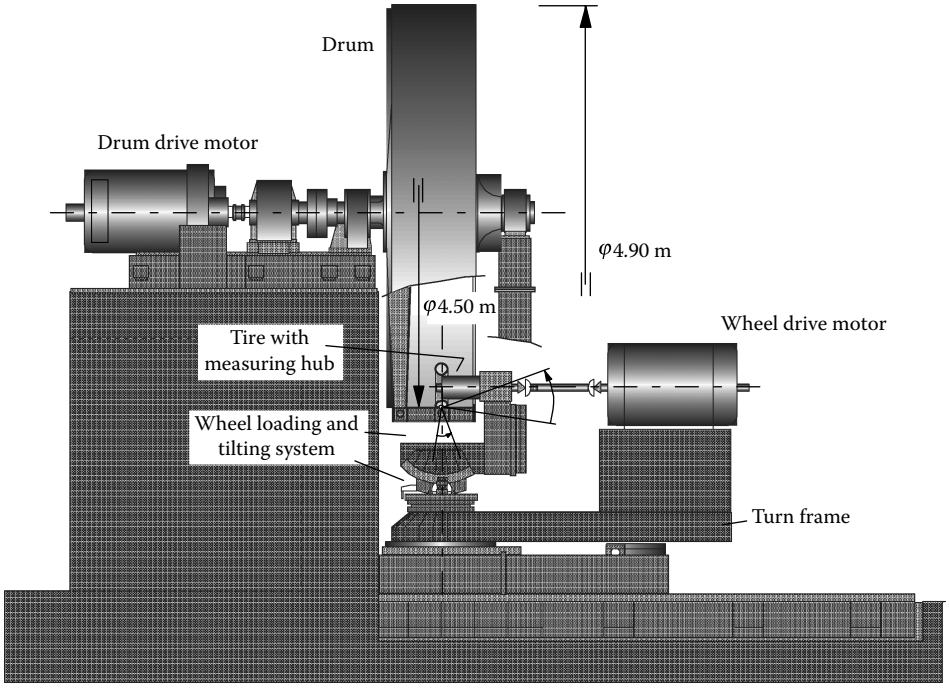

FIGURE 17.43 Internal drum test stand originally possessed and operated by Porsche.

Figures 17.43 and 17.44 show the layout of two internal drum test stands (cf. [26,27]). The drum of Figure 17.43 can also be used on its outer surface with a maximum speed of 250 km/h. These large rigs are operated at the Karlsruhe University of Technology. The arrangement of the wheel loading, tilting, and steering system enables center point steering and tilting about a line that touches the inner drum surface and lies in the wheel center plane. The order of changing the wheel attitude angles, first steering about the always vertical axis and then tilting about the new (still horizontal) x-axis, ensures that each of the angles, defined about and with respect to the vertical, remains unchanged when the other is varied. Of course, this principle also holds for the system of Figure 17.41 but not for the flat track machine of Figure 17.42. The configuration of Figure 17.44 exhibits a hydraulic wheel drive motor with which the wheel slip ratio can be controlled. Here, the force measuring unit rotates together with the wheel. This avoids the otherwise necessary constructional measure to suppress parasitic forces and cross talk such as the brake torque interaction with aligning torque that arises due to misalignment. With a stationary measuring hub, a double-Cardan-coupling drive shaft (including a length change compensation element) is an example of such a measure that ensures that practically only the drive/brake torque is transmitted to the wheel. Instead of a pair of these couplings, a set of two membranes (thin flexible discs) or other devices (see Figure 17.46) may be used. Accurate alignment remains necessary. With the UMTRI configuration (University of Michigan), cross talk has been prevented by positioning the brake system between the nonrotating, stationary measuring system and the tire. One of the drawbacks of rotating measuring systems is the fact that the sensitivity about the vertical axis (for the small aligning torque) cannot be chosen larger than the sensitivity about the horizontal longitudinal axis about which the moment may become relatively large.

Figure 17.45 shows the Delft flat plank machine (cf. [16,25]) now owned by the Eindhoven University of Technology. With this rig, accurate measurements can be conducted at a low speed of 2.3 cm/s. The plank has a maximum stroke of 7.5 m and can be tilted about the longitudinal center line on the test surface. Hereby, pure camber step responses can be established. The wheel axle, equipped with a measuring hub, can be steered and cambered, and the wheel can be braked. The vertical axle position or the vertical tire load can be adjusted. Cleats can be mounted on the plank surface. Typically, tire static

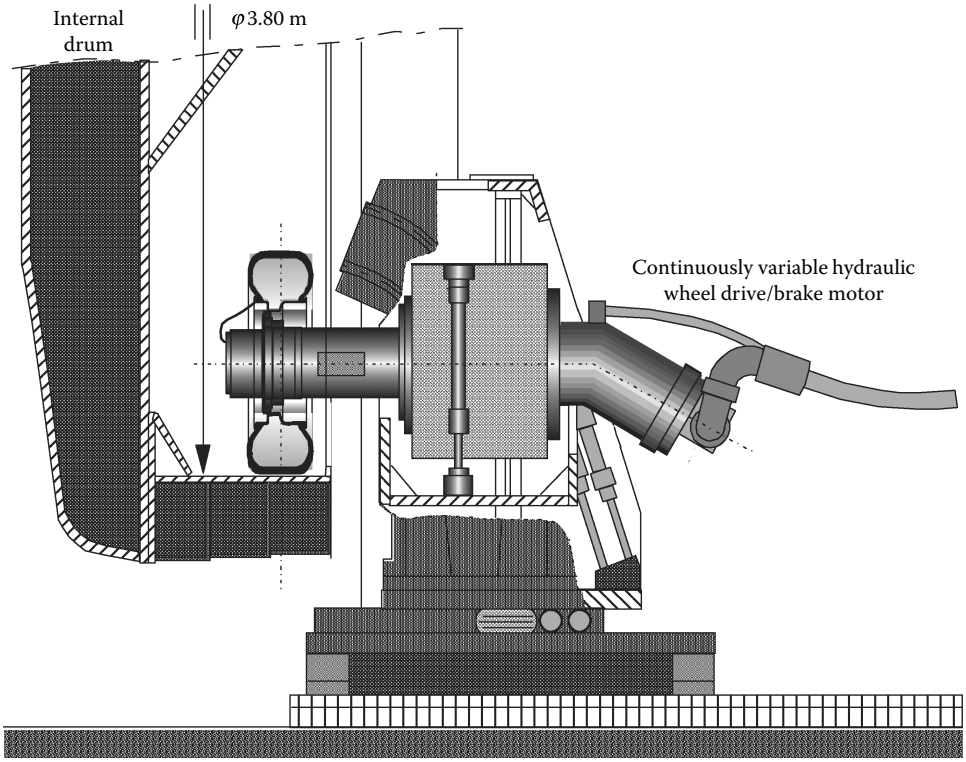

FIGURE 17.44 The Karlsruhe internal drum test stand.

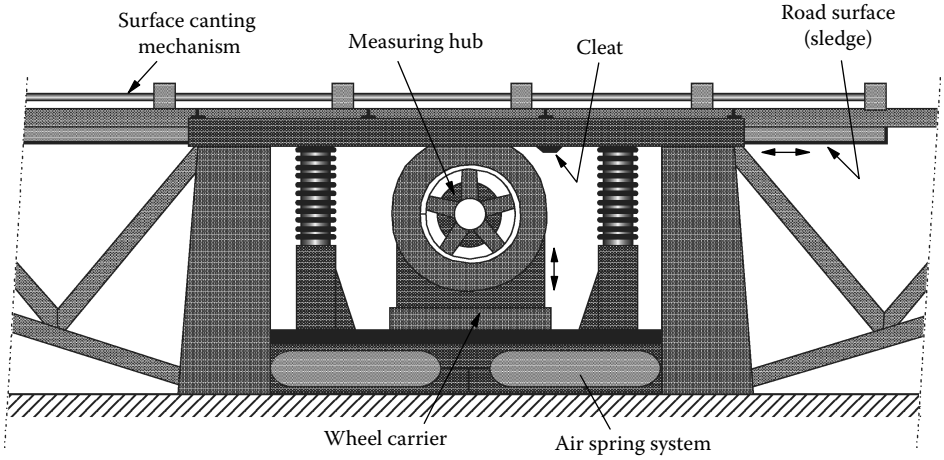

FIGURE 17.45 The flat plank machine with stroke of 7 m and road canting system.

stiffness tests (vertical, longitudinal, lateral, yaw, and camber), transient (step) side slip and camber tests (relaxation length), impulse turning, and cleat tests are performed on this machine.

The indoor drum test facility of the Delft University of Technology is based on two coupled drums with a diameter of 2.5 m that can run up to a maximum speed of 300 km/h. On top of one of the drums, a measuring tower (for low- or moderate-frequency yaw and brake experiments) can be installed (not shown). This rig [20,25] can be turned about a vertical axis that passes through the tire contact center and through the top of the drum surface. On the other drum, a rig can be mounted that is designed for measuring in-plane tire dynamics (Figure 17.46, [19]). Much care has been taken to make the

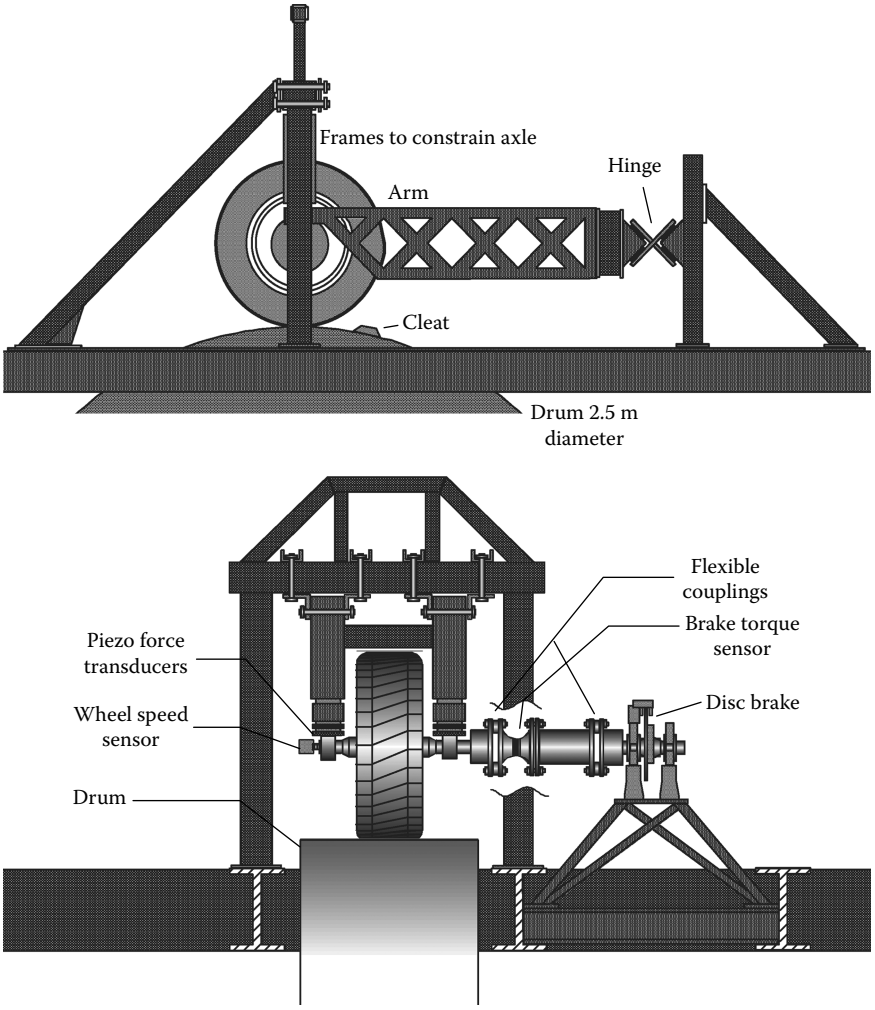

FIGURE 17.46 Dynamic brake and cleat test facility in side and front view. Tests may be conducted up to ca. 65 Hz enabling the assessment of tire/wheel in-plane inertia and stiffness parameters including residual stiffnesses and rigid modes of vibration.

rig sufficiently rigid. This resulted in a lowest natural frequency of just over 100 Hz that allows the use of test data up to ca. 70 Hz. In addition, to avoid force and moment cross talk, the brake shaft is connected with the wheel shaft through an intermediate shaft with two flexible couplings. These couplings represent an alternative solution for the double-Cardan coupling of Figure 17.43. They are flexible in all directions except about the axis of rotation. If properly aligned, this ensures that only the brake torque is transmitted to the wheel and that other parasitic forces and moments are largely suppressed. The brake torque is measured with strain gauges attached to the intermediate coupling shaft. A hydraulic servo system is used to control the brake pressure fluctuations (bandwidth up to ca. 60 Hz). Piezoelectric load cells placed on top of the bearings of the wheel shaft provide the signals from which the forces and moments that act on the wheel (except the brake torque) can be derived. In a different setup the machine is used for response measurements to vertical axle oscillations (<20 Hz).

On the other drum, rigs may be mounted for out-of-plane tire dynamic experiments. One is the trailing arm "pendulum" test stand [14,20] with at one end a vertical hinge and at the other the steering head (for adjusting the average slip angle) with piezoelectric measuring hub (cf. Figure 17.47). At that point the arm is excited laterally up to ca. 25 Hz by means of a hydraulic actuator. The wheel

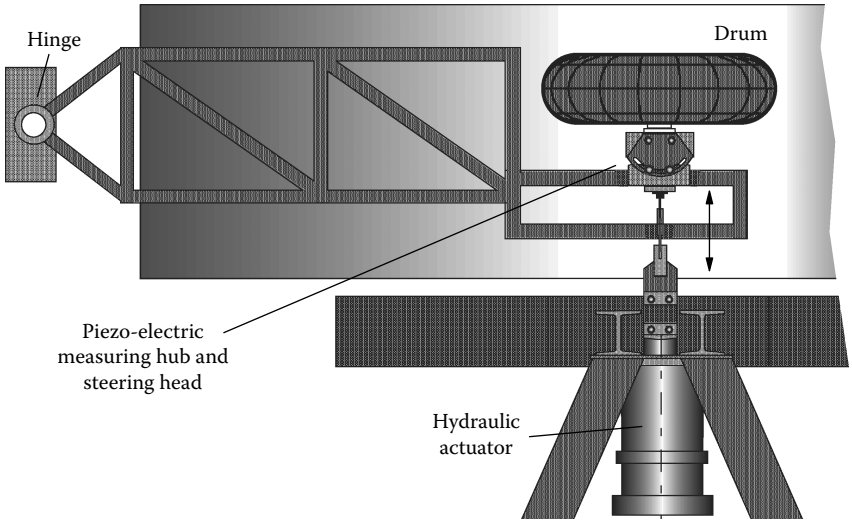

FIGURE 17.47 The trailing arm "pendulum" test rig exciting the tire almost purely laterally. Frequencies up to ca. 25 Hz adequate for assessing the tire relaxation length and gyroscopic couple parameter.

load is adjusted by tilting the vertical hinge slightly forward. The arm length is 1.65 m and the tire is subjected to an almost purely lateral slip variation. The rig is useful to assess the overall relaxation length and the gyroscopic couple parameter. In Figure 17.48, the so-called yaw oscillation test stand [20] is depicted that can be used for tests around an average steer angle that can be set at a value between −5° and +5°. The structure is light and very stiff. The two guiding members with flexible hinges intersect in the vertical virtual steering axis that is positioned in the wheel center plane (center point steering). A hydraulic actuator is mounted to generate the yaw vibration (typically random with a bandwidth of 65 Hz). The wheel axle is provided with a piezoelectric measuring hub. The tire is loaded by mechanically adjusting the axle height above the drum surface.

18.1 INTRODUCTION

It is needless to state that tire properties and tire models are playing, since the very beginning of simulation, a most essential role in all kinds of vehicle dynamics investigations. However, there is a growing demand on ever better and more detailed models, which essentially widen the range of applicability. Today's simulation technology increasingly extends the classical fields of steady-state or low-frequency vehicle dynamics into regions of higher frequencies—with respect to both road excitation and dynamic tire response, in time and in frequency domain.

At the same time, with ever-growing detailing and accuracy of suspension models, the tire models as well are expected to be more and more accurate. Simulation today is no longer a matter of principle investigations, as it might have been in the past. Simulation today no longer means to predict only an order of magnitude but rather two, three, or more decimals of the result. At least, this is what most users would expect an expensive software package be able to achieve.

Moreover, this accuracy is desired not only in operating points that are covered by respective measurements but also for conditions that need extrapolation. For sure, many users of a multibody system (MBS) suspension model would like the tire model to accurately predict tire forces in complex but relevant situations. Imagine a vehicle, passing an obstacle in a sharp curve when braking at the same time, with an anti-lock braking system (ABS) controller being active. What if in addition, the tire is damaged by the obstacle and loses pressure? And what if all this happens during heavy rain or if the vehicle tends to roll over? No doubt, all these are relevant questions of vehicle dynamics, which are much more than just of academic interest. And simulation experiments will have to provide answers, sooner or later.

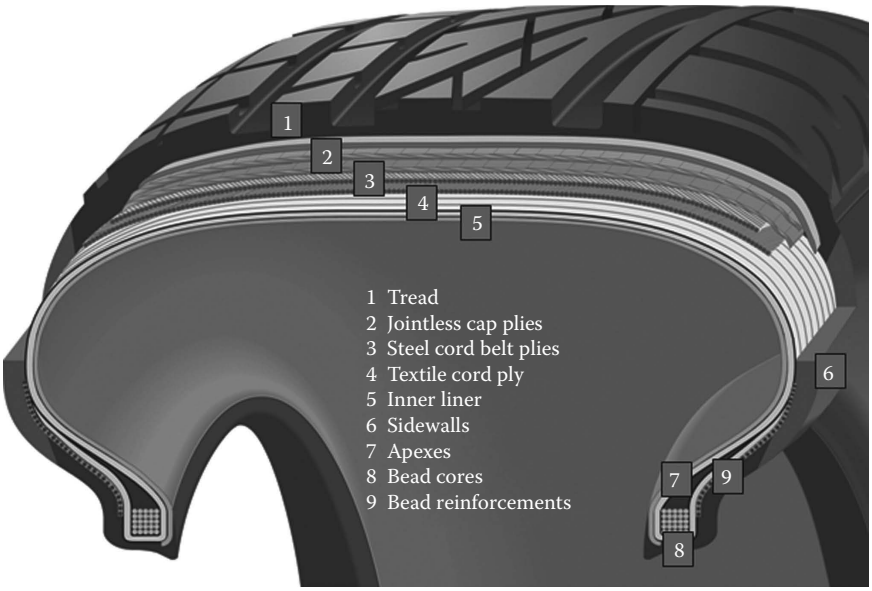

FIGURE 18.1 Components of a passenger car radial tire. (Image courtesy of Continental AG, Hanover, Germany.)

On the other hand, from a modeling point of view, the tire is a tough nut. Its design is a complicated compound of many, very different materials, vulcanized together after an elaborate building process (Figure 18.1). Several physical domains are decisive for its behavior: structural mechanics, thermodynamics, fluid dynamics, chemistry, tribology, heat transfer, and more. From the system dynamics point of view, a tire behaves highly nonlinear. This is not only due to large, up to extreme deflections but also due to nonlinear rubber behavior, unilateral contact forces in the footprint, and friction phenomena during cornering, driving, and braking.

The tread pattern has a large influence on many tire properties. Its geometry ranges from simple (some agricultural, aircraft, and racing tires) to extremely complex (most passenger car tires). The tread pattern of a passenger car tire is a nightmare for those trying to simulate aquaplaning by a combination of mechanical tire models with computational fluid dynamics (CFD) models (Figure 18.2). And it is a nightmare when trying to simulate tread pattern-related noise generation or when trying to predict traction and cornering forces on snow or soft soil.

Putting all this together, by relating the user's demands (wide and ever-growing application range, high frequencies of excitation and response, high absolute accuracy demands, validity and reliability in situations where no respective measurements are available) to the tire's properties (extreme nonlinearity, complicated geometry, complicated material properties, tremendous variety of designs and sizes, comprising tires for bicycles, scooters, motorcycles, passenger cars, SUVs, trucks, trailers, agricultural machines, aircrafts, earthmovers, all-terrain vehicles (ATVs), race cars, and more), it is obvious that simple models will not be sufficient for all this in the long term. Models are required, which orientate themselves as close as possible toward the physics of the tire, but which can be evaluated with bearable computational effort at the same time.

Clearly, it makes a difference whether a tire model will be used in tire industry, to assist in developing and improving the tire itself, or whether it is used by the development department of a vehicle (or a suspension component) manufacturer. The primary interest of the latter will not be to improve the tire but rather to have a description of the tire used or planned for use together with the vehicle under development. As stated earlier, this description has to be as accurate, reliable, and efficient as possible. But it need not necessarily describe the influence of tire design modifications on tire performance.

A tire developer, on the other hand, has (or should have) the best possible knowledge about the tire design and all geometry and material data items that are necessary to generate a detailed finite

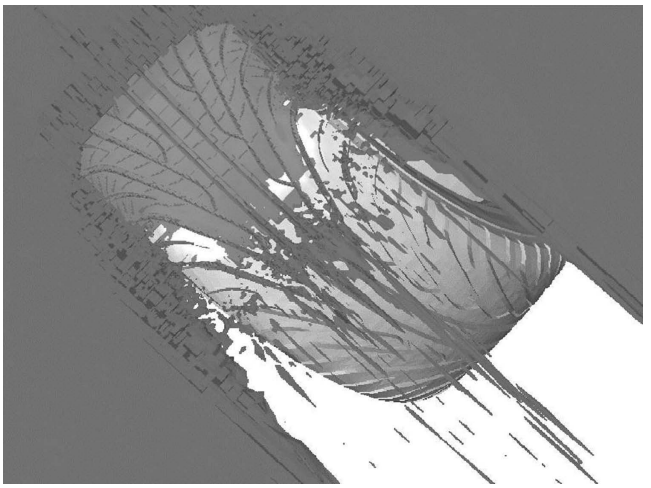

FIGURE 18.2 Hydroplaning simulation using an explicit FEM/FVM code. (Image courtesy of Yokohama Tire, Tokyo, Japan; From Okano, T. and Koishi, M., A computational procedure to predict transient hydroplaning of a tire, *Proceedings of the 19th Annual Meeting and Conference on Tire Science and Technology*, Akron, OH, 2000.)

element (FE) model. FE analysis (FEA) is the most important computer-aided engineering (CAE) tool during tire development. Very much simplified, a tire designer will be ready to spend time and effort to develop FE tire models, because these models are directly related to his primary task and because he has all the available items that are needed.

A vehicle designer, however, typically does not have access to such detailed tire design data. Nor is he or she ready to lose much time in establishing and running an FE model of a product that he is not responsible for. Moreover, the tire model needs to be coupled to his vehicle model. Simultaneously running four FE tire models (or even much more, 12, say, for a typical European tractor–trailer combination), in addition to his vehicle model, would mean unacceptable long computing times. This is the reason why there is a growing demand on tire models, which are

- Based upon a detailed mechanical approach, to be predictive in all relevant situations
- Far less complex than FE models, to be fast enough for full vehicle simulations with standard vehicle dynamics maneuvers in time domain

The biggest challenge for all such models is the supply of model data, subsequently called parameterization. Many of the parameters of a mechanical tire model "below FE" cannot be easily determined or measured directly, even if they have a well-defined physical meaning. So, parameterization tools play a crucial role for mechanical models (as they do of course, even more, for phenomenological models like MF-Tyre and MF-Swift™, which are based upon the famous Magic Formula [1]).

There are two approaches of parameterization. The first uses measurements of

- Static behavior (radial, longitudinal, lateral stiffness, etc.) of a standing tire
- Steady-state behavior (handling characteristics) of a rolling tire
- Modal properties (resonance frequencies and related mode shapes) of an unloaded or loaded tire
- Dynamic response to transient excitation (cleat tests on different types of cleats, at different rolling speeds and vertical loads)

in order to identify the model data. This identification process will be performed or at least assisted by some parameter identification software.

The second approach requires a detailed FE model, either to compute the data of the "coarser" model by applying some static or modal condensation technique or to generate "virtual" measurements of static, steady-state, modal, and transient type.

For both approaches, time and cost effort is considerable. Either sophisticated measuring rigs or detailed FE data are required. Typically, the tire manufacturer seems to be the only place where both are available. Therefore, a suspension designer working for a vehicle manufacturer will try to get a ready-to-run data file from there. However, in turn, the tire model then needs to be accepted and available at the tire manufacturer. This strive for interchange of model data between tire and vehicle manufacturers is one of the reasons why there are only very few tire models actually being used in daily work, as opposed from so many more being published.

18.2 TIRE FINITE ELEMENT ANALYSIS

A survey among leading tire manufacturers revealed that all are intensively applying FEA during tire development. Most companies said the share of FEA among all kinds of CAE computations is more than 80%; some said it is even more than 90%. One manufacturer mentioned their development delays had been cut by 50% in the last 8 years, through applying FEA, with models similar to the one shown in Figure 18.3.

Moreover, nearly all companies being questioned are developing, maintaining, and using proprietary in-house FE software. Apparently, the importance of tire FEA justifies such considerable effort. It seems this is still the easiest way to map the company's tire know-how onto simulation models. Commercially available FE software in use was said to be the ABAQUS™, LS-DYNA™, and PAM™ software family. Few mention NASTRAN™ and Marc™. Clearly, emphasis is put on highly nonlinear models, including large displacement, contact, and friction treatment.

The list of FEA applications being mentioned is long and reflects the complexity of the tire development process. On top of the list are routine calculations like static footprint analyses, comprising shape prediction and computation of ground pressure distribution. The same is performed also during steady-state rolling (Figure 18.4) and, sometimes under certain transient conditions, to predict dynamic wheel loads. Other routine calculations (in order of importance)

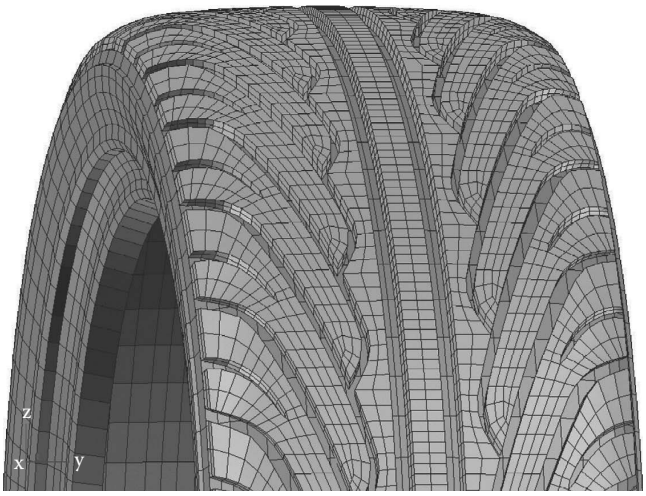

FIGURE 18.3 FE model with medium-scale mesh size. (Image courtesy of Yokohama Tire, Tokyo, Japan; From Okano, T. and Koishi, M., A computational procedure to predict transient hydroplaning of a tire, *Proceedings of the 19th Annual Meeting and Conference on Tire Science and Technology*, Akron, OH, 2000.)

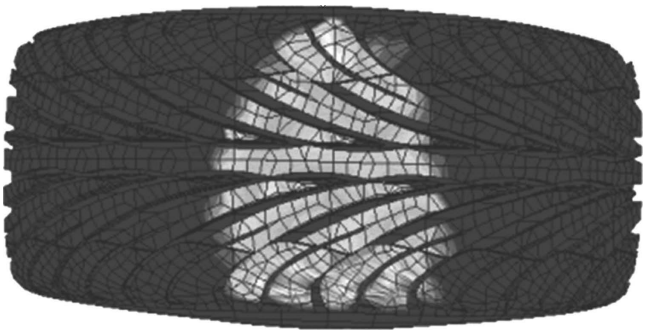

FIGURE 18.4 Pressure distribution at sideslip simulation with in-house FE model. (Image courtesy of Toyo Tires, Osaka.)

are stress and strength in carcass and belt, modal analysis, and prediction of steady-state traction and cornering forces.

More advanced FEA applications, being mentioned by few companies only, are

- Rolling resistance prediction and optimization
- Tire enveloping characteristics on short-waved obstacles
- Tire inflating process and tire–rim fitting including prediction of ease of mounting and dismounting
- Traction on water, snow, and compactable soil
- Estimation of friction energy dissipation, thermal maps, and chemical evolutions
- Tread wear simulation
- Impact and misuse analysis
- Coupled acoustic–structural analysis including excitation process of tread block contact on different ground textures
- Tire building process, including polymer synthesis

Clearly, some of these applications are nonstandard, or nothing more but fundamental research. Several manufacturers had mentioned that making such applications more reliable and cost-efficient will be an important activity in the near future. Other directions of development were said to be

- The integration of isolated FEA runs into an integrated standard procedure to automatically characterize all performance criteria and a further integration of this procedure into the CA process chain
- The improvement of material models for rubber compounds, fibers, and foams, taking simultaneously into account the nonlinear dependency on strain level, excitation amplitude, frequency, load history, and temperature
- Geometrical refinements, going hand in hand with a further increase in computing power
- The improvement of friction models, by trying to better understand thermo-viscoelasticity and taking into account nonstationary friction laws
- The development or improvement of ground models for mud, snow, and sand
- Crack initiation and crack arresting effects by damage simulation
- Simulation of the tire mixing/forming/building process with its consequences on material properties

[2–47] is an incomplete collection of papers dealing with modeling techniques and applications of FEA for tires. More application reports can be found in the journal [48].

18.3 MECHANICAL TIRE MODELS OF REDUCED COMPLEXITY, USING DEDICATED SOFTWARE

In contrast to "true" FE models, which are using a commercial or in-house FEA package, there are a couple of mechanical models under development using software written and optimized for the sole purpose of dynamic tire simulation [49–74]. Models of this kind show reduced complexity, compared to full FE models. Expressed somewhat simplified, the model structure in multipurpose FEA is described merely by the input files, whereas it is "hard-coded" in dedicated software. Such a program might better take full advantage of some tire-specific mechanical and numerical properties. Moreover, it can easily be exchanged across companies, without having available the same FE package at both places, and it can be coupled more easily to MBS suspension models. Using a true FE model would require a complicated co-simulation of FE and MBS solver.

As already stated, there is an ever-growing demand on multipurpose tire model solutions, which are simultaneously applicable in many important fields of vehicle dynamics. Reasons are quite obvious:

- Developing, or purchasing, one model rather than several saves time and money
- Parameterization is to be done only once for each tire size
- Inexperienced users don't need to select "the right" tire model separately for each application
- The model can be used in situations that are influenced by several aspects of vehicle dynamics

Typically, such optimized mechanical tire models use much less degrees of freedom (DOFs) than an FE-based model would. This choice of the number and kind of DOFs has to follow a compromise. The range of applicability, sometimes expressed (in an oversimplified manner) by a maximum frequency value, is to be compared with the implementation effort, the computing time, the numerical stability even in extreme situations, the accuracy, and the effort for parameterization.

As far as range of applicability is concerned, such tire models today are used for

- Handling studies on even and uneven surface
- Ride comfort
- Durability (by generating time-domain load histories)
- Tire misuse (running over deep potholes, say, at high speed)
- Study of tire dynamics interaction with suspension and brake control systems
- Noise, vibration, and harshness (NVH) studies, sometimes using linearized model variants

The tremendously growing computing power of ever cheaper personal computers (PCs) and workstations surely will result in the development and usage of more and more complex simulation models, further widening this range of applications. Let just one number illustrate this power: A standard PC (for about 500 US$) with quad-core central processing unit (CPU) can compute, in every millisecond, far more than one million arithmetic "basic operations" of the form $a = b + c \times d$ with 15-digit precision. In practice, however, there is a risk that non-appropriate numerical algorithms waste a large share of this power.

When specifying the tire model's DOFs, it seems to be quite natural to seek a reasonable balance between tire and suspension model complexity. This complexity can be expressed both in terms of computing time and in terms of model "granularity." In most cases, it will not make much sense to using a zero-DOF point contact tire model together with a highly detailed suspension model, which today typically reaches frequency ranges of 100 Hz and more. Nor is it reasonable to load a complicated FE tire model with only a simple two-mass oscillator.

One of the tire's structural stiffness properties that have the highest impact on the overall tire dynamics is the steel belt's longitudinal stiffness. This stiffness, for example, essentially influences the tire's enveloping characteristics when passing over short obstacles. On the other hand, the stiffness, being quantified by Young's modulus of the belt chord threads, together with the distributed belt mass, is one cause of the numerical stiffness of the resulting simulation model. Such a numerically stiff system can only be integrated either with an explicit solver and an extremely small step size or with an implicit solver. Essentially, the maximum time step h_{max} of an explicit solver is determined by the speed of sound in steel and by the smallest distance of two nodes (i.e., the mesh size Δs):

$$h_{max} \approx \frac{\Delta s}{v_{sound}}$$

The speed of sound of longitudinal waves in thin steel rods is close to 5000 m/s, and a typical mesh size will be less than 20 mm, to resolve even small obstacles. This would result in a maximum step size $h_{max} \approx 4$ μs. Such a value is unrealistically small, if simulations of several seconds or even minutes are to be carried out with the full vehicle.

The use of an implicit solver avoids such a numerical stability restriction. But, on the other hand, this requires to establish and to solve a large linear system of equations. This system is to be updated either in each time step or at least repeatedly after a small number of such steps. The coefficient matrix of the system of equations is closely related to the linearized system matrix of the model, and this matrix in turn is determined by the linearized mass, damping, and stiffness matrix of the mechanical model ([50,56]).

The structure of these matrices is the most important starting point to reduce computing effort. Apart from the geometry of the tread pattern, and some undesirable imperfections, the unloaded tire structure is "nearly" axisymmetric. This axisymmetry can help to considerably reduce computing time for linearization. Even more important, however, is the sparsity pattern of the system matrix (cf. Section 6.1.5). If this sparsity pattern is carefully taken into account in the solution algorithm, computing time can be reduced to only growing linearly with the number of DOFs rather than being a quadratic or even cubic function.

To gain any advantage of these special features, it turns out that tire models will have to perform the integration of their inner state variables by themselves. The numerical integrator becomes an inseparable part of the model software. This approach is followed by most of the commercially available, mechanically based tire models, like FTire™, CDTire™, and RMOD-K™ [71,75].

Being advantageous on the one hand and helping to efficiently solve the model equations, on the other hand, this local integration might turn out to be problematic for the MBS integrator. Most MBS packages are using, by default, complicated, step-size controlling integrators. The accuracy estimation, and thus the step-size control algorithm, might be very sensitively affected by such kind of hidden state variables. As a consequence, the interfacing between MBS packages and tire models plays a crucial role in tire simulation model development. This holds for physical aspects, for numerical aspects, as well as for implementation and coding aspects.

18.4 INTERFACING BETWEEN SUSPENSION AND TIRE MODEL

From the point of view of an MBS program, a tire is nothing but another force element, providing forces and moments acting on the rim, which are depending on all 12 state variables of the rim (Figure 18.5). Of course, the tire's force/moment response is influenced by road attributes, like height and friction coefficient, as well as by the previously mentioned inner states of the tire. In a detailed mechanical tire model, the auxiliary kinematical slip values (longitudinal slip, sideslip angle, and turn slip) are only used as additional output signals. Especially at low speed, tire response

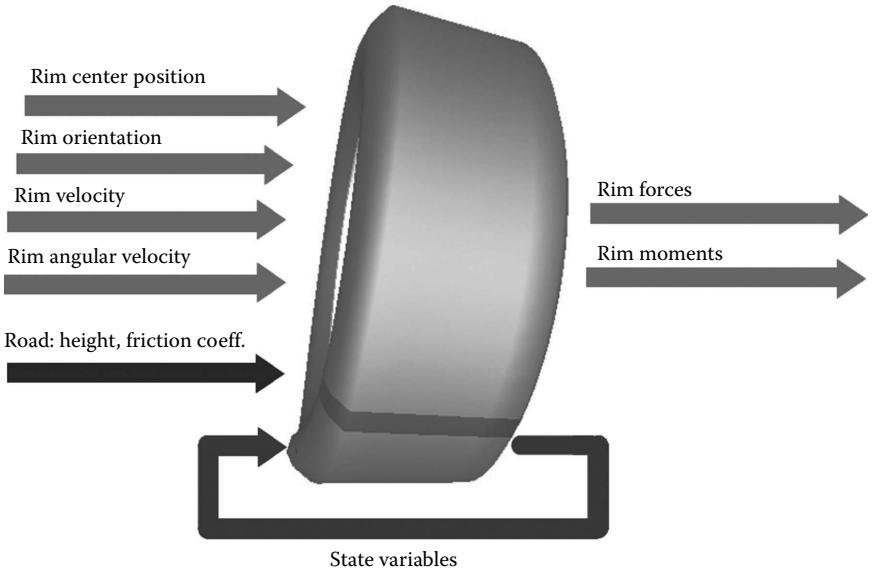

FIGURE 18.5 Tire model interface signals (without ground reaction forces).

cannot be expressed as a function of only these values but rather depends in a more complex way on all rim states at the same time.

If the road surface cannot be considered to be perfectly rigid, tire reaction forces in the contact patch also have to be provided. This might be of importance for heavy truck simulations or aircraft landing gear simulations. Moreover, any snow or soft-soil model to be connected to the tire model will require contact forces as input and react with ground geometry as output. Unfortunately, there is not yet any unified approach for the description of these distributed variables in the tire model program interface. This unification is the precondition to promote further development of soil and tire models independently.

Just like a real tire in the real world, the virtual tire needs to fit to different wheels—the "wheel" in the virtual world being replaced by the calling simulation software. Many users expect that they can use the same tire model together with many different packages capable of simulating motion or dynamics like (in alphabetical order) ABAQUS, FEDEM™, ADAMS™, CarSim/TruckSim/BikeSim™, dSPACE/ASM™, Dymola/Modelica™, MADYMO™, MATLAB®/SIMULINK®/SimMechanics™, MotionSolve™, PAM-CRASH™, RecurDyn™, SAMTECH™, SIMPACK™, veDYNA™, and Virtual. Lab Motion™, as well as on all important operating systems.

There is an activity going on that tries to unify and standardize the program interfaces between MBS packages and tire models—the standard tire interface (STI) of the TYDEX Working Group [76]. This standardized program interface mainly was meant to dock simple tire models with very few and "numerically harmless" states only to a wide variety of MBS packages. This is why the STI does not fit very well to models with many DOFs, being of numerical stiff nature. It is desirable to redesign this interface, using a time-discrete approach, as well as to modernize data formats and coding style.

Despite this necessary revision, such a standardized interface is very useful. It encourages users to compare and evaluate different tire models together with their respective vehicle model. A similar unification is needed for the program interface between tire model and road evaluation routine. The TYDEX Working Group defined a proposal for this task as well ([76]). As opposed to the tire/vehicle interface, this proposal never reached the necessary acceptance. A revision should include time-dependent moving surfaces (like test drums and test rigs with hydraulic actuators) and allow putting out reaction contact forces, to enable soft-soil modeling.

18.5 FREQUENTLY USED MECHANICAL TIRE MODELS

Clearly, it is difficult to gain a comprehensive overview on all tire models in use today. However, only a few are frequently mentioned in application reports and are commercially available. Mechanical models "below" FEs can be roughly categorized into 2D or 3D spokes models, 2D or 3D rigid belt models, and 2D or 3D flexible belt models. The so-called modal models follow a completely different approach.

Spokes models [52,66] can serve as a simple approach to resolve even short-waved road irregularities, if the excitation of structural tire vibrations is not of interest. The application range of this kind of models will be very much limited by this restriction. Spokes are nothing but unilateral spring–damper elements, connected at one end to the rim and occasionally being in sticking or sliding contact to the road at the other end. These spokes replace the stiffness of the tire structure and that of the tread at the same time. The spokes might be placed in the rim midplane only, to simulate pure in-plane events, or might extend over the tread's width as well.

In more realistic models, some kind of inertia is placed between the structure's elasticity and the tread's elasticity. The simplest models of this kind are the rigid belt models. Here, the heaviest vibrating part of the tire structure, the steel belt, is concentrated into one rigid body with three or six DOFs (2D or 3D case, respectively). The spokes are no longer connected to the rim but to this rigid body instead—looking more like a brush than like spokes now. Of course, only the rigid-body modes of the tire structure can be seen as vibrations of such a model. After all, the respective eigenfrequencies can reach the order of magnitude of 100 Hz, depending on the kind of tire.

Models of this kind are

- The author's brush and ring tire (BRIT model, [53,49,63], development abandoned)
- The low-end member of the RMOD-K 6-tire model family ([61,64,71], formerly commercially available)
- The RMOD-K 7 RB member of the RMOD-K 7-tire model family (successor of RMOD-K 6, commercially available)
- RTire (rigid-ring tire model, a "low-end member" of the FTire model family, [77], development abandoned)
- The member CDT20 of the CDTire model family (comfort and durability tire model, [72], commercially available). All model family members of RMOD-K 6 and CDTire have common roots, going back to Böhm [38]

The most widely used rigid belt model, however, seems to be the commercially available

- MF-Swift (short wavelength intermediate frequency tire model, [1])

In the strong sense, MF-Swift is not exactly a model of the type described earlier. In fact, it does not replace the tread by a brush of contact elements. Rather, the horizontal contact forces are not computed on the basis of brush displacements but by a Magic Formula approach. The reaction to short-waved road irregularities is improved by applying a special nonlinear road filter. A very similar approach is implemented in the

- Rigid-ring tire model of Mancosu et al. [70]

If in-plane or out-of-plane flexible belt vibrations are taken into account, both the frequency range and the accuracy can be extended tremendously. All models of this kind replace the rigid-ring belt model by a lumped-mass system. Typically, some 50–2000-point masses make up such a system; there is a smooth transition to coarse-mesh FE models. The masses are connected between each other and to the rim by a system of discrete, mostly nonlinear springs (or generalized elasticities),

and by certain damping elements. Several models also take into account internal forces along the inner liner surface normal, due to inflation pressure. As an example, the author's

- FTire (flexible belt tire model, [75,78–84], commercially available)
- FETire (coarse-mesh FE tire model, commercially available)

are discussed in the succeeding text. The latter is based upon

- DNS-Tire (dynamical nonlinear spatial tire model, [49,50,55])

Other models of this kind are

- The high-end member of the RMOD-K 6-tire model family
- The RMOD-K 7 FB member of the RMOD-K 7-tire model family
- The members CDT30 and CDT40 of the CDTire model family
- The model of Mousseau et al. [68], implemented as subsystem in ABAQUS

The RMOD-K 7 FB (flexible belt) model (Figure 18.6) is quite similar to FETire, both in model structure and in the level of detail.

Quite different from the earlier listed "lumped parameters" models are modal models, an example being the

- Flexible body tire model of Mancosu et al. [68]

This model describes the tire structure as a general flexible body within ADAMS. The actual shape of such a flexible body is defined by a linear combination of the first low-frequency mode shapes of

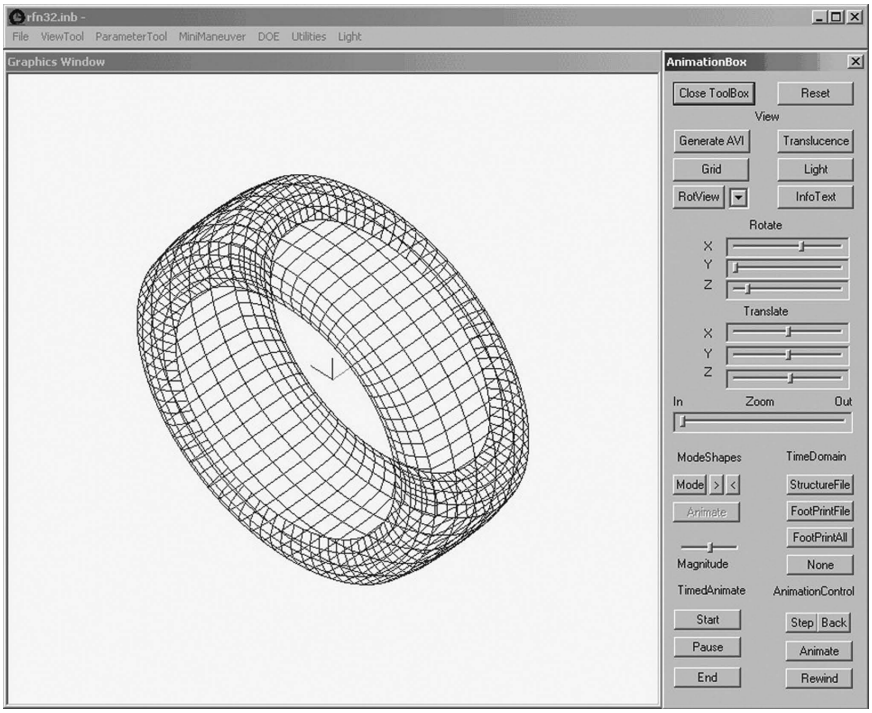

FIGURE 18.6 RMOD-K™ 7 pre- and postprocessor. (Image courtesy of IAT Dynamics GmbH, Berlin.)

the unloaded tire. The coefficients of this linear combination are the DOFs of the structure model. The road contact is established in a similar way than with the lumped parameters models. Such a flexible model requires the availability of a respective full FE model, to provide the modal data. An advantage of the approach is the exact reproducibility of arbitrary eigenfrequencies and related mode shapes. A disadvantage, however, is the intrinsic linearity of the structural stiffness, which will be violated for large displacements. As one consequence, the extremely small circumferential extensibility of the steel belt cannot be guaranteed when rolling over high obstacles.

18.6 FTire MODEL FAMILY

Being a typical representative of detailed mechanical tire models "below" true finite element method (FEM) models, the author's model family FTire (Flexible Ring Tire Model) will be discussed in greater detail here. FTire development started in 1998, using certain ideas and numerical concepts of the author's "coarse-mesh" FE model DNS-Tire [49,50,55] and the spatial nonlinear "rigid-ring/brush" model BRIT [53,59,63]. This first version of FTire has been essentially improved since then. It is available as advanced tire model of ADAMS, SIMPACK, and MotionSolve and is as well implemented into several other commercial and noncommercial simulation programs and as a blockset in MATLAB/SIMULINK. FTire is completed by a redesign of DNS-Tire (called FETire) and a compatible implementation of the 2002 version of the Magic Formula model, called HTire. FTire, FETire, and HTire together set up the FTire model family. FTire and FETire are presented in greater detail in the succeeding text.

18.6.1 Flexible Ring Tire Model

FTire is the most important member of the FTire model family. Like most other mechanical tire models, the kernel of FTire consists of two separate parts. The first part describes the tire's structural stiffness, damping, and inertia properties (the "structure model," for short). The second one is the tread/road contact model, comprising road evaluation and computation of contact pressure distribution and distributed friction forces (subsequently called "tread model").

The underlying idea of the structure model is to introduce only as few DOFs as necessary, to represent all tire properties that are relevant for the application. Main objectives during development had been

- Fully nonlinear 3D model, working in time domain
- Valid up to 150 Hz both in-plane and out-of-plane
- Both longitudinal and lateral wavelengths ≤ 2 cm, including sharp-edged obstacles
- Parameterization as easy and flexible as possible
- Usage of "easy-to-measure" static, steady-state, and modal properties in parameterization
- Computing time $\leq$5 to 20 times real time, and even real-time capable in an optimized version
- Valid for ride and handling, both in steady-state and dynamic conditions
- Simple and flexible interfacing to vehicle and road models

Potential applications of FTire comprise

- Tire models for passenger cars, motor cycles, race cars, trucks, trailers, ATVs, aircrafts, earth-moving machines, etc.
- All kinds of vibrations up to about 150 Hz, induced by tire/road contact
- Vibration excitation through tire imperfections
- Generation of load histories for durability simulations
- Traction and handling on extremely uneven roads

- Rolling resistance studies on even and uneven road
- Tire misuse in different conditions
- Steering torque amount when parking
- Assessment of highly dynamic suspension control systems
- Moving ground, all kinds of test-bench simulations
- Tire temperature and its influence on road friction
- Tread wear
- Pressure loss and tire puncture of standard and run-on-flat tires
- Sinkage and traction on soft soil
- Influence of elastic and viscoelastic rim deformation under large vertical and horizontal loads
- Air cavity vibration

Most model extensions, like thermal and wear model, tire misuse, tire imperfections, and flexible rim model, have been stimulated by users in vehicle and tire industry. Of course, there are still many effects that are of relevance in suspension design and optimization, but cannot be analyzed using FTire, like noise generation and hydroplaning.

18.6.1.1 Structure Model

The FTire structure model consists of several lumped-mass nodes (typically some 60–360), replacing the tire's steel cord. These nodes are connected to the rim and to each other by several nonlinear, inflation pressure-dependent stiffness, damping, and friction elements. Moreover, the nodes are subject to inflation pressure forces in radial direction and to the forces of the tread model. The part of the tire structure that is associated to one such belt node is called belt segment. Each belt segment has $4 + x$ DOFs (Figure 18.7):

- Longitudinal, lateral, and vertical displacement
- Rotation angle about the circumferential axis ("belt torsion")
- Bending in lateral direction, perpendicular to the circumferential axis (described by x independent eigensolutions of the bending beam equation)

The elastic coupling between belt nodes and rim is described by nonlinear force elements in radial, circumferential, and transversal direction, comprising springs, dampers, Maxwell elements, and spring-friction series connections ("elasto-plastic" elements). Figure 18.8 shows the radial force element of one single belt node; circumferential and transversal elements are placed analogously. Maxwell elements are used to describe the "tire stiffening" at higher rolling speeds, whereas the dry friction element replaces rubber hysteresis. The effect of this hysteresis on overall tire radial stiffness can clearly be seen in measurements, as well as corresponding FTire simulations (Figure 18.9).

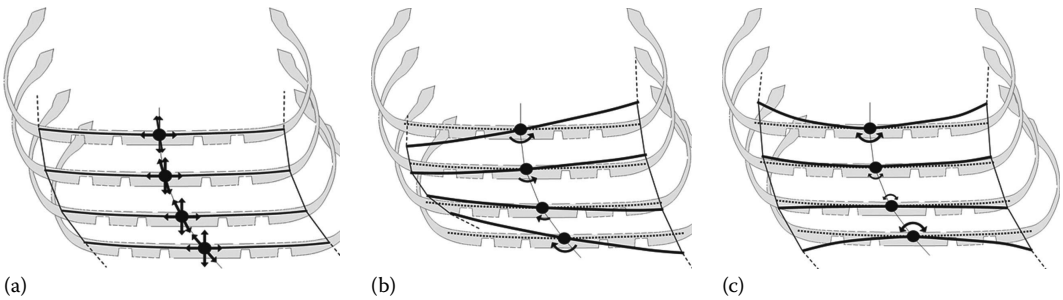

FIGURE 18.7 Belt segments' DOFs (degrees of freedom): (a) translation, (b) torsion, (c) lateral bending.

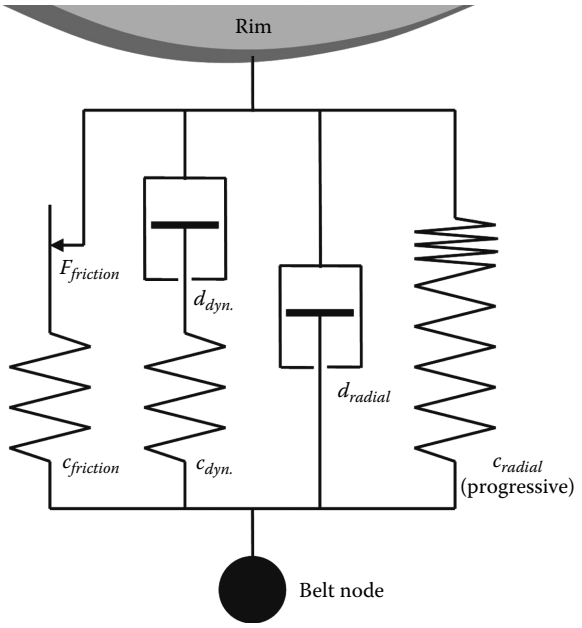

FIGURE 18.8 Radial force elements between each belt node and rim.

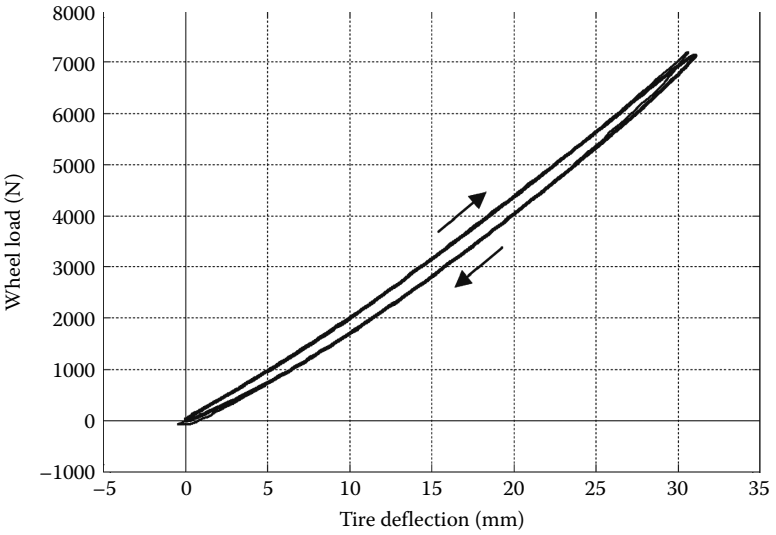

FIGURE 18.9 Measurement (bold line) and FTire simulation (thin line) of radial tire characteristic with hysteresis.

The radial stiffness elements are completed with unilateral stiff springs, located along the radial direction at the rim flanges. When tire deflection exceeds a certain value, these springs will come into contact with the inner side of the belt, thus generating a highly progressive radial stiffness characteristic (Figure 18.10). Depending on camber angle, this rim-to-belt contact can happen on one rim flange only, or on both at the same time. Rim-to-belt contact enables to simulate certain tire misuse situations.

In addition to the translational force elements, a torsional spring $c_{torsion}$ (cf. Figure 18.11) is located between each belt segment and the rim. These torsion springs serve as "elastic foundation"

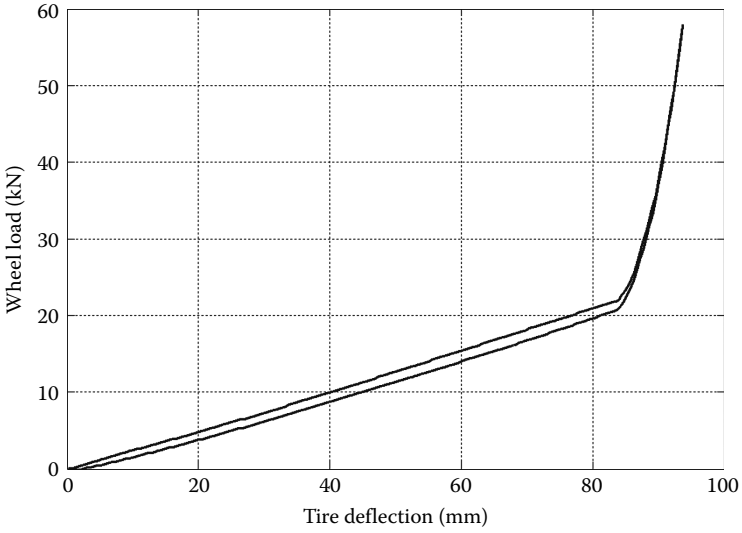

FIGURE 18.10 Progressive radial stiffness due to rim flange contact.

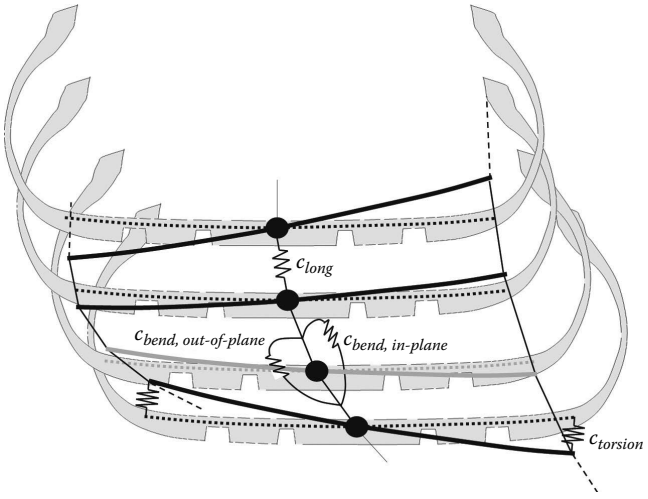

FIGURE 18.11 Belt flexibility stiffnesses.

of the belt segments' torsion DOF. Moreover, a bending stiffness acts against lateral belt bending. Together with the radial stiffness, they describe left and right sidewall stiffness.
The following additional force elements are connecting neighboring belt nodes:

- A very stiff translational spring c_{long} (Figure 18.11) providing the belt extension stiffness
- Another torsional spring, connecting the torsion DOF of two adjacent nodes (this spring is not depicted in Figure 18.11)
- A bending stiffness $c_{bend,in\text{-}plane}$ (Figure 18.11), connecting three nodes in line, acting against belt bending perpendicular to the lateral axis ("in-plane bending stiffness")
- Another bending stiffness $c_{bend,out\text{-}of\text{-}plane}$ (Figure 18.11), acting against belt bending perpendicular to the radial axis ("out-of-plane bending stiffness")

All stiffness values depend on the actual inflation pressure. The pressure is treated as "operating condition" and might be arbitrarily changed during a running simulation. This will not disturb the

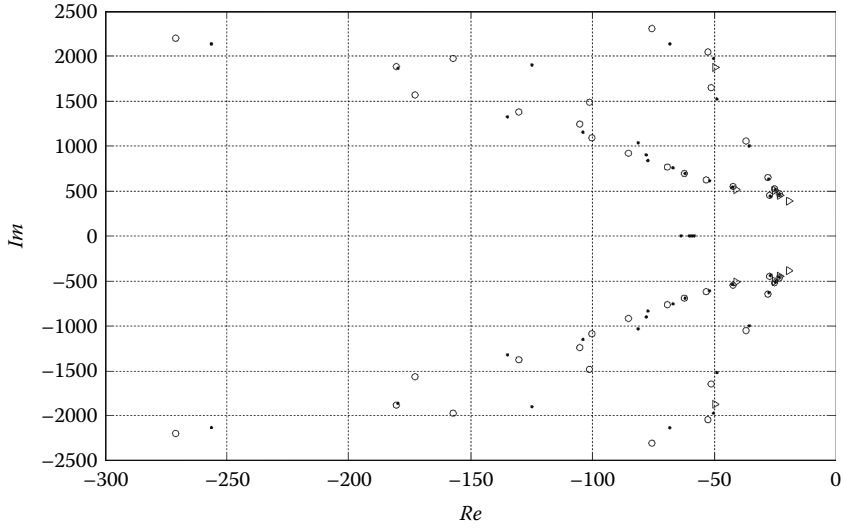

FIGURE 18.12 FTire eigenvalue location of linearized structure model: ▷, unloaded tire; ■, 20 mm deflection; ○, 40 mm deflection; real and imaginary axes are scaled differently.

integration process in any way. Moreover, actual inflation pressure depends on tire temperature, which is the output of the thermal model (cf. Chapter 6.1.3). Inflation pressure does not only affect the stiffness values but generates extra forces, which act on the belt nodes in radial direction. These forces generate a membrane tension, by expansion of the longitudinal springs. This leads to a further "stiffening" of the steel belt, similar to that one caused by the in-plane bending stiffness.

Figure 18.12 shows the first eigenvalues of the linearized structure model, for three different radial deflection values. The linearization technique applied here can be used to compute transfer functions under different operating conditions as well.

Several optional types of imperfections, to better match a real tire, complete the structure model. These imperfections comprise static and dynamic imbalance, radial and tangential nonuniformity, ply steer, conicity, and geometrical runout.

18.6.1.2 Tread Model

Between two neighbored belt segments, there are placed a certain number of massless contact and friction elements, to establish road contact (Figure 18.13). Their number, typically 30–100, is selected by the user, depending on the desired road irregularity resolution. These contact elements constitute the brush-type tread model.

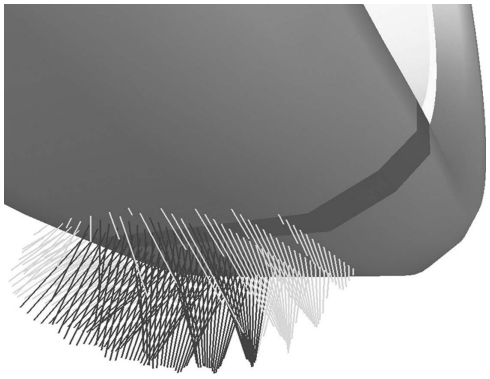

FIGURE 18.13 Distributed contact forces during parking maneuver.

The contact elements are placed in such a way that both the longitudinal and the lateral resolution, defined by the minimum distance of two elements, are optimized with as few as possible elements. The exact positions, in global coordinates, at which the contact points are attached to the distorted belt segments are smoothly interpolated, using the coordinates of the four nearest-by belt nodes, as well as the actual belt's cross-sectional geometry. Vice versa, the forces that are generated by the contact elements will contribute to the external forces of either of these four belt nodes. The actual belt's cross-sectional geometry is defined by all DOFs of the two nearest-by belt segments.

If the tread pattern is given in terms of a black-and-white bitmap file, the contact elements' lengths (i.e., the local tread rubber height) may be set according to this pattern. In Figure 18.14, the computed contact pressure of such a model is shown. Here, 120 segments and 50 contact elements had been used; the contact elements are placed along 25 parallel lines. This resulted in a tread resolution of approximately 0.5 × 12 mm for the large truck tire. Clearly, it would require a much larger number of contact elements to resolve more complicated patterns, like those of typical passenger car tires. However, as demonstrated in the succeeding text, computing time grows less than linearly both with the number of contact elements and the number of belt segments.

During any integration step, for each contact element, a rapid test is performed to check whether the element might have road contact. This test uses the position of the nearest-by belt element. If the test is passed, the exact distance of the contact element to the road surface is computed. Only if the contact element penetrates the road, the contact computation is continued. The next steps then are determining the road surface tangential plane, the element's normal deflection, the resulting normal force, the tangential sliding velocity, and finally the resulting friction forces.

The road tangential plane is computed individually for each contact element, by evaluating the road height in three different locations near the contact element. This is necessary to resolve even sharp-edged obstacles, like cleats and potholes. Road surface may depend on time, like it does for four-post test rigs and rotating drums. In that case, both normal and tangential surface velocities are taken into account as well.

The normal force is a function of deflection and deflection velocity, describing tread rubber compression stiffness and damping. These values, in turn, are determined on the basis of the tread rubber's Young's modulus, the tread pattern's net-to-gross ratio, the local tread depth, and more. Clearly, pressure distribution and thus normal force strongly depend on the tire's cross-sectional geometry, most of all on the belt curvature in unloaded condition as well as on tread depth as function of the lateral coordinate. This is why this geometric data can be prescribed in a very detailed way, by using lookup tables with smooth spline interpolation.

After having computed the normal force, in the next step the vector-valued friction force in the tangential plane is determined. Its amount is given by

$$\left|F_{friction}\right| = \mu(v_{slide}, p_{ground}, T_{tread}) \cdot F_{normal}$$

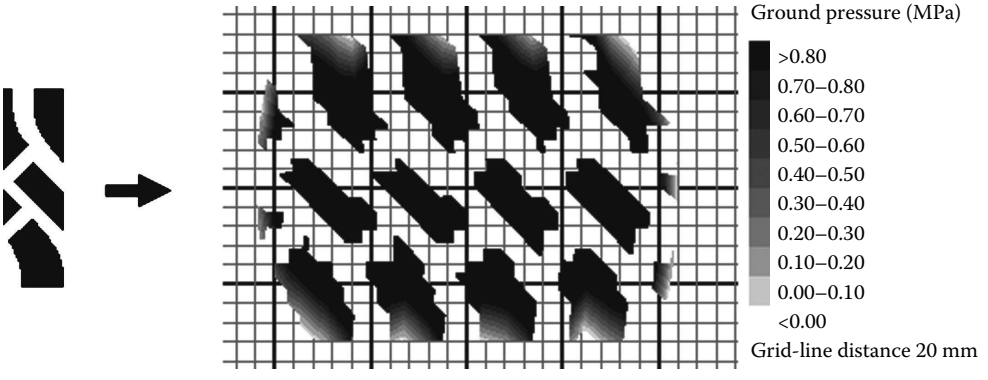

FIGURE 18.14 Tread pattern bitmap and resulting FTire contact pressure distribution.

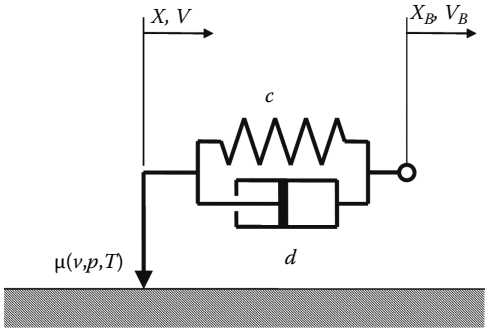

FIGURE 18.15 Contact element tangential displacement model.

and its direction is the negative sliding velocity direction. Sliding velocity is determined by using the vector-valued force equilibrium condition of friction force, elastic shear forces, and shear damping force of the contact element (Figure 18.15), in the road tangential plane.

This force equilibrium condition results in a differential equation for the element's tangential displacement. Depending on the nature of the friction coefficient as function of sliding velocity, this differential equation might have a discontinuous right-hand side or even might be locally unstable. The only way to numerically solve such an equation is using implicit integration. It turns out that this integration requires an additional discrete state variable, which memorizes whether the element, in the previous time step, was sticking to ground or sliding.

18.6.1.3 Thermal Model and Wear Model

The tread model is completed by a thermal model and a by model for tread wear estimation. The thermal model consists of

- The thermodynamic computation of the actual inflation pressure as function of filling gas mass, "cold tire inflation pressure," tire temperature, and actual interior volume.
- A heat generation and transfer model, introducing state variables for the temperature of the tire structure (including filling gas), and the individual temperature of each tread contact element. Heat generation and heat transfer are driven by the power loss distribution due to structural damping and dry friction on the road surface. As already mentioned, tread temperature in turn influences the road friction coefficients.

In the heat generation and transfer submodel, the tire is assumed being separated into three regions, having different thermal properties each (Figure 18.16): the tire structure (including bead, sidewalls, belt, and air volume), the tread without contact patch, and the contact patch. The following assumptions are made for the three different regions.

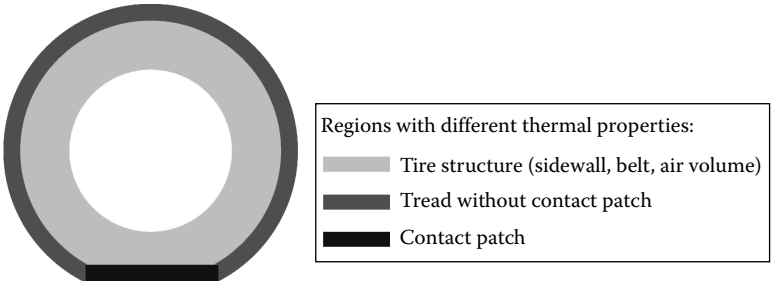

FIGURE 18.16 Regions of the thermal model.

The tire structure is described by one global temperature only. The product of rate of change of this temperature and the tire structure's overall heat capacity is balancing the sum of

- The power loss in all energy dissipating force elements in the belt and sidewall, excluding friction and damping of the tread elements.
- The heat that flows from the tire structure into the two tread regions. This heat transfer is determined by the respective temperature differences, multiplied by an appropriate heat transfer coefficient. This heat transfer coefficient is assumed to be independent on rolling speed.
- The heat that is transferred from the sidewalls into the air flowing around the tire. This transfer is determined by the temperature difference between tire structure and ambient air, multiplied by an appropriate heat transfer coefficient. This heat transfer coefficient is assumed to be strongly and nonlinearly dependent on rolling speed.

A distributed temperature field is assigned to the part of the tread outside the contact patch, providing one temperature value individually for each contact element. The product of rate of change of this temperature and the tread element's heat capacity is balancing the sum of

- The power loss in the tread element due to material damping.
- The share of the heat that flows from the tire structure into the particular tread element, as described earlier.
- The heat being transferred from the tread element to the air flowing around the tire. This heat transfer is determined by the temperature difference between tread element and ambient air, multiplied by an appropriate heat transfer coefficient. Again, this heat transfer coefficient is assumed to be strongly and nonlinearly dependent on rolling speed but has the same value for all elements not in contact to the road.

The contact patch is described in a similar way like the remainder of the tread, with the following exceptions: additional power loss due to road friction is taken into account, and heat is transferred to the road instead of the surrounding air. Heat transfer coefficient between tread and road is assumed to be independent on rolling speed.

As an example, Figure 18.17 shows the resulting temperature distribution in contact patch, after 2 s cornering at 4 kN wheel load, 4° camber angle, and 8° sideslip angle.

The tread wear model uses the friction power (which is the product of friction force and sliding velocity) and a functional relationship between friction power and wear rate. These variables are used to update, individually for each contact element, the actual local tread depth:

$$\dot{d}_{tread} = -f_{wear}\left(\left|F_{friction}\right| \cdot \left|v_{slide}\right|\right)$$

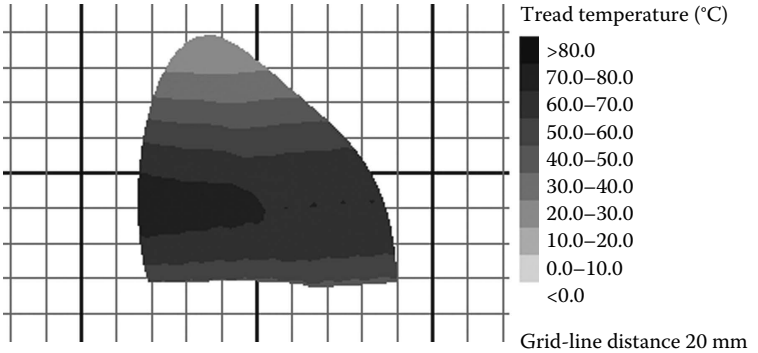

FIGURE 18.17 Temperature distribution in contact patch during cornering at 6° camber angle.

Accompanied by this reduction in tread depth, all tread properties that depend on tread depth will be modified respectively: compression stiffness and damping, shear stiffness and damping, heat capacity, and tread mass distribution. Thus, even imbalance and runout caused by a locked braking will be seen as result of a respective simulation experiment. Clearly, both the thermal and the wear model can be deactivated. Constant temperature and constant tread depth will be used in that case.

18.6.1.4 Model Data and Parameterization

As already discussed in Chapter 1, ease of parameterization is one of the most important objectives of any tire model, and this of course especially holds for FTire. Here, a clear distinction is made between data used in the model equations ("preprocessed data") and data to be supplied by the user ("basic data"). The underlying idea is to define basic data, which are as easy as possible to obtain and which at the same time yield complete information to determine the preprocessed data in a unique way.

This preprocessing requires the solution of several nonlinear systems of equations and will take some seconds of computing time. After successful completion, the resulting preprocessed parameters are appended to the data file. When using this data file the next time, it will be checked whether basic data have been changed in any way. If not, preprocessing phase is skipped, using the appended data instead.

Speaking about effort and cost of measurement-based parameterization, obviously it is hard to say whether certain parameters are "easy to obtain" or not. What is "easy" at one test facility might be difficult or impossible to get at another one. This is why there are different alternatives and combinations for some of the basic data, especially for that of the structure model. Moreover, not all data items are equally relevant for all applications. For example, in many cases, belt out-of-plane bending stiffness does not affect the tire response when rolling over a transversal cleat, and the friction coefficients nearly do not influence the radial tire characteristic.

Besides elementary data like tire and rim size, load index, speed symbol, mass, and rolling circumference, the structure model requires one out of several different combinations of static and modal data of the total tire. During preprocessing, the corresponding internal stiffness, damping, and inertia data are determined such that the resulting FTire model shows exactly this prescribed global behavior.

The following data enumeration only reflects one such possible combination. A comprehensive and up-to-date list of all data items can be found at www.cosin.eu. Tools to assist in parameterization will be discussed in Chapter 7.

A typical FTire parameterization might use

1. Tire size, load index, and speed symbol
2. Rolling circumference
3. Tire mass
4. Rim diameter and rim width
5. Tread width and tread depth as function of lateral tread coordinate
6. Distance of tread grooves to steel belt ("cap base height")
7. Tread pattern net-to-gross ratio (alternatively, tread pattern bitmap file)
8. Mean lateral belt curvature radius of the unloaded tire's cross section (alternatively, detailed spline data of cross-sectional geometry)
9. Young's modulus of tread rubber
10. Tread rubber adhesion friction coefficient for one up to three contact pressure values
11. Tread rubber sliding friction coefficient for two sliding velocities and one up to three contact pressure values
12. Footprint contour and footprint pressure distribution at different vertical loads, camber angles, and inflation pressure values

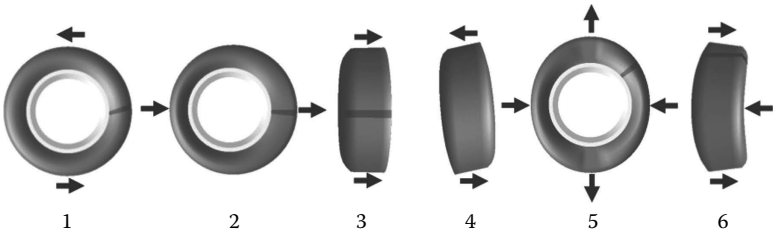

FIGURE 18.18 First unloaded vibration modes for use in FTire parameterization and validation.

13. Natural frequencies and modal damping of vibration modes 1, 2, 4, and 6 (cf. Figure 18.18), for an unloaded, inflated tire with fixed rim, for one or two inflation pressure values
14. Vertical force:
    a. Of standing tire on a flat surface, for two deflection values and one or two inflation pressure values
    b. Of standing tire, on both a transversally and a longitudinally oriented cleat, for one or two inflation pressure values
    c. Of standing tire at large camber angle, on both a flat surface and a transversally oriented cleat, for one or two inflation pressure values
    d. Of rolling tire on flat surface, for two different rolling speeds
15. Horizontal forces of a blocked tire, pulled in longitudinal or lateral direction until it starts sliding

18.6.1.5 Numerical Aspects and Implementation

As discussed in Chapter 4, tire models need to be very versatile with respect to the calling MBS software and the computing environment. For that reason, FTire is implemented in a mixture of Fortran 90 and C, making best use of both the still outstanding "number-crunching" features of modern and standardized Fortran and the system-focused C functionality like multithreading, library plug-in technology, interfacing to OpenGL graphics, data piping, and function pointers.

The interface to the calling MBS solver is organized in terms of a C++−, C−, and Fortran-compatible application programming interface (API) and compiled for all 32 and 64 bit Linux, Windows™, and Mac OS X™ operating systems. Seemingly arbitrarily many instances of the model can be simulated in parallel, in a thread-safe manner and without interfering with each other.

The numerical integration basically is performed in two steps for each time increment. This time increment might be of fixed or variable length. It will be automatically subdivided into smaller steps if rim rotation increment exceeds a certain angle threshold (1°, say). Thus, FTire can be easily linked to MBS software, which uses step-size controlling integrators and yields sufficient accuracy independent on rolling speed. As with all highly dynamic subsystems, the MBS solver's integrator should be configured to limit the communication interval between MBS model and tire model to a reasonable value. In the case of FTire, a value less or equal to 1 ms is recommended. Otherwise, the MBS model cannot accurately follow any high-frequency tire excitation. Just one number might illustrate this: the tire's total contact time to a cleat, ran over at a speed of 200 kph, is not more than 4 ms. Even though FTire accumulates the forces of the internally used smaller steps, the feedback due to the change in rim velocity is decisive as well.

In the first step of each local time increment, the contact processor is called. It will perform all necessary updates of the tread model-related state variables and compute the generalized forces that act between tread rubber and belt segments. The contact processor also calls the road evaluation routine, to determine location—and time-dependent road height and friction value modification. A simple program interface to these evaluation routines was chosen and implemented, to enable the connection of FTire to a wide variety of user-written and application-specific road implementations.

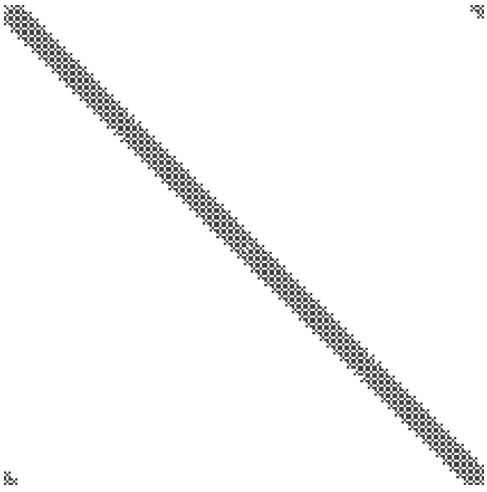

FIGURE 18.19 Sparsity pattern of stiffness matrix.

In the second step, the tire structure model is updated. The size of this system is determined by the number of the belt segments' DOFs. Integration is done by a slightly modified implicit trapezoidal scheme, which in turn is a special case of the widely used Newmark integrator. This integrator requires certain system Jacobian: the matrices of partial derivatives of acceleration variables with respect to position and velocity states. These matrices, being closely related to the linearized structural stiffness and damping matrices, are extremely sparse. Moreover, even though they depend on the actual values of the tire structure states, they can be computed analytically in only short extra computing time. Figure 18.19 shows the nonzero pattern ("sparsity pattern") of these matrices, which are the so-called cyclic band matrices, in the case of 80 belt segments. Only 3.9% of all matrix elements are nonzero. Even after the Cholesky factorization, this value is only about 7.8%. This is important because the number of arithmetic operations to solve the system is closely related to the number and location of nonzero elements of the Cholesky factor.

Figure 18.20 shows the resulting measured CPU time of FTire, in dependency on both the longitudinal contact element distance (which determines the spatial contact patch resolution) and the number of

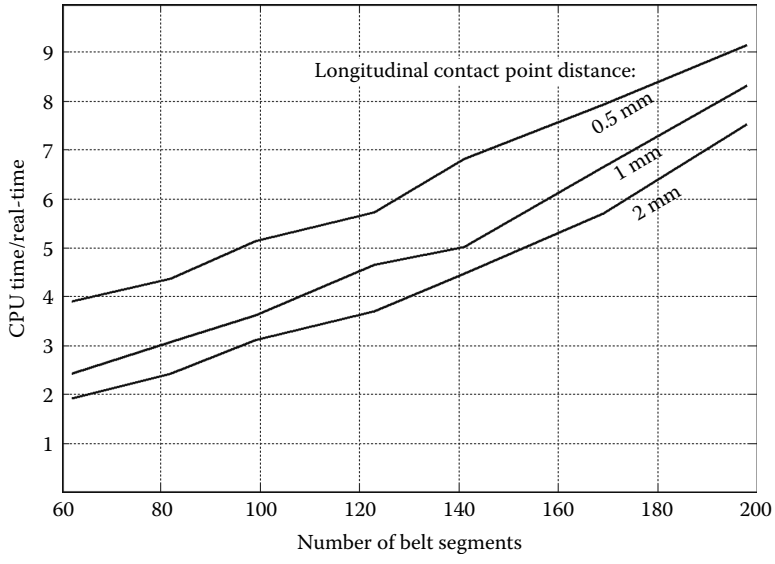

FIGURE 18.20 CPU time of FTire, depending on belt segments and contact patch resolution.

belt segments. Computations had been performed on a standard PC. The diagram shows the real-time factor (RTF), which is the quotient of CPU time to real time. Apparently, computing time depends nearly linearly both on the number of belt segments and on the number of contact elements. For a reasonable numerical tire discretization (60 belt segments and 1 mm contact patch resolution), FTire even can be optimized to reach real-time computation speed and consequently is available in a real-time version.

More about FTire, the complete documentation, required experimental data, and some applications and validation results can be found at [77].

18.6.2 FETire: Coarse-Mesh FETire Model

As mentioned earlier, FTire is completed with a "coarse-mesh" FE model (FETire) and a compatible Magic Formula 2002 implementation (HTire). All the members of this FTire model family, being of very different complexity, use exactly the same program interfaces. At present, FTire is understood as the most important member of the model family, because it seems to be the best compromise between application range, accuracy, and computing time for most vehicle dynamics investigations.

FETire, on the other hand, requiring about 50–100 times more CPU time than FTire, today is mainly used for

- Assistance in the parameterization of FTire
- Theoretical investigations on tire response to "nonstandard" excitations
- Studies about influence of tire design characteristics to handling and ride comfort properties

However, with ever-growing computing power and complexity of suspension models, FETire might be used more widely in the future, even with full vehicle models. RTF is about 200 at present, so 10 s multithreaded simulation of a full vehicle, completely equipped with FETire, would take about 33 min CPU time. This might be a tolerable effort for occasional or special investigations.

Similarly as FTire, FETire comprises a structure model and a tread model. The structure model (Figure 18.21) uses some 1000–5000 lumped-mass nodes, having three translational DOFs each

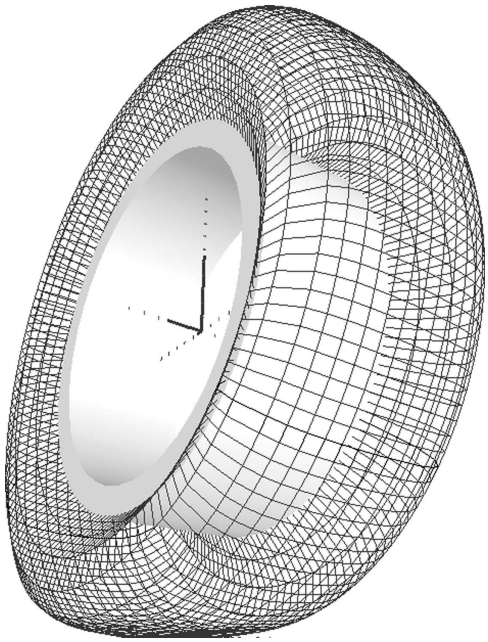

FIGURE 18.21 FETire: mesh of structure model.

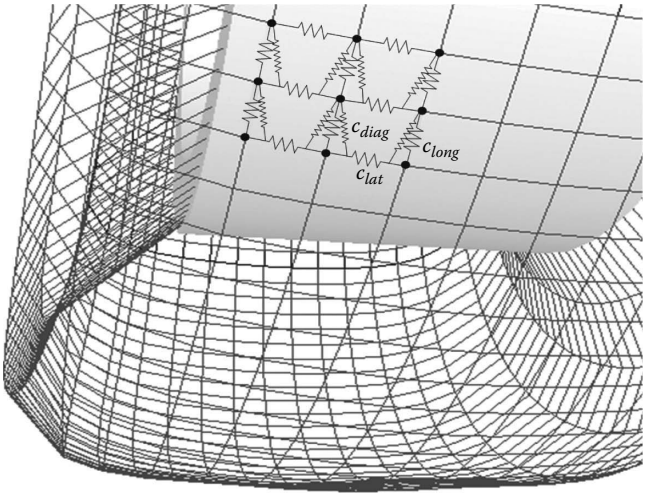

FIGURE 18.22 Springs replacing anisotropic membrane stiffness.

and being connected by a nonlinear network of springs and dampers (Figure 18.22). This coarse FE mesh is automatically generated, using the cross-sectional geometry of the unloaded and uninflated tire only. The distributed membrane stiffness and damping of the layered tire shell structure, consisting of carcass layers, belt layers, bandage layer, bead filler, etc., are computed during preprocessing. It is replaced by the earlier mentioned anisotropic, geometrically fully nonlinear spring and damper network (dampers not displayed in Figure 18.22). Stiffness and orientation of the springs are computed such that the resulting linearized stiffness matrix exactly coincides with the membrane stiffness matrix of the layered structure, separately in each cross-sectional region. By this procedure, for example, very stiff springs are created in the belt region, following the two belt cord direction angles (c_{diag} in Figure 18.22).

This membrane stiffness model is completed by the plate stiffness model, which uses discrete bending stiffness elements. These elements connect any three longitudinally and laterally neighbored nodes in the belt and sidewall region (Figure 18.23).

Finally, radial forces due to inflation pressure contribute to the nodal forces. They act along the shell normal direction, being in turn a nonlinear function of all neighbored node positions. Inflation

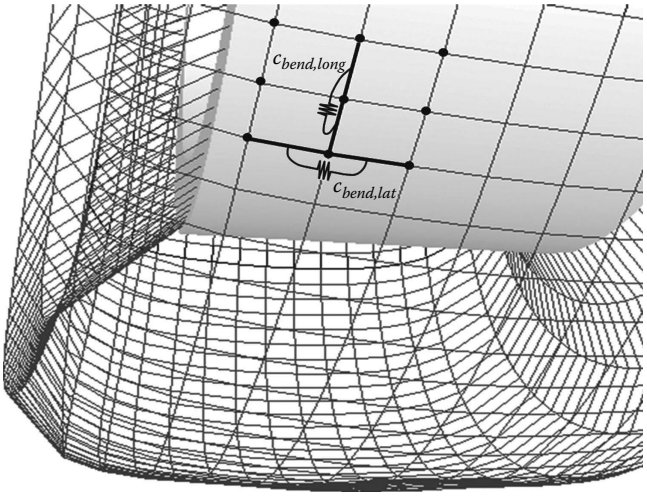

FIGURE 18.23 Longitudinal and lateral bending stiffness in shell structure.

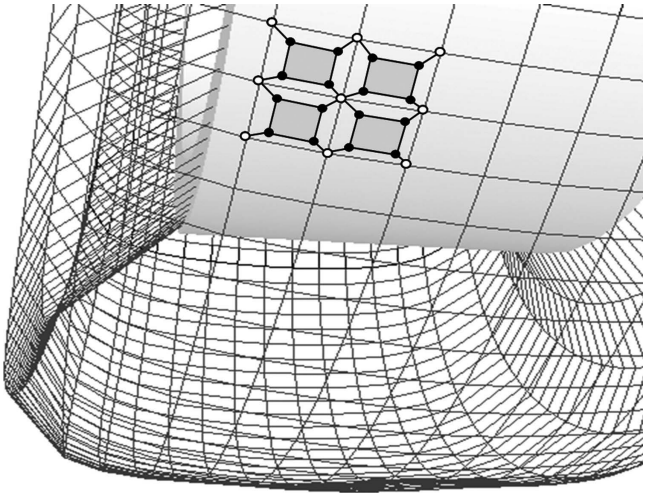

FIGURE 18.24 Tread nodes (●) with associated shell nodes (○).

pressure is computed as thermodynamic function of inner volume and air temperature. Inner volume, in turn, is a simultaneous function of all shell node positions.

Similarly as with FTire, a highly specialized Newmark-type implicit integration is applied to the nodal DOFs. This integrator takes full advantage of the sparsity pattern of the system Jacobian and exploits the fact that the tire structure undergoes largest strains in the vicinity of the contact patch only.

In contrast to FTire, the tread model consists of FEs that are equipped with mass (Figure 18.24). To each quadruple of neighbored shell nodes in the belt region (○), a certain number (4, say) of tread nodes (●) are associated. These tread nodes are coupled by a nonlinear radial and tangential stiffness each to four associated shell nodes. The treatment of road contact and friction is essentially the same as in FTire.

There are two special versions of FETire available. FETire/modal performs linearization and modal analysis of the unloaded tire (Figure 18.25). FETire/static is used for rapid nonlinear static load-case calculation of the loaded but standing tire (Figure 18.26). The latter uses mesh refinement near the contact patch. For rolling tires, this refinement would lead to an unacceptable computational overhead when shell nodes enter or leave the refinement region.

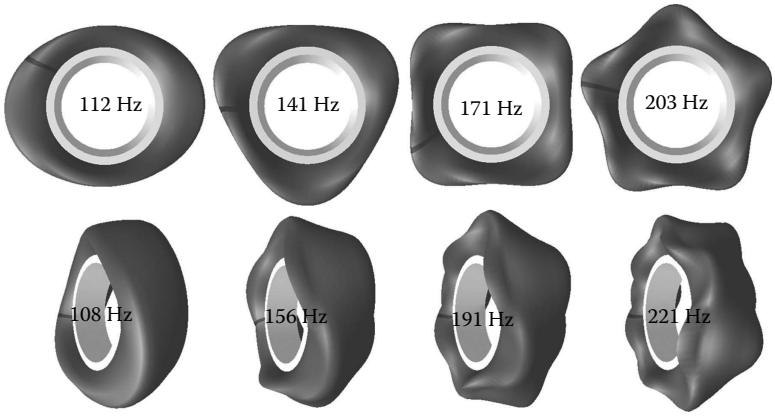

FIGURE 18.25 FETire/modal: first eight in-plane and out-of-plane bending modes of an unloaded passenger car tire. 5130 DOFs, 6 s CPU time for all modes.

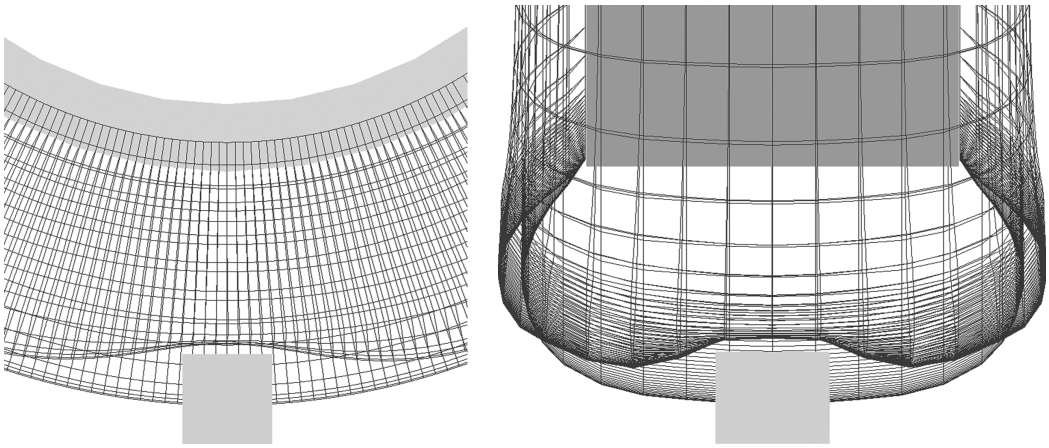

FIGURE 18.26 FETire/static: load-case "transversal cleat" and "longitudinal cleat." Deflection 35 mm, structural distortion compared to that of unloaded tire. 6750 DOFs, 92 s CPU time per load case.

Both special versions are optimized for CPU time and can be used to assist in FTire parameterization (cf. Section 18.7).

To compute stiffness data of the shell structure, FETire uses a parameterized description of the plies and all other important tire compounds. This description is implemented in terms of template files, called tire design data files. Each tire design data file qualitatively describes a certain class of tires, like passenger car tires and motorcycle tires. In such a file, the tire's cross section is separated into several regions, like bead core, apex, sidewall center, shoulder, and belt zenith. Associated to each region, there is a layer list, enumerating each layer together with its thickness, matrix rubber stiffness, cord stiffness (if any), and cord thread angle. Figure 18.27 gives an example of such a layer list.

A layer list does not contain numerical values but rather few variables only. The actual values of these variables, like belt cord density, belt cord direction angle, and layer height, together with a spline-based description of cross-sectional geometry and tread depth, finally are added to the tire design data file to describe a specific tire. To a certain degree, this approach allows a very simple extrapolation, starting from the data of one tire size to estimate the data of another, but similar, one.

Of course, the accuracy of FETire does not reach the one of detailed FE models. FETire is a proven compromise between accuracy and computational efficiency. It is of value as long as detailed FE models cannot yet be used, for many different reasons, in time-domain nonlinear vehicle dynamics simulations.

18.7 PARAMETERIZATION TOOLS

Parameterization of any tire model, as mentioned earlier, always is a delicate task. Basically, there are five different procedures conceivable:

1. Direct determination of parameters by using appropriate measurements
2. Usage of a detailed FE model, together with a "condensation process," to directly compute the parameters
3. Usage of measurements of the global tire behavior to estimate the model parameters by means of least squares approximation ("parameter identification")
4. Performance of simulations with a detailed FE model, to generate "virtual measurements," subsequently used for parameter identification as in (3)
5. Usage of a well-validated data file and application of certain "extrapolation formulae" to estimate the tire data of another size, "not too far away" from the validated size

Clearly, due to the different nature of model parameters, none of these five procedures will be used unadulterated. Some data will always be measured directly, for example, simple geometric properties that are only depending on tire size or on tread rubber friction coefficients. Some other data can never be determined directly, for example, a property as artificial as "the stiffness matrix coupling two adjacent belt segments." For the FTire model family, as an example, tools that assist with procedures of types (3), (4), and (5) are available (cf. Figure 18.28).

The first one, called FTire/calc, performs modal analysis using FETire/modal as well as a series of static load-case calculations with FETire/static. These calculations are controlled by a simulation script and run fully automatically. They compute the static tire forces and moments under varying conditions, like

- Vertical deflection on a flat surface
- Vertical deflection on a transversally and a longitudinally oriented cleat
- Vertical deflection with different camber angles on flat surface and on cleats
- Lateral wheel displacement, at a high friction value
- Longitudinal wheel displacement, at a high friction value
- Wheel rotation about vertical axis, at a high friction value

All these computations are performed with several different deflection values and inflation pressures. The resulting static data are completed by the first resonance frequencies and modal damping values, computed with FETire/modal. Here, the same tire design data is used as with FETire/static. Some of the results are used to generate an FTire input file, and some others to validate the respective FTire model. A full cycle of an FTire parameterization with FTire/calc takes less than a minute CPU time.

FTire/fit, the second tool, assists with several procedures of type (3), completed by some handy routines for preparation and preprocessing of experimental data. It provides optimization routines that aim to minimize the least squares distance between measurement data and respective simulations with FTire, for static load cases, for steady-state rolling conditions, as well as for cleat tests. In addition, FTire/fit assists in repeatedly and rapidly performing script-based validation runs and generating detailed result reports.

FTire/fit is not meant to be a "black-box tool," which provides results by few mouse clicks only. Rather, it requires a certain expertise to select and prepare appropriate experimental data and to decide what parameters should be determined by what kind of tests and in what sequence. Moreover, it requires expertise as well to assess whether or not the overall identification result is optimal. As with all applications of computer optimization, there is no guarantee at all that the global optimum really was found. This introduces uncertainty about the quality of the result, which only can

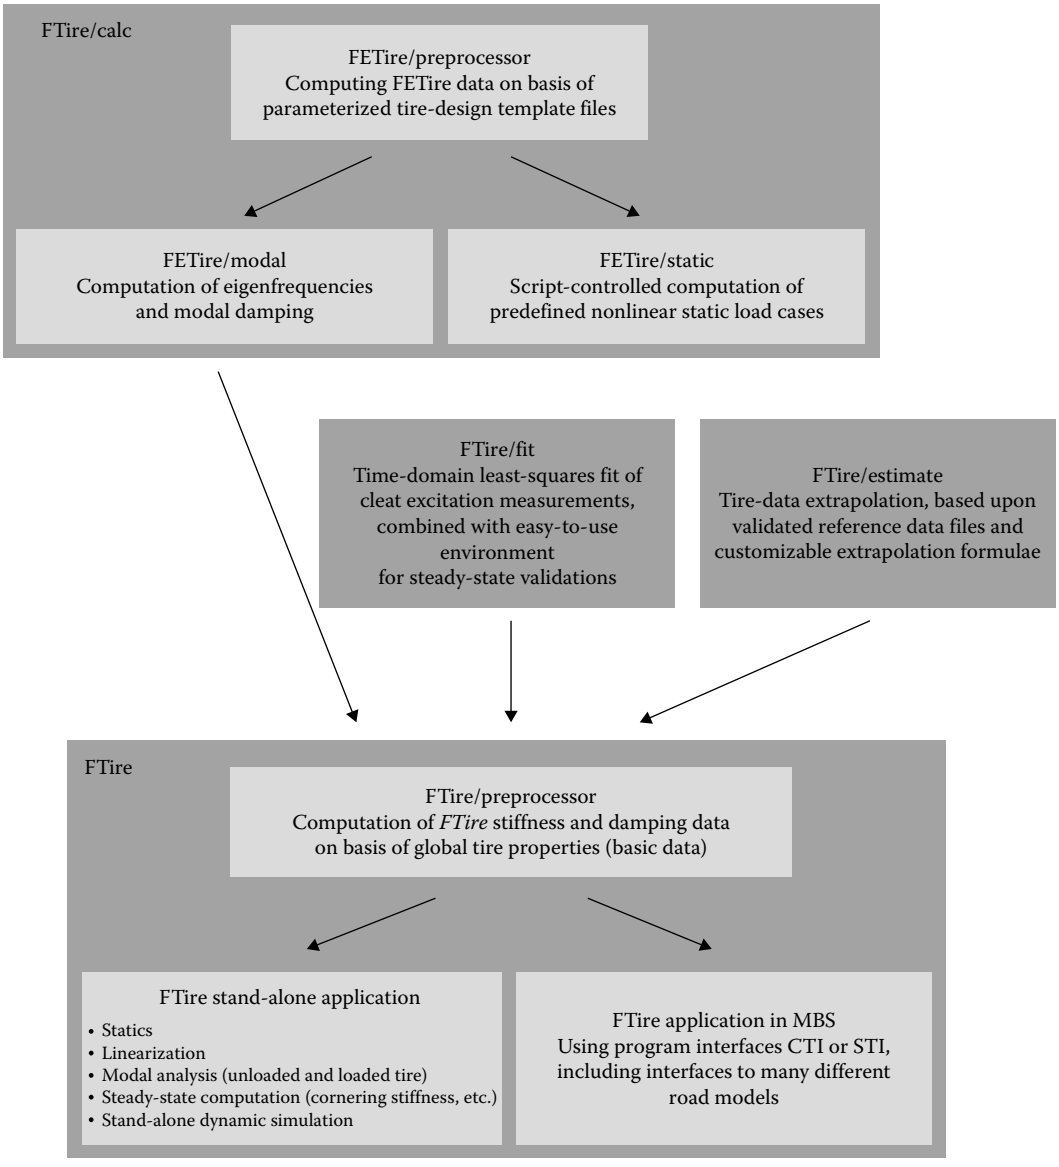

FIGURE 18.28 FTire parameterization tools.

be overcome by having experience with previous similar computations. It seems to be logical to only use a standardized measuring procedure and to use FTire/fit always in the same way in conjunction with this procedure. This is the best way to achieve comparable FTire data for different tires.

Finally, there is a third tool (FTire/estimate, Figure 18.29) available that implements a procedure of type (5). FTire/estimate uses a well-validated FTire data file, representing a whole family of similar tires. Using this tire, it relates its stiffness and modal data to the respective values of other tires in the family, which might differ in section width, aspect ratio, rim size, mass, maximum load, maximum speed, radial stiffness, or nominal inflation pressure.

This relation is described in terms of functional dependencies: The changes in static and modal tire data are functions of the change in one or more influence parameters. These influence parameters are tire section width, tire diameter, sidewall height, tire mass, rated maximum load, rated maximum speed, radial stiffness, and nominal inflation pressure.

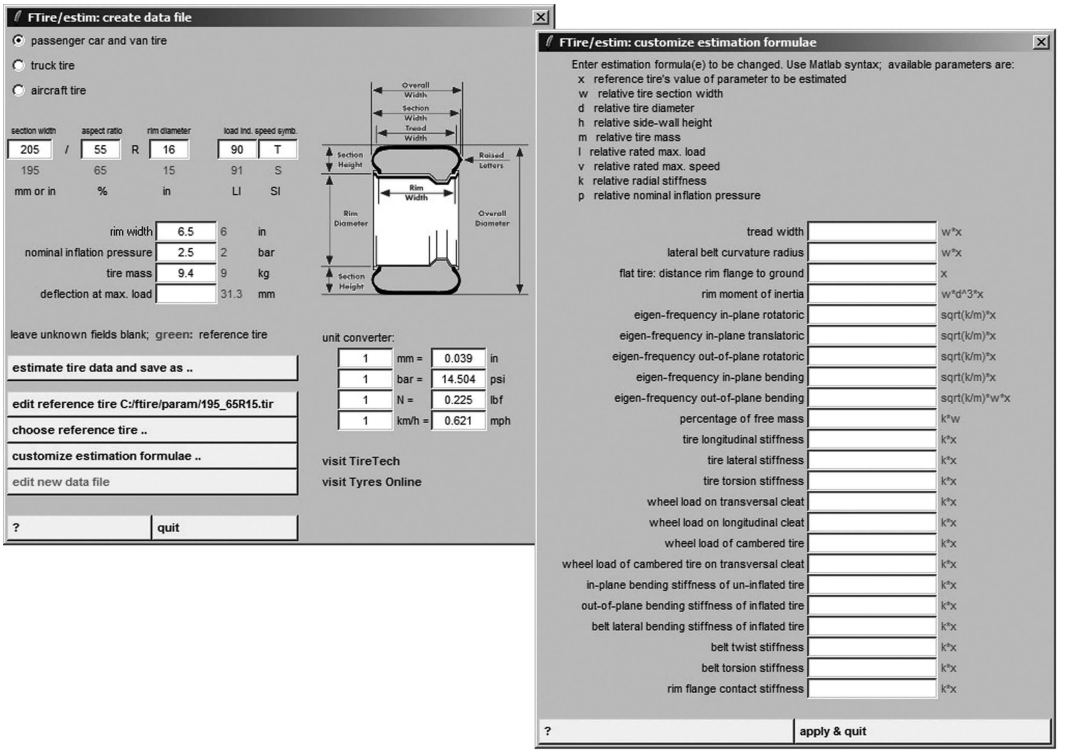

FIGURE 18.29 FTire/estimate user interface (GUI) showing default estimation formulae.

Clearly, these data items are not all independent on each other. The estimation program provides some of them for completeness only. For example, it might be more natural to express the dependency of an eigenvalue on mass than on tire size, even if both will change simultaneously. In any case, it is sufficient to use only the most relevant influence parameters in the formulae.

The influence functions used by default are based upon simple mechanical analogy considerations. However, they can be easily customized. A user might wish to enhance his copy of FTire/estimate, based upon his experience, in the sense of an expert system. Clearly, this experience can be easily completed by studies with detailed FE models or by evaluating respective measurements.

19.1 INTRODUCTION

The pneumatic tire ("aerial wheel") was conceived by R.W. Thompson (1845) and then reinvented by J. Dunlop (1888) as a composite material structure. More than 200 different raw materials are used to build a modern pneumatic tire. The pneumatic tire (briefly called tire in the sequel) is truly one of the very first successful applications in the field of composite materials [1].

The mechanics of pneumatic tire presented in Chapters 17 and 18 can be understood better if proper attention is paid to the chemical and physical properties of the materials that the tire is made from. For such a better understanding, also the construction process, the details on tire inner structure, and the safety assessment tests are to be taken into account.

The specific literature on tire materials, structure, and manufacturing is relatively limited, the up-to-date information can be found on the Internet; this is the reason why many references to web pages have been introduced at the end of the chapter [2].

In the chapter, the radial pneumatic tire will be considered [3]. The characteristics of materials, manufacture, and testing of other tire types (bias, diagonal) are not much different from the ones of the radial tire.

In the first part of the chapter, the materials used to build a pneumatic tire are presented. In the second part of the chapter, the manufacturing process is introduced. In the third part of the chapter, the tire's inner structure is analyzed. In the fourth and last part of the chapter, the tests that are performed to deliver a tire are listed and commented.

19.2 MATERIALS

The pneumatic tire is made from many components, both reinforcement materials and compounds (Figure 19.16). Compounds are specific blends of materials developed to achieve the specific performance required. The main families of materials in the pneumatic tire are

- Rubbers
- Fillers (carbon black, silica)
- Curing system (sulfur, accelerators)

TABLE 19.1
Typical Material Composition of a Pneumatic Tire (Reinforcement Excluded)

Component	%	Type
Rubber	50.0	Rubber
Carbon black	17.5	Filler
Silica	17.5	Filler
Oil	10.0	Processing aid
Resins	2.0	Enhancers of different properties
Antioxidant	1.0	Protective system
Wax	1.0	Protective system
Zinc oxide	2.0	Activator of the curing system
Stearic acid	0.8	Activator of the curing system
Accelerator	0.5	Curing system
Sulfur	0.8	Curing system

- Protective system (antioxidant, antiozone, wax)
- Processing aids
- Steel and textile cords

A typical material composition of a tire could be the one reported in Table 19.1 (the reinforcement cords are excluded). Obviously, before and during the tire manufacture [4], special control tests are performed in order to monitor all of the parameters that characterize each material of the compound and the compound itself.

19.2.1 Rubber

There are many kinds of rubber either natural or synthetic involved in the manufacture of the tire [3,5].

19.2.1.1 Natural Rubber

The natural rubber (NR) is obtained from the sap-like extract (latex) of *Hevea brasiliensis* (Pará), a tall tree that is grown in zones near the earth equator (latitude ±20°) where the rainfall rate is about 1500–2000 mm/year. Such zones are Amazon rainforest, Central America, Central Africa near the Atlantic Ocean, India, and Southeast Asia. Natural rubber is mostly composed by *1,4-cis-polyisoprene* (C_5H_8 is the monomer). Natural rubber was scientifically discovered by C.M. de La Condamine in 1745, although C. Columbus noted rubber balls used by native Americans (rubber was used since 1600 BC by Mesoamerican people). Natural rubber resists more to stress and has less hysteresis than synthetic rubbers. Several types of natural rubber are identified and used [1].

19.2.1.2 Synthetic Rubber

Since about 1945 synthetic rubber was employed for tire manufacturing. *International Institute of Synthetic Rubber Producers (IISRP)* provides the classification of synthetic rubbers [6].

The more used synthetic rubber is *styrene-butadiene* (SBR), which has a good hysteresis that implies a good grip. *Polybutadiene* (BR) has a good fatigue and wear resistance. *Butyl* rubber, and *halobutyl* in particular being impermeable to gases, is used in the inner liner of the tire to prevent air leakage. Obviously, the rubbers have to be mixed with the other components in order to obtain a balance of desired material properties.

Mechanical properties of rubbers are greatly influenced by the *glass transition temperature* T_g, which identifies primarily the viscous behavior of the material. Information on T_g can be found in [7].

19.2.2 Fillers

Fillers are very important parts of the tire rubber compounds, because they offer abrasion resistance and reinforcement. Fillers are solid granular materials.

19.2.2.1 Black Fillers

Carbon black (obtained from the combustion of natural gas or hydrocarbons) is the more used filler. Carbon black was added to rubber since about 1915. Carbon black is made of particles of fine size. Its use is devoted to improve fundamental properties such as mechanical resistance, elastic modulus, tear strength, abrasion resistance, UV rays resistance, and hardness.

The technical specifications of carbon black [8–11] include structure, particle size, particle porosity, and overall physical–chemical nature of particle surface. These factors strongly influence the degree of reinforcement and also cure rate [3] (for cure rate and curing, see Section 19.2.3). There are several grades of black fillers ([1] ASTM 1765).

According to the production cycle, the carbon black can have different pH: acid black fillers tend to retard the curing process. On the contrary, alkaline black fillers (made by furnace processing) produce a rate-enhancing effect on curing. If black filler acidity is wrongly tuned, it can give rise to scorching (i.e., vulcanization starts too early).

The particle size of the filler has a primary role. The smaller the particle size the higher the reinforcement, but the poorer the process efficiency because of the longer time needed for dispersion and the greater the heat produced during mixing. Such an occurrence can be explained thinking of black filler that is dispersed into the voids among rubber chains. The finer the black filler, the better the positioning into the voids (and more difficult the dispersion). The finer the dispersion, the higher the modulus of elasticity of the rubber.

19.2.2.2 Nonblack Fillers

The most powerful nonblack filler involved in tire manufacture is silica, because of its small particle size and complex aggregate structure. Silica precipitates impart the highest degree of reinforcement to rubber among all the nonblack particulate fillers. Silica is employed for manufacturing the tire tread, due to wet grip improvement and low rolling resistance. Additionally for off-road tire, it has proved to guarantee the reduction of chucking (a special type of damage of the tread in which small pieces of compound are removed) and tear resistance.

The silica (obtained from special sand) is more expensive than carbon black but produces less rolling resistance and higher grip at low temperature [3,5].

The reason why silica was never used as the primary filler was a lack of compatibility between silica and the other polymers used in the tread (actually special bonding agents—silane—are to be used); in addition silica does not disperse very well during the mixing process. The silane coupled with silica is also useful in improving the abrasion resistance of silicas up to levels of carbon blacks and promotes their use in the treads.

Silica can also be used in blend with carbon black.

19.2.3 Curing System

One of the most essential components of any tire compound is sulfur, which allows the rubber to be vulcanized. Vulcanization was (accidentally) discovered by C. Goodyear in 1839. During vulcanization the sulfur creates cross-links between the carbon backbones of polymer chains when the compound is heated. Cross-linking increases the strength of the rubber by preventing polymer chains from slipping one another. In order to speed up the vulcanization process, ingredients called accelerators are used together with sulfur; the most common accelerators are sulfenamides. Zinc oxide and stearic acid are also used as activators of the curing system: they react with the accelerator so that a "sulfurating complex" is formed. The "sulfurating complex" creates the cross-link network [1].

Figure 19.1 shows a schematic representation of polymer chains before and after vulcanization.

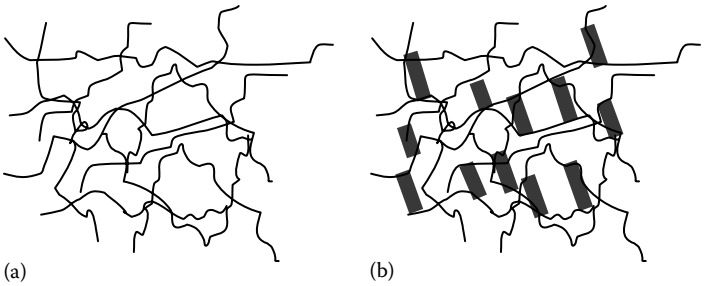

FIGURE 19.1 Schematic representation of polymer chains before (a) and after (b) vulcanization. During vulcanization, sulfur creates cross-links between the carbon backbones.

Sulfur tends to form chains composed by its own atoms (as carbon and silicon do). The cure sites on the rubber molecule can be defined as the sites that are attractive to sulfur atoms. At each cure site on the rubber molecule, a sulfur atom can attach itself and from there a sulfur chain can grow until it reaches a cure site on another rubber molecule. The sulfur bridges can be from 1 up to 10 atoms long, differently from typical polymer in which the carbon backbone is many thousands of atomic unit in length.

19.2.4 Protective System

There are several indices that describe the service life of the rubber products: one of these is the aging index [12–14]. Practically, the aged rubber is more brittle than the nonaged one.

The kind of elastomer is the main factor for aging property. The more the backbone of the elastomer is saturated, the better the aging properties can be expected. Actually, the environment brings the tire in contact with air, and the ozone concentration in the atmosphere rapidly reacts with the carbon elastomer mainly in the backbone unsaturated zones. In general, unsaturated polymers are susceptible to thermal or ozone oxidation. Thus antioxidants and antiozonant are needed to extend the life of the product. Heat and relatively high temperature enhance oxidation. A rise in working temperature of 10° doubles the rate of the unwanted process. Flex cracking is a common mode of fatigue failure in the rubber compound. Flex cracking involves not only mechanical fatigue but also oxidation, which is accelerated by heat generated during the flexure cycle. The higher the rate of flexure, the greater is the heat generation and the worse is the fatigue life of the rubber compound. Conversely, oxidation reaction is accelerated by stress, stretching, and bending of the elastomer. There is a critical elongation below which cracks do not form. Such a critical elongation is 5%–10% of maximum material elongation.

The chemical reaction of rubber with ozone is very fast. Due to this short time, the ozone cannot diffuse inside the tire and remains on the surface. The antiozonant protectors initially sacrifice themselves reacting with ozone, but this reaction produces a protective surface layer that avoids the ozone to continue deteriorating the tire surface. Paraffinic waxes are also widely used as protective agents: they bloom on the surface of the compound to form an inert film.

UV rays deteriorate rubber. In the compound, some anti-UV ingredients are commonly added; they can be simply carbon black or UV stabilizers. The UV light reacts with the surface creating small cracks that form a typical pattern called *crazing*. The ions of iron and copper (coming from steel belt and bead wire) and the ions of manganese and cobalt (in the compound) even if present in small amounts give a great contribution to rubber oxidation. They affect the breakdown of peroxides, so they produce a further acceleration in the oxygen attack. The most sensitive rubber to this phenomena is the vulcanized natural rubber.

19.2.5 Processing Agents

Natural rubber has to be subjected to mastication, and the efficiency of such a power-consuming operation can be increased by adding *peptizers*. Upon a certain temperature, peptizers fasten the

rate of breakdown of rubber chains (common peptizers are thiophenols and diphenyl-disulfides). Peptizers are used to make the rubber soft and tacky, to facilitate mixing operation, especially if a big amount of carbon black is added.

Many rubber types are involved in the compound, and they need to have the same mechanical behavior during the mixing process. To fulfill such a condition, different rubbers have to adapt themselves to the processing cycles. To facilitate such an adaptation, specific *plasticizers* are added. A great influence of such ingredients can be seen on the diene-hydrocarbon rubbers (SBR, IR, BR); for such materials hydrocarbon oils are preferably used. These oils (generally known as softeners) decrease the polymer viscosity and reduce hardness and low-temperature brittle point of the cured product. Three main types of softeners exist: aliphatic, aromatic, and naphthenic. The aromatic oils have been banned and replaced by grades with lower content of PAH (polycyclic aromatic hydrocarbons); the naphthenic grades are also widely used.

Natural rubbers exhibit the phenomena of tack (i.e., when two clean surfaces of masticated rubber are brought in contact, the two surfaces strongly adhere one to each other). Synthetic rubbers in general show low tackiness, so that it is necessary to add *tackifiers* (hydrocarbon resins are widely used). A proper tack is essential during the tire manufacturing.

19.2.6 Resins

Different families of resins are used in compounds for tires. Resins used in the tread compound are mainly grip enhancers: they are essential for increasing hysteresis while keeping the elastic modulus unchanged. Phenolic resins are often used in compounds for bead filler, carcass, and belts.

19.2.7 Steel and Textile

19.2.7.1 Steel

Steel cords are the fundamental structural components of tire. Typical steel involved is the ASTM 1070 steel tire wire; a usual value for tensile strength is 2750 MPa. There are two kinds of steels, one for the belts and one for the bead; their chemical compositions are reported in Table 19.2.

The two steels in Table 19.2 are similar, and little difference on the carbon content can be found.

The steel wire is produced by wire drawing, a cold deformation process. The steel wire passes through a series of dies. The traction is produced by *capstans*. Starting from a rod of 5.5 mm diameter,

TABLE 19.2
Average Chemical Composition of Steel for Belts and Beads

	Steel Belts	Bead Wire
Carbon	0.67–0.73%	0.60% min.
Manganese	0.40–0.70%	0.40–0.70%
Silicon	0.15–0.03%	0.15–0.30%
Phosphorus	0.03% max.	0.04% max.
Sulfur	0.03% max.	0.04% max.
Copper	Trace	Trace
Chromium	Trace	Trace
Nickel	Trace	Trace
Coating	66% Copper	98% Brass
	34% Zinc	2% Tin

wires are obtained whose diameter is a few hundredths of a millimeter. As the cord is 1.2 mm of diameter, it is brass plated and then further reduced in diameter.

Two kinds of wire drawing processes exist, dry or in bath. They differ either for the kind of lubricant or the way the capstan acts. A maximum of wire deformation is accepted for each die; the wire size has to be reduced by means of a series of passages in order to avoid nano-defects inside the metal material lattice. Also microscopic and macroscopic defects like the Chevron creek or broken point (which require welding) are not accepted by tire manufactures. The more the steps of wire deformation, the more the ultimate tensile stress and the less the elongation at rupture.

The wires have to be submitted to brass coating to let rubber adhere firmly to steel. Actually rubber does not bond spontaneously to steel. Brass (copper more exactly) and sulfide create protuberances on the steel wire that help rubber adhere to the wire itself.

Adhesion can sometimes be degraded if copper sulfide is formed on the rubber joining the wire. This implies a weak brittle bound with the underlying brass-plated steel cord and is prejudicial to good adhesion. To avoid such problem, the proper concentration of ingredients in the compound must be used; concentration of copper in brass, as well as the thickness of brass coating, is also crucial to get a good adhesion. Wires are used to produce cords. For instance, a $3 + 6 \times 0.22$ cord is composed by three filaments warped with additional six wires with a diameter of 0.22 mm [1].

19.2.7.2 Textile

Polyester (PET) and rayon are used primarily for carcass plies (see Figure 19.16). Nylon-6, nylon-66, and aramid (aromatic polyamide) are used mainly for 0° ply (see Figure 19.16).

PET is used for passenger, light truck, or farm tires. Nylon-66 is preferred to nylon-6 due to higher melting temperature. Nylon has a good fatigue resistance, tenacity, and durability. Unfortunately, it has low dimensional stability.

Aramid is used as a metal substitute in tires that have to be as light as possible (for racing applications, aramid can be used for belts; see Figure 19.16).

19.3 MANUFACTURING PROCESS

The manufacturing process of a tire is based on

- Mixing
- Calendering/extrusion
- Building
- Curing

19.3.1 Mixing

Mixing the rubber compound is the first phase of the tire manufacture. The Banbury machine is used for mixing. The mixer consists of two counterrotating spiral-shaped blades sheathed in segments of cylindrical shape (Figure 19.2). The movement of the blades leaves a space for the compound between them. The blades are usually made to let a fluid flow inside them; the fluid can be both cold and hot, depending on the material involved. The body and structure of this machine are strong, and they let be suitable heavy-duty mixing. The structure is made of a feed hooper, with a large cross-sectional area for rapid feeding. Rotors are usually made from alloy steel, for mechanical property and capability of productivity. Through the door for discharge control in temperature can be done. Finally, there are a series of seals to avoid dust and there is a cooling system. In Figure 19.3, it is possible to see the sheet of compound leaving the mixer. In Figure 19.4, the parts of interest of the mixer are explained, and three different types of mixer are shown.

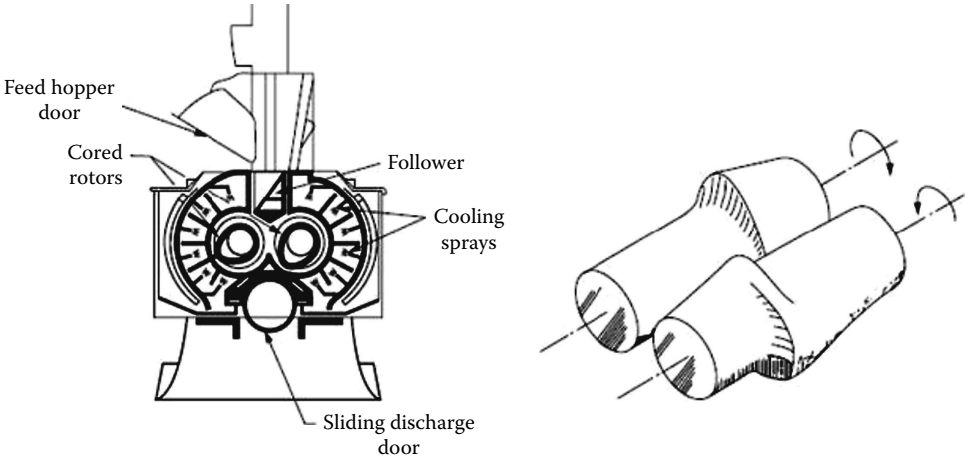

FIGURE 19.2 Banbury chamber and rotors.

FIGURE 19.3 Compound from Banbury.

19.3.2 Calendering/Extrusion

19.3.2.1 Calendering

One fundamental process involved in the tire manufacture is calendering. Calendering is a continuous process and it is used to produce compound sheets of several thickness. Calendering is also used to rubberize cords for plies and belts: both metallic and textile cords are covered with appropriate rubber compounds to get fabrics.

The feeding compound is usually heated, to achieve a viscosity suitable for the process. Usually when the sheet leaves the rolls, it has to be cooled and then rolled on a drum.

The fabric is created by inserting metallic/textile cords between two sheets of compound passing through two or more rolls (see Figure 19.5).

Many different arrangements for calender lines exist, having different numbers and positions of the rolling mills.

Figure 19.6 shows a typical scheme of a calender for metallic fabrics.

19.3.2.2 Extrusion

An energy-demanding operation in the tire manufacturing is extrusion. The extrusion process is designed to continuously convert a feeded material into a desired shape, by means of a die.

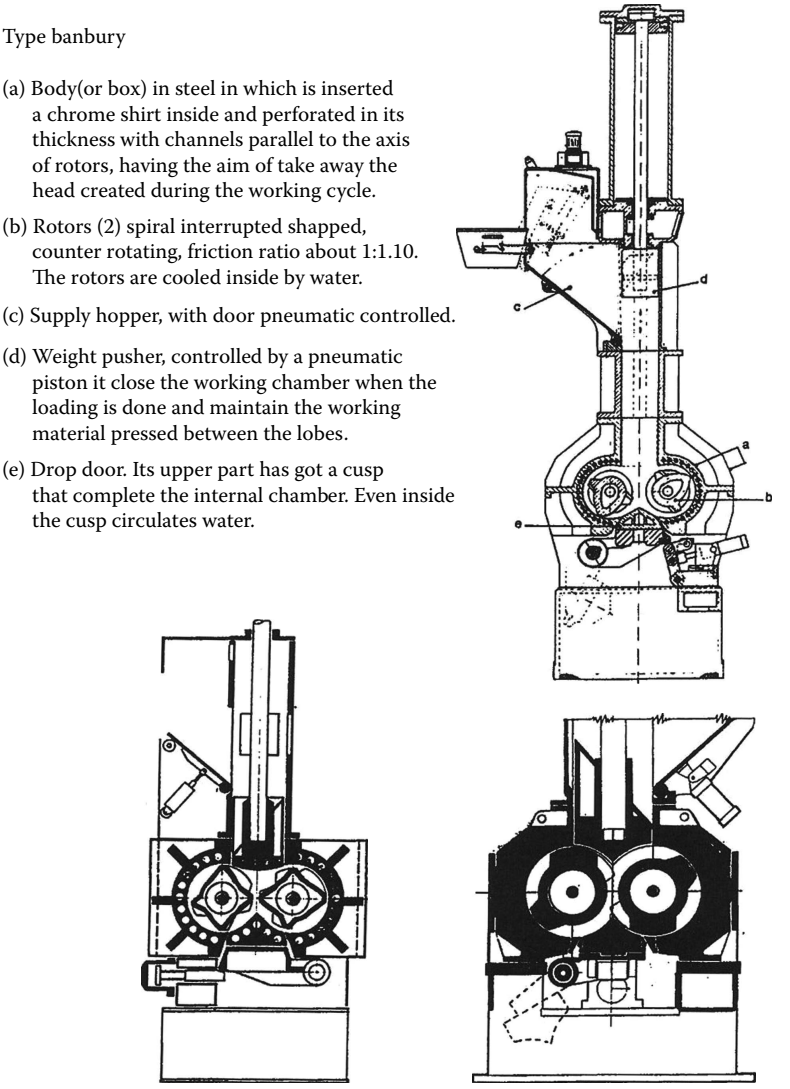

FIGURE 19.4 Banbury, Werner, and Intermix machines.

The material is carried out by the action of a screw, heated till it is squeezed through a die (Figure 19.7). Such operation is mainly used on tread and sidewall–rim cushion compounds.

The environment can contain even the external heat generators. The pressure on the material grows up with the decrease of the distance from the feeder up to the die and reaches the maximum just before it enters into the die. The pressure on the compound forces it through an adapter and then into the die. The die is a shaped open one, to give the extruded compound the desired shape (Figure 19.8).

The control of the process is very important, and the exit temperature of the extruded compound must be in a specific range in order to avoid early vulcanization.

If the temperature have to be reduced, it is possible to act by means of a cooler. The most important component of any extruder is the screw (Figure 19.9). It is proper of one material and cannot

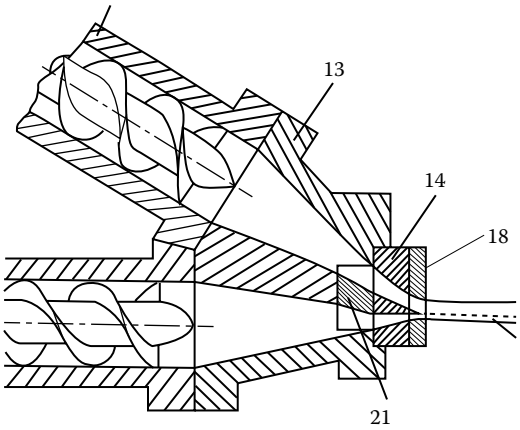

FIGURE 19.8 Double compound extrusion die.

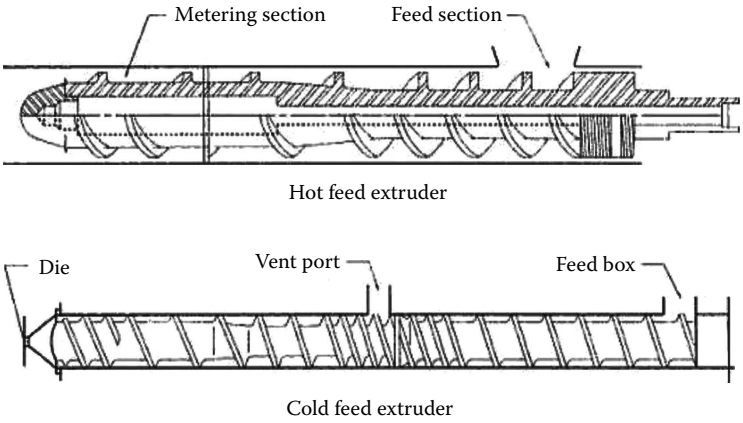

FIGURE 19.9 Cold feed and hot feed extruders.

be used for others. The screws are often fabricated with a 4140 alloy steel in cylindrical shape with a helical channel cut into it. The helical ridge formed by this machining is called the flight, the distance between the flights is called lead, and it can vary along the screw axis. The helix angle is called pitch, and this is properly chosen in order to optimize the feeding characteristics; an angle of 17.6° can be considered as an average, and it usually varies between 12° and 20.1°. The screw outside diameter is generally a few hundredth of millimeter less than the internal diameter of the vessel. This little clearance avoids high steady increase of the compound inside the barrel wall and brings maximization in the heat transfer. The screw flights are usually submitted to heat treatment, in order to increase the hardness, growing up the wearing resistance.

The feeding system can be "hot" or "cold" (Figure 19.10). In the hot feed system, strips of green compound are fed from warm-up mills into an extruder feed box and then into the vessel. This system normally has got short barrel and screws with short compression and metering zones, because the compound is already hot and has a low viscosity as it enters to feed the hoopers; barrel length to diameter ratio from 4:1 to 6:1 and 8:1 is typical. Cold feed systems feed the rubber compound directly into the extruder system, and they have much larger length to diameter ratio because of the requirements of reducing green compound plasticity.

The compound from the extruder machine can be made by more die head to form a sheet with more than one compound.

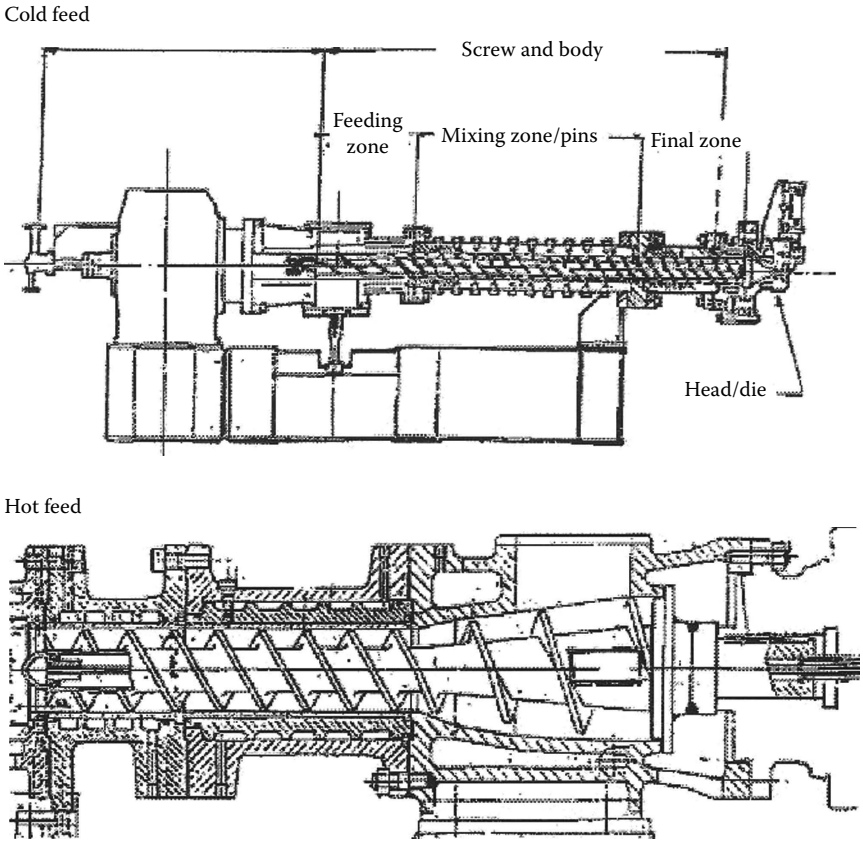

FIGURE 19.10 Complete scheme of hot feed and cold feed extruders. Cold feed: length of the screw from 12 to 16 times its diameter. The screw is divided into three zones: (1) feeding/supply zone, (2) mixing zone due to central pins, and (3) anti-pulsation end zone. Hot feed: length of the screw from 6 to 8 times its diameter. The screw is divided into two zones: (1) conic feeding zone and (2) cylindric extrusion zone.

19.3.3 Building

As the semifinished materials, such as liner, plies, beads, belts, sidewalls/rim cushion, and tread, have been obtained by the previous processes, the next step is the tire building. It can be divided into two phases: first stage and second stage.

19.3.3.1 First Stage

This phase of the manufacture consists of building up the tire by laying down on the surface of a cylinder the different parts of the tire structure (see Section 19.4): liner, carcass plies, beads and relative fillers, and sidewalls and rim cushions. To avoid the presence of air between the parts, a roller process is performed: by means of pressure, the air is forced to flow out to form a homogeneous set.

The obtained manufacture looks like a sleeve, called *first phase carcass* (see Figure 19.11a).

19.3.3.2 Second Stage (Conformation)

The output of the first stage is a product that has a cylindrical shape. The second stage consists of laying down on a drum (with higher diameter than the first stage) the two steel belts, nylon 0° and the tread band (Figure 19.16). By means of conformation, the final shape of the tire (close to a toroid) is obtained. The beads (Section 19.4.3) are moved one toward the other (Figure 19.11b) by means of inflation.

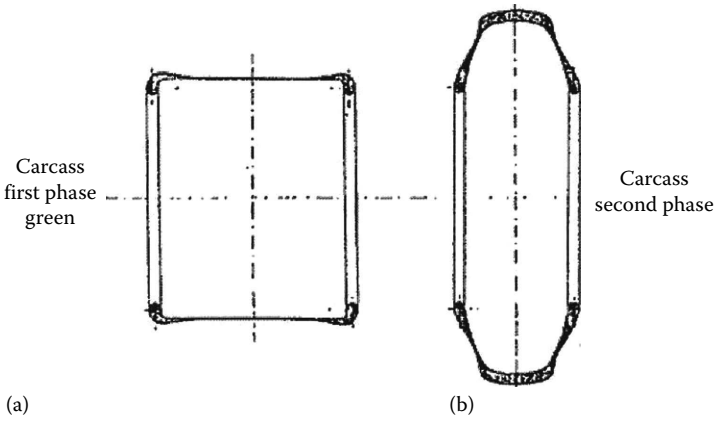

FIGURE 19.11 Phases of carcass creation. (a) Confection. (b) Conformation.

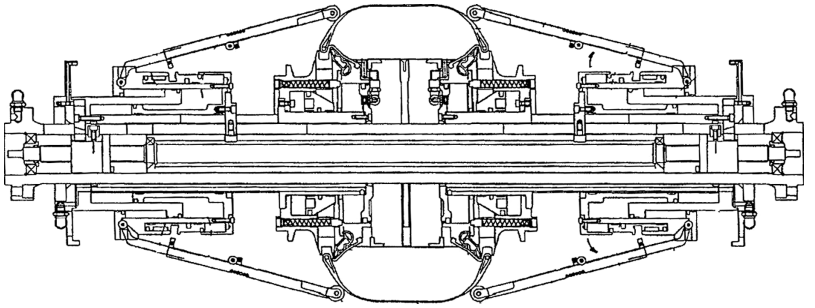

FIGURE 19.12 Confection machine. In the middle the tire can be seen.

Like in the first phase, after conformation, there will be a rolling operation around this new shape. At the end of this step, the tire is called *uncured tire* or *green tire*, ready to be cured to obtain the final product.

Figure 19.12 shows a second stage tire-building machine during the conformation phase.

19.3.4 Curing

19.3.4.1 Introduction to Curing

Curing is the process of vulcanization. The unvulcanized rubber can be considered a set of polymer chains disposed randomly in the space (Figure 19.1). If submitted to deformation, they will not return to their original shape. Vice versa, the vulcanized rubber [15–17] will return to the original shape after the deformation is ended, due to cross-links created by sulfur (Figure 19.1).

The main problem related to the curing process is how to determine the optimum amount (or density) of cross-links. Such a density is closely related to the heat provided during curing.

The final properties of the rubber compound depend on cross-link density and type of links (Figure 19.13). Such properties are hysteresis, tear strength, tensile strength, and stiffness. They are defined, respectively, as follows (see Figure 19.13).

Hysteresis is related to the ability of a material to come back to its original shape when the load is removed. The more the cross-links, the less the hysteresis. The higher the hysteresis, the higher the grip of the tire on the ground.

Stiffness is directly related to the modulus of elasticity (Young modulus). The more the cross-links, the more the stiffness.

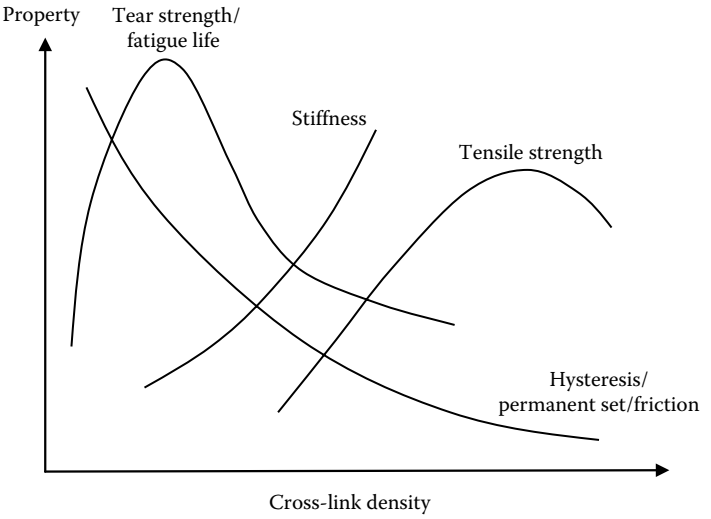

FIGURE 19.13 Effects of cross-links obtained in the rubber by vulcanization process.

Tensile strength reaches a maximum at a relatively high cross-link density. This is due to the brittle nature of a rubber with an excessive cross-link density. Actually in this case, the nature of the cross-link changes.

Tear strength reaches a maximum at a relatively low cross-link density.

In the curing phase, the external part of the green tire is subjected to high temperature and high pressure: it is pressed against the mold so that the tread pattern is created.

In the internal part of the green tire, the cohesion of all the components is also achieved.

19.3.4.2 Curing Cycle

Ideally, constant values of temperature and pressure during the curing process could be prescribed. However, for actual applications, the vulcanization is based on time-varying temperature and pressure. The final vulcanization result (cross-link density) depends on the energy that is provided. However, the nature (mono-, di-, or polyatomic chains) of the sulfur bridges depends strongly on the curing cycle (pressure–temperature and time histories). A variation of 10° can double or halve the curing time, producing different sulfur bridges.

19.3.4.3 Curing Mold

A tire-manufacturing mold has got a pattern corresponding to the outer profile of the tire being molded. The pattern influences steering, wear, roadholding, and noise characteristics of the tire.

The curing apparatus consists of many components, such as bladder, steam supply, and mold (Figures 19.14 and 19.15). The outer surface of the raw tire is closely in contact with the face of the mold; this is due to the action of the bladder acting on the inner surface of the tire. After the curing cycle, the tire pattern (and the whole tire) will have the desired shape.

According to the production volume, basically two materials are used for the mold, aluminum or steel: The former, for low amount of production, facilitates forming the deep and complex features, and the latter has got higher strength and durability.

19.3.4.4 Lubricant for Curing Cycle

A relative motion occurs between the outer contact surface of the bladder and the inner surface of the tire. Such a motion happens during the expansion phase (bladder inflated) and at the end of the curing cycle when the bladder has to come back to the original configuration (bladder deflated). Lubrication between the surfaces experiencing the relative motion is essential to avoid buckle

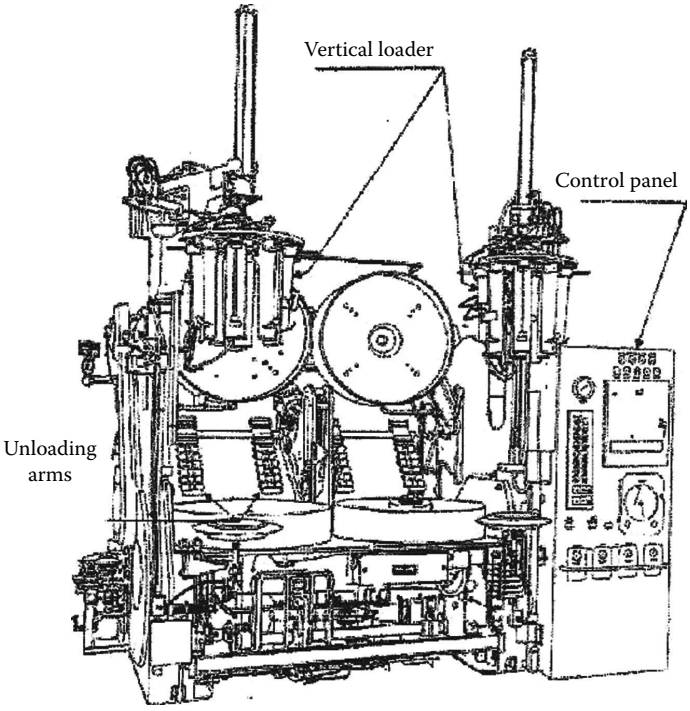

FIGURE 19.14 Curing machine. The green tire is positioned inside the molds (the four cylindrical parts visible) and then pressure and temperature are raised up to the desired values.

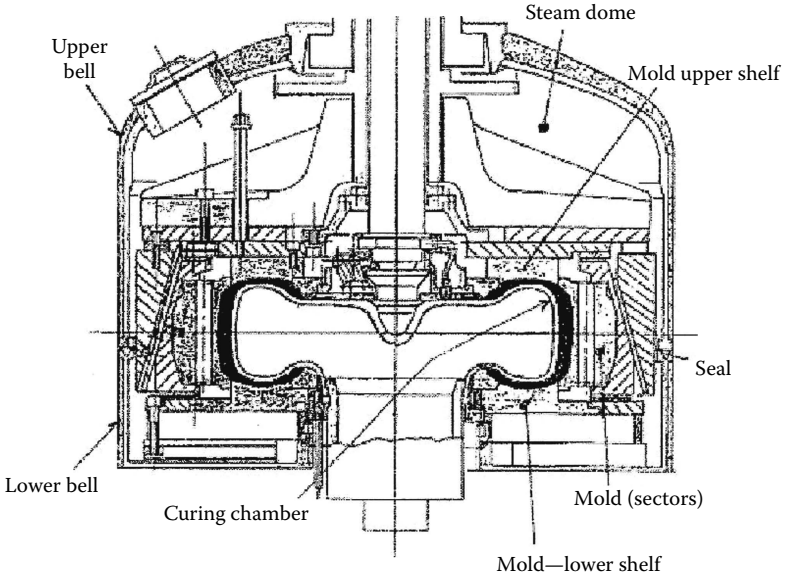

FIGURE 19.15 Curing chamber. The upper and lower parts of the mold (upper shelf and lower shelf) are joined to contain the green tire.

(a phenomenon that refers both to defects of the shape of the tire and wear problem on the bladder). If lubrication, heat, and pressure are not sufficient during the curing process, air may be trapped inside the tire structure.

The green tire is pre-lubricated to avoid buckle. The majority of lubricants are water based and can contain elements such as bentonite clay, polydimethysiloxane, sodium benzoate, mica, and kaolin clay.

19.3.4.5 Spews

When the green tire is pressed versus the mold, there is air between them. Since the pattern is made with protrusion from the surface of the mold, the air must have the possibility to escape. If air is trapped, on the surface of the cured tire, small dimples can appear, known as shortage, but also bubbles may be formed. To discharge the air between the raw tire and the mold, small vent holes, with usual diameter from 0.1 up to 2 mm, are created in the mold faces; such vent holes cause spews on the surface of the vulcanized tire. Spews are the unwanted small projections on the tire outer surface.

Spews formed on the tread face will be easily removed during running. On the contrary, spews on the sidewall will not be removed.

The mold can be composed by sectors, and between neighborhood surfaces micro-clearances remains. From these clearances air can escape, while the rubber cannot flow inside. Since they are extremely thin, bubbles would not be produced on the surface of the tire.

19.4 TIRE STRUCTURE

When a tire has to be designed, the aim is to satisfy a so-called *target letter* coming from a car manufacturer. Alternatively, generic specifications for a tire can be derived referring to the requirements from the market. Design targets are physical and mechanical performances, in particular mileage, rolling resistance, noise emission, wet grip, and others. Based on such specifications, the tire is implemented and tested (Figure 19.16).

In the past, tire companies worked without a standard on the final product. However, to guarantee a constant quality product, the companies issued (and issue) inside standards for defining the desired production cycle to be followed. Such internal standards created a basis for quality control

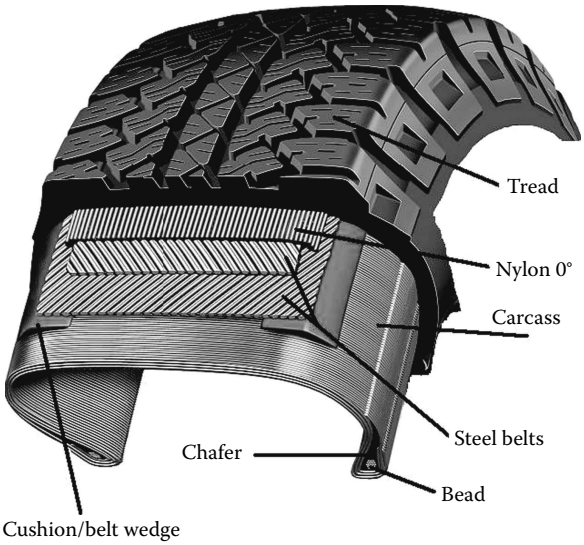

FIGURE 19.16 Tire nomenclature. (Adapted from http://www.avontyres.com.au/technical/images/cutaway-passenger.jpg)

on the whole manufacturing process. Quality control led to a more efficient production and to more tight product tolerances.

The first standards constrained the dimension of the tire. The inflated tire has to be bounded in both radial and transversal directions. TRA [18] and ETRTO [19] issued important standards on tire dimensions.

DOT/ECE (see [7] for an overview of the topic) issued important standards on tire safety.

The addressed standards are aimed to let companies adopt uniform technical prescriptions for wheeled vehicles; competition tires are an exception.

Relatively recently [20,21], a European legislation was introduced to guarantee the quality of the final product.

19.4.1 Inner Liner

The inner liner (Figure 19.17) is usually made with a compound based on *halobutyl* rubber; this polymer cures faster compared with *butyl*, and it needs smaller amount of curative agents. It can also be co-cured more readily in contact with other elastomer making a good rubber product. The inner liner prevents gases from migration into the carcass plies or towards the belt plies of the tire (Figure 19.18). It looks soft and has a relatively low tear strength and elastic modulus compared with the other rubbers used in the tire. The inner liner has to be limited in nonstressed areas of the inner tire. Inner liner should have a good moisture permeability, a good adhesion to carcass compounds, flex fatigue resistance, and durability. The air barrier properties and flex fatigue result from low level of cross-link density.

19.4.2 Plies

Plies are made from rubber compound and textile cords (Section 19.2.7.2) in order to give the needed structural reinforcement (Figure 19.19). Plies encircle the bead (Figure 19.19) and they are

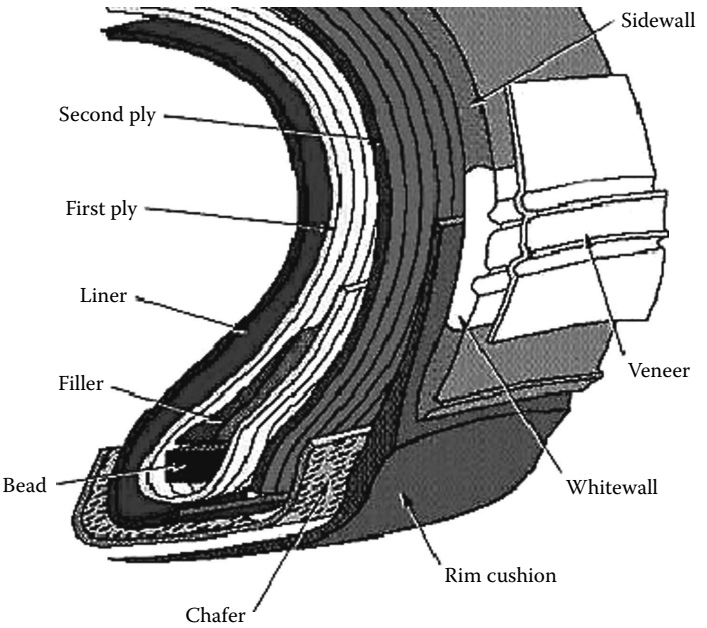

FIGURE 19.17 Tire nomenclature for inner parts. (Adapted from http://www.2405.com/press-library/Hummer-H3-2006/cutaway-of-the-bridgestone- lt285-75r16c-33-inch-on-off-road-radial-tire.jpg)

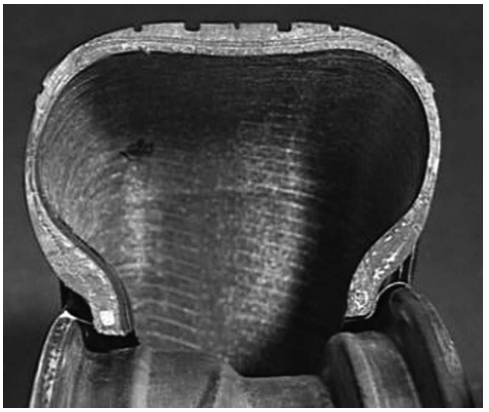

FIGURE 19.18 Tire section.

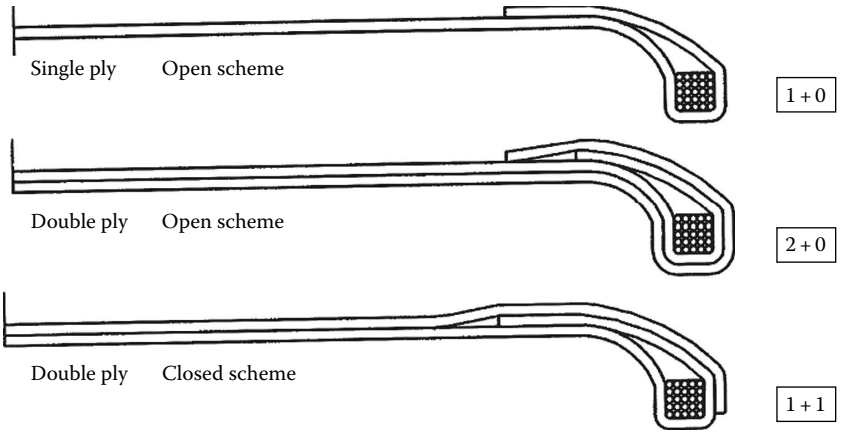

FIGURE 19.19 Schemes of plies forming the bead.

positioned by special machinery. A ply is a highly flexible part, but due to the internal pressure of the tire it can support the weight of the car (see Chapter 11). Plies embody the carcass of the tire.

19.4.3 Bead and Filler

The beads are made from high-resistance steel, according to ASTM 1070. Their function is to fit the pneumatic tire on the rim (Figure 19.20).

The bead filler is the most stiff compound in the tire. It constraints the bead wire to maintain its desired position. Due to this, the beads do not affect wheel balance, as they are firmly constrained to the rim.

19.4.4 Chafer and Rim Cushion

The chafer consists of a thin layer of fabric placed around the beads (Figure 19.17). The aim is to protect the bead steel cords against unexpected rise of problems such as wear and cutting action due to the contact with the rim. Due to its location, it can also distribute the stresses. Additionally, it is a boundary from external undesired particle of dirt or moisture that can flow inside the tire. Sometimes it is absent.

The rim cushion is made from a compound with high grip in order to avoid slipping on the rim. It provides the necessary air tightness to prevent leakage.

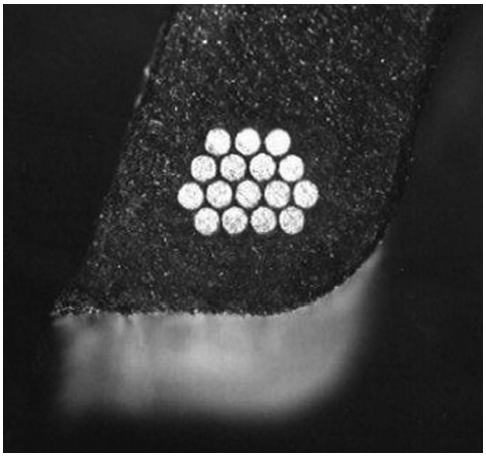

FIGURE 19.20 Bead cross section.

19.4.5 Sidewall

It is placed in between the beads and the tread, in the side outer part (Figures 19.16 and 19.17). It is made usually from natural rubber (NR) and polybutadiene (BR). It covers the carcass and protects it from abrasion. It has good fatigue resistance, low hysteresis, and low modulus of elasticity.

19.4.6 Belts

Belts are placed under the tread over the carcass of the tire (Figure 19.16), and they can be more than one and are made from steel, coated with rubber. The functions of such components are various. They strengthen the whole tire structure constraining the carcass cords to keep their radial desired position. They resist to the hoop tension (the prestress directed tangentially with respect to the tread, due to tire inner pressure). They also resist to a puncture from an external object.

The steel cords are sloped with respect to the meridian plane of the tire by an angle ranging from 20° to 35°. This is due to resist side forces. Usually, passenger tire has two belts whose slopes are opposite. Such an anisotropy is directly related to ply steer [3]. To avoid the buckling of the belt package, the cord size and the cord encount (number of cords per cross width) are properly chosen.

19.4.6.1 Nylon 0°

The nylon belt is placed between the belt package and the tread and improves tire safety. Primarily it resists centrifugal forces. It improves tire uniformity and isotropy. It resists the hoop tension [3]. Experience states that a better ride comfort is provided by tires with nylon 0° belt (Figure 19.21).

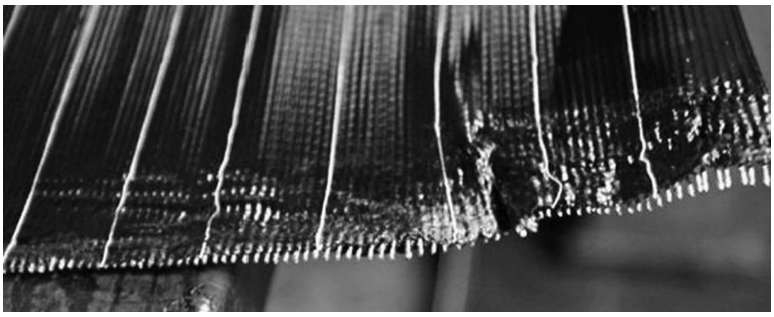

FIGURE 19.21 Nylon belt.

19.4.7 Belt Wedge: Edge Cover

This component is not present in every tire, sometimes it is needed for safety and durability improvement. It is placed at both sides of the belts (Figure 19.22). Joining together the edge parts of the belts, it strengthens them and so improves tire fatigue resistance. It also prevents dangerous phenomena like belt separation.

19.4.8 Tread

The tread is the outer part of the tire in contact with the ground. It is placed upon the belts (Figure 19.23). The designer, according to the mission of the tire, defines the proper rubber compound for the desired wear resistance. Also, other performances are obtained mainly by the proper choice of rubber compound.

The design of ribs and grooves is of primary importance for tire dynamics. To avoid aquaplaning, the grooves must be either longitudinal or sloped. Traction is improved if groves in lateral position are transversal. The noise perceived inside the vehicle is related to the spacing of the transversal grooves. An unequal spacing flattens and enlarges the noise spectrum. Moreover, the correct phase of the two lateral sets of groves along the shoulders reduces the amplitude of the spectrum.

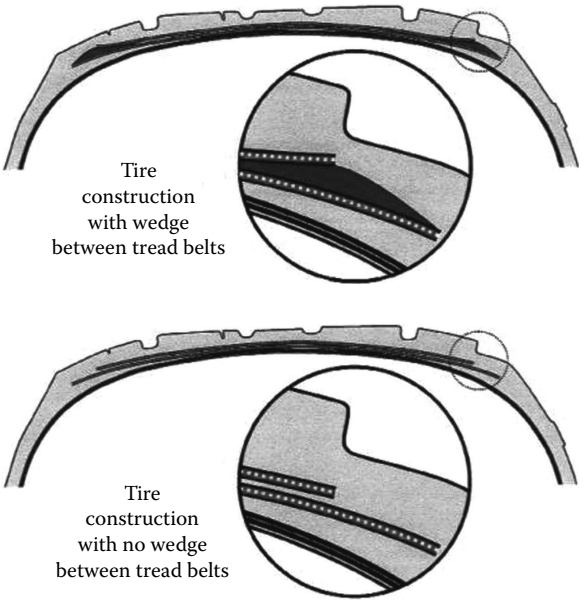

FIGURE 19.22 Wedges between belts. (Adapted from www.tirelitigation.com)

(a) (b)

FIGURE 19.23 Treaded (a) and slick (b) tires.

The variety of requirements for different car segments drives the design of the tread, starting from off-road tire up to slick. Even in the slick tire, the tread is present.

Road car tires need a compromise between mileage and dynamic performances. Strongly varying temperature conditions (hot summer, cold winter), water on the road, and snow have to be taken into account. The ratio between the area of voids and the rubber in the tread (ratio "land and sea") is approximately ranging between 25% and 30% for passenger summer tires. For winter tires (M + S), the ratio is 35%–40%.

Another important aspect is ecology. The tire tread greatly influences (together with the compound and the geometrical dimensions—i.e., curvatures) the rolling resistance. Typical values are 10 N in longitudinal direction per 1000 N in radial direction, the minimum being 7 N and the maximum 12 N.

Tread wear indicators are placed according with the UN/ECE standard [22,23]. The purpose is to give an idea of the residual tread when its height is less than 1.6 mm.

19.5 TIRE STANDARDS AND TESTS

19.5.1 UN/ECE Regulations

The UN/ECE 1958 Agreement [22] on "vehicle type approval and its mutual recognition" is an international forum (promoted by the United Nations) providing the legal framework under which tire technical regulations are developed. More than 50 countries from various regions of the world including the European Community have adhered to the UN/ECE 1958 Agreement.

The UN/ECE 1998 Global Agreement purpose is to further enhance the process of international harmonization through the development of global technical regulations (GTR), which may cover countries that are not contracting parties to the 1958 Agreement.

The European tire industry initiated the development of a GTR for tires in close cooperation with Japanese and U.S. colleagues [10].

The main "tire" technical regulations (useful for product development and certification) are [10]

- UN/ECE Regulation 30: tires for motor vehicles and their trailers [22,23]
- UN/ECE Regulation 54: tires for commercial vehicles and their trailers
- UN/ECE Regulation 64: temporary-use spare wheels/tires
- UN/ECE Regulation 75: tires for motor cycles and mopeds
- UN/ECE Regulation 106: tires for agricultural vehicles and their trailers
- UN/ECE Regulation 117: tires rolling sound emissions and adhesion on wet surfaces
- UN/ECE Regulation 108: retreaded tires for motor vehicles and their trailers
- UN/ECE Regulation 109: retreaded tires for commercial vehicles

ECE standards introduced the so-called tire type, a set of categories in which the tires can be classed according to

- The manufacturer
- Tire size
- Category of use (ordinary [road-type] or snow tire or for temporary use)
- Structure (diagonal [bias-ply], bias-belted, radial-ply, run-flat tire)
- Speed category
- Load capacity
- Tire cross section

In Table 19.3, the possible structural characteristics for tires are reported.

TABLE 19.3
UN/ECE 30 Table 1

Structure	Angle of Ply Cord	Belt under Tread	Extra Reinforced Carcass	Temporary-Use Notation	Flat Tire Running Mode
Diagonal or bias-ply	Less than 90°	X	X	X	X
Bias belted	Less than 90°	V	X	X	X
Radial	90°	V	X	X	X
Reinforced or extra load	X	V	V	X	X

X = no, V = yes.

19.5.1.1 Markings

Each tire (except motorsport tires and other tires for special use) has to show on the sidewall specific symbols grouped into four categories (A, B, C, D) as shown in Figure 19.24.

The rim can be classified as theoretical rim, design rim on which the final tire is supposed to be mounted on, or test rim, the ones used for testing; see for further details [19].

In Tables 19.4 through 19.6, the lists of load capacity and speed indices are, respectively, reported.

If the speed is greater than 210 km/h, the load index (Li) is modified according to the values reported in Table 19.6. For intermediate speeds, a linear interpolation is accepted.

If the speed is lower than 60 km/h, the load index (Li) is modified according to the values reported in Table 19.7.

The values reported in the preceding tables guarantee the basic tire functions, that is, carrying a given load at specific speed, steering, and applying the traction/braking forces to the ground.

19.5.1.2 Tire Dimensions

In the ECE standard Regulation 30 [22,23], the tire dimensions are defined. The section width (Figure 19.25) depends on the rim on which the tire is fitted. The relationship between the section width and the rim width is given by the formula

$$S = S_1 + k(A - A_1)$$

where

S is the actual "section width" expressed in mm
S_1 is the "nominal section width" (in mm) as shown on the sidewall of the tire in the designation of the tire as prescribed
A is the width (expressed in mm) of the actual rim
A_1 is the width (expressed in mm) of the reference rim
k shall be taken equal to 0.4, more details on k are reported in the standard [23]

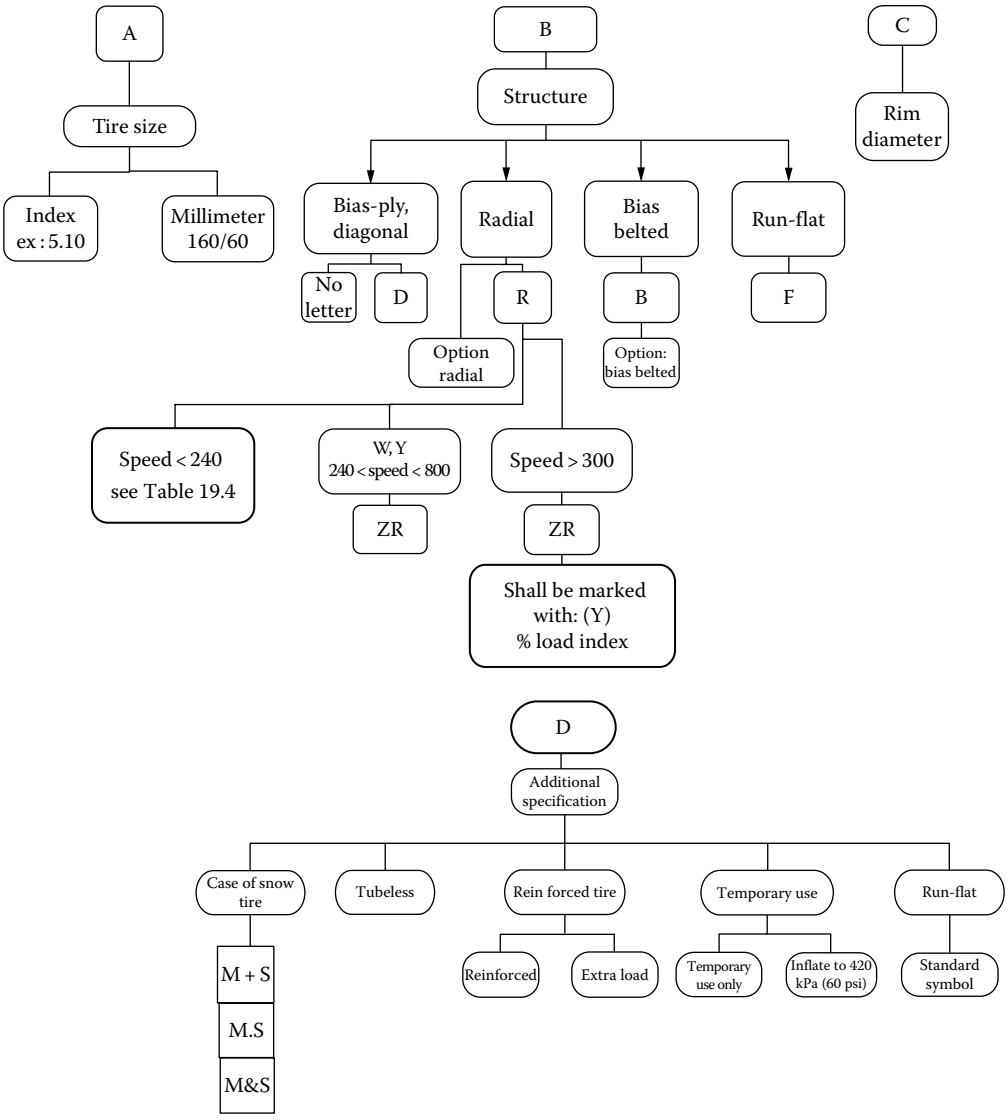

FIGURE 19.24 UN/ECE tire marking scheme.

29	103	60	250	90	600	120	1400
30	106						

Li, load capacity index; kg, mass of the vehicle resting on the single tire that is to be carried.

The outer diameter can be calculated with the formula

$$D = d + 2H$$

where

D is the outer (overall) diameter expressed in mm
d is the conventional rim diameter expressed in mm
H is the nominal section height in mm, equal to $H = 0.01S_1 \cdot R_a$, where S_1 is the nominal section width in mm and R_a is the nominal aspect ratio, as shown on the sidewall of the tire in the tire size designation

Higher values of the width of the manufactured tire are accepted up to 6% or 4%, respectively, for bias-ply or radial/run-flat tires. If the tire has specific ribs for rim protection, the width can exceed 8 mm than the nominal value.

60	110

The external (outer/overall) diameter of the tire must not be outside the values D_{min} and D_{max} obtained from the following formulae:

$$D_{min} = d + 2Ha$$

$$D_{max} = d + 2Hb$$

where

H and d have been defined earlier (Figure 19.25), otherwise

$H = 0.5 \cdot (D - d)$

$a = 0.97$

$b = 1.04$ (radial or run-flat tires) or $b = 1.08$ (diagonal or bias-belted tires)

For snow tires, the maximum allowable outer diameter is $1.01D_{max}$.

In the Annex 6 of UN/ECE Regulation 30 [23], a procedure is given to measure the dimensions of a tire.

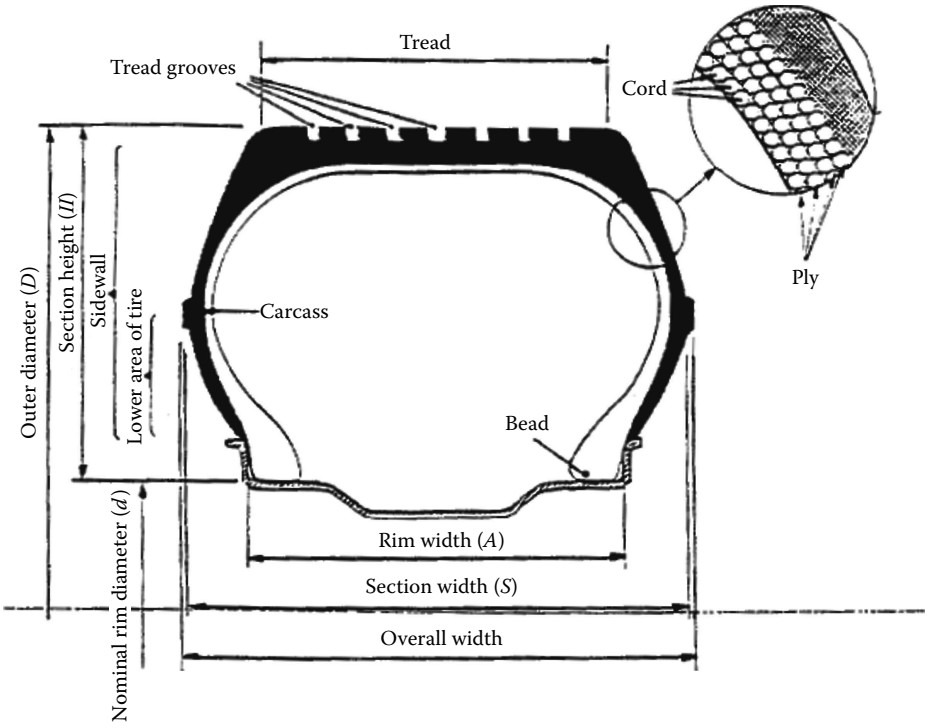

FIGURE 19.25 Tire dimensions. (From United Nations, Uniform provisions concerning the approval of pneumatic tyres for motor vehicles and their trailers, UN/ECE Regulation 30, E/ECE324, 2007.)

19.5.1.3 Load and Speed Performance Test

In the Annex 7 of UN/ECE Regulation 30 [23], a procedure is given to test the integrity of the tire.

The tire has to be mounted on the test rim, then inflated to pressure according to Table 19.8. For T tires (temporary use), a pressure equal to 4.2 bar is adopted.

The procedure for assessing the tire integrity is reported in Figure 19.26. Basically, the tire is inflated, loaded at 80% of the load index. Then the speed is rumped up near the maximum speed

TABLE 19.8

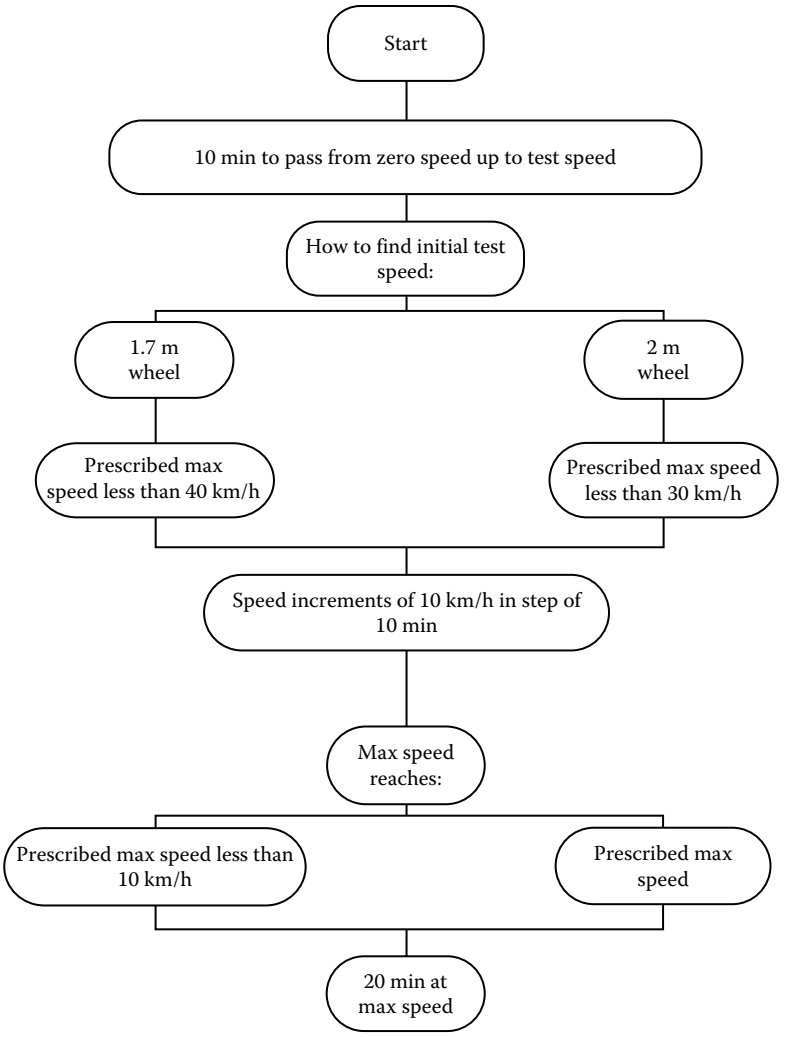

FIGURE 19.26 Load and speed performance test as defined in UN/ECE Regulation 30, E/ECE324. (From United Nations, Uniform provisions concerning the approval of pneumatic tyres for motor vehicles and their trailers, UN/ECE Regulation 30, E/ECE324, 2007.)

and then increased by steps of 10 km/h (lasting 10 min) up to the very maximum speed, defined by the speed index (such speed has to be maintained for 20 min). Exceptions (and technicalities) are reported in [23] and in Figure 19.26. For example, a test performed with a wheel (drum) of 1.7 m with a radial tire marked H (speed index_210 km/h) and load index 100 (800 kg) is organized as follows: the tire is inflated at 2.8 bar, loaded at 640 kg; in 10 min the speed is raised at 170 km/h; and then the speed is increased at 180 (for 10 min), 190 (for 10 min), and 200 (for 20 min).

For tires belonging to the Y speed category (see Figure 19.24), a special test is performed to assess integrity at high speed (see [23], Annex 7).

A tire which after undergoing the load and speed test does not exhibit any tread separation, ply separation, cord separation, chunking, or broken cords shall be deemed to have passed the test. Chunking means the breaking away of pieces of rubber from the tread, cord separation means the parting of the cords from their rubber coating, ply separation means the parting of adjacent plies, and tread separation means the pulling away of the tread from the carcass.

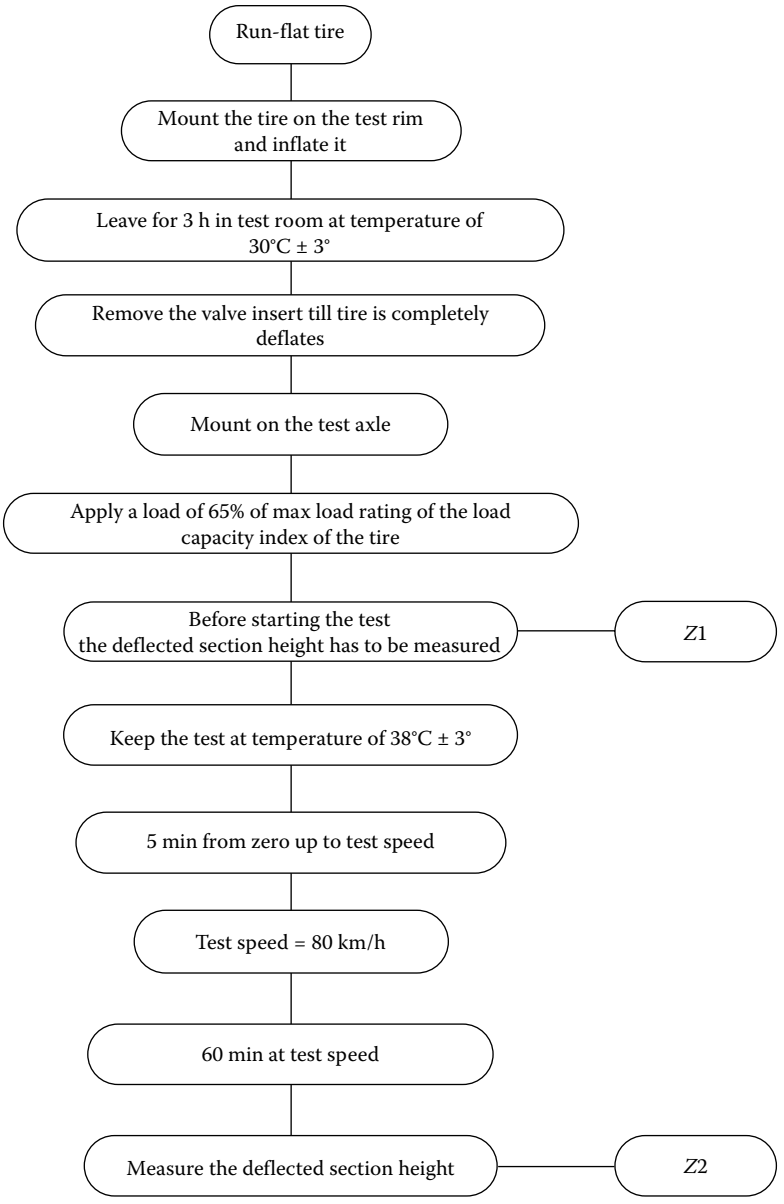

FIGURE 19.27 Integrity test for run-flat tires. (From United Nations, Uniform provisions concerning the approval of pneumatic tyres for motor vehicles and their trailers, UN/ECE Regulation 30, E/ECE324, Annex 7, 2007.)

The outer diameter of the tire, measured 6 h after the load and speed performance test, must not differ by more than ±3.5% from the outer diameter as measured before the test.

Y speed category tires pass the test even if they show blistering on the tire tread. For run-flat tires, in addition to the test described in Figure 19.27, the integrity is tested as shown in Figure 19.27, which refers to the deflated running condition. At the end of the test, the measure of the deflected section height ($Z2$) is taken. The change in percent of the deflected section height compared to the deflected section height at the start of the test ($Z1$) is calculated: $([Z1 - Z2]/Z1) \times 100$ (the deflected section height is measured according with the standard in [24]). If such a figure is higher than 20% and no other defects are visible, the tire is deemed to have passed the test.

19.5.1.4 Approval of the Tire

The approval corresponds to the homologation of the tire. The public administration certifies that the manufacturer has obtained a product that complies with the standards. The historical certifications are obtained from DOT or ECE.

19.5.2 DOT Tests FMVSS139

DOT [25,26] has issued integrity tests similar to the ones reported in the previous section [27]. Unseating resistance, strength, endurance, and high-speed performance tests are prescribed. Three specimens have to be used for one tire, one to test bead unseating and strength, one for tire endurance, and the last one for high-speed test.

19.5.2.1 Tire Dimensions

The dimensions of the tire have to be bounded, in accordance with the inflating pressure specified by the manufacturer, according to Figure 19.28.

19.5.2.2 Bead Unseating Test

The tire has to be clean, dry in the beads, and mounted at the specified pressure on a painted and clean rim, without use lubricant or adhesives. For this test a specific structure is provided, as shown in Figure 19.29.

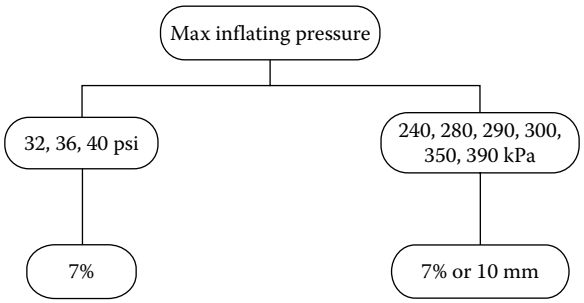
The test has to be carried out applying a load at a specified distance from the rim on the sidewall, the rate of increase is usually set to 2 in./min (i.e., 50 mm/min), and the initial position of the load arm is parallel to the tire and rim. The test stops if the beads unseating or the value specified for the load is reached. The procedure has to be repeated in order to cover a 90° shift between each test.

The test is performed at a pressure lower than the reference one. The load is applied at a defined position on the sidewall. The loads are reported in [27] and, depending on tire size, are bounded in the range 6,700–11,100 N.

19.5.2.3 Tire Strength

The test consists of forcing a 3/4 in. (19 mm) diameter cylindrical steel plunger with hemispherical end perpendicularly into the tread rib, as close to the center of the tire as possible, avoiding penetration into tread groove, with a rate of 2 in./min. The test is repeated for every 72°. The tire is inflated at the pressure adjusted as specified in [27].

The force is recorded in kilograms (lb), penetration is recorded in millimeters (inches), and energy is computed in joules (inch pounds) for each load application. If the tire fails to break before



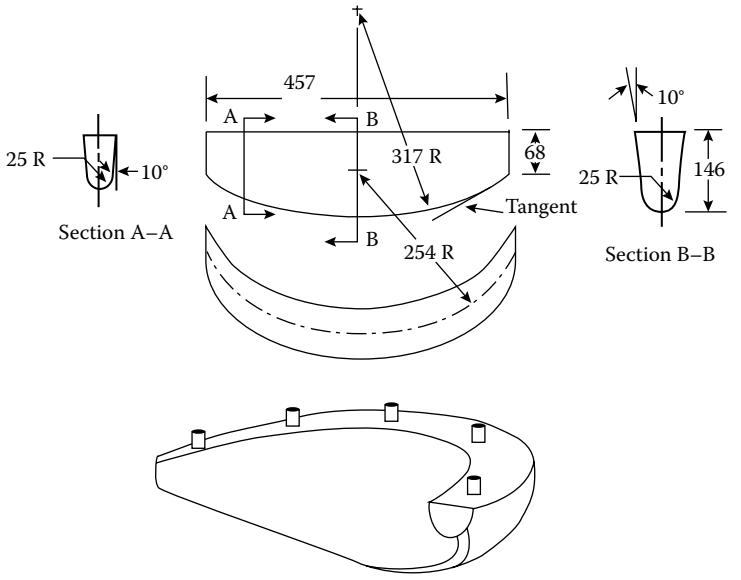


FIGURE 19.28 Max inflating pressure DOT tests.

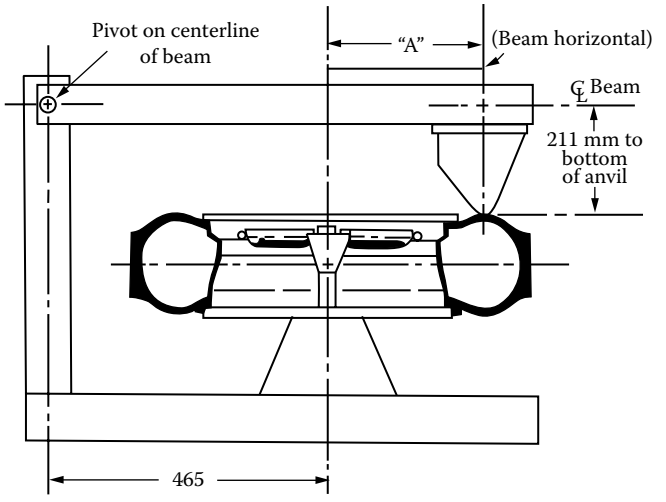

FIGURE 19.29 Bead unseating test device.

the plunger is stopped by reaching the rim, record the force and penetration as the rim is reached and use these values in the formula indicated in the following:

$$W = \frac{FP}{2}$$

where

W is the energy (inch pounds)
F is the maximum force (pounds)
P is the maximum penetration (inches)

The final value of the breaking energy is the average between the five tests.

TABLE 19.9
Requirements for Tire Strength Test (Minimum Static Breaking Energy)

Source: NHTSA, Laboratory test procedure for FMVSS no. 139, New pneumatic radial tires for light vehicles, Washington, DC, January 2006.

Note: For rayon cord tires, applicable energy values are 60% of those in table.

If none of the first four applications has resulted in carcass breakage below the minimum energy value, the fifth (last) plunger application is to be taken beyond the minimum limit to casing failure or to the point of tire compression against the rim, whichever occurs first.

The minimum energy required is reported in Table 19.9.

19.5.2.4 Tire Endurance

The test is basically a fatigue-damaging process (it differs from the high-speed test of the ECE standard (Section 19.5.1), which is an integrity test at the maximum speed).

The tire is mounted on the rim and inflated according to standards [27] and maintained into a room at 100°F ± 5°F (38°C ± 3°C). The tire is pressed against a wheel with a diameter of 67.23 in. (1708 mm). The test velocity is imposed at 120 km/h, and the load is set accordingly to what specified in Table 19.10.

The test is passed if the pressure is not dropped and if the tire meets all visual inspection criteria, that is, no visual evidence of tread, sidewall, ply, cord, inner liner, belt, or bead separation, chunking, open splices, cracking, or broken cords.

TABLE 19.10
Loads to Be Applied for the DOT Tire Endurance Test

Testing Hours (h)	Percent of Load Rating (%)
4	85
6	90
24	100

19.5.2.5 Low-Pressure Test

This test is conducted following completion of the tire endurance test (see previous section), using the same tire and rim assembly. The tire has to be deflated to the appropriate pressure reported in [27] (for passenger car tires, the pressure can be either 1.4 or 1.6 bar).

The test conditions (such as temperature) are similar to the endurance test ones. The test lasts 90 min at a speed of 120 km/h at 100% of load capacity. Between 15 and 25 min after the completion of the 90 min test, the pressure should be not less than 95% of the initial pretest pressure. Other visual tests are to be performed.

19.5.2.6 High-Speed Performance

The test conditions (such as temperature) are similar to the endurance test ones. The tire is mounted on the rim and inflated according to standards [27]. The tire is pressed against a wheel with diameter of 67.23 in. (1708 mm). The load is set to 85% of the maximum load capacity.

A break-in cycle shall be conducted for at least 2 h at 80 km/h (50 mph). At the conclusion of the run, unloading the tire will be allowed to cool.

The main test will commence within 30 min after the cooling cycle. All test cycles (140, 150, and 160 km/h or 87, 93, and 99 mph) will be conducted for 30 min each, without interruption.

The tire passes the tests if the pressure does not drop and no damages can be detected as in the previous tests.

19.5.3 Internal Experimental Tests

Tests have to be performed in the whole process of tire production, starting from the design phase and during the current production (quality control).

Inside each company, specific (and severe) standards are defined and used, and many of them are statements on the way the tests have to be performed. Such tests can be classed as described in Figure 19.30.

19.5.3.1 Type A Tests

The typical standards provide information on how to evaluate the structural integrity of tires (Figure 19.31).

The fatigue tests are carried out on a drum, under specific conditions of pressure, speed, vertical load, and external temperature. The aim is to find the number of revolutions before a failure occurs. Failures at the end of the test can be either the separation of the belt edges, due to shear action, or disjunctions at the bead area. The test parameters are tuned to reproduce the desired kind of failure in the target market.

19.5.3.2 Type B Tests

The handling test is not dealt with in this chapter; see other chapters in this book. The comfort issues are dealt with in the sequel.

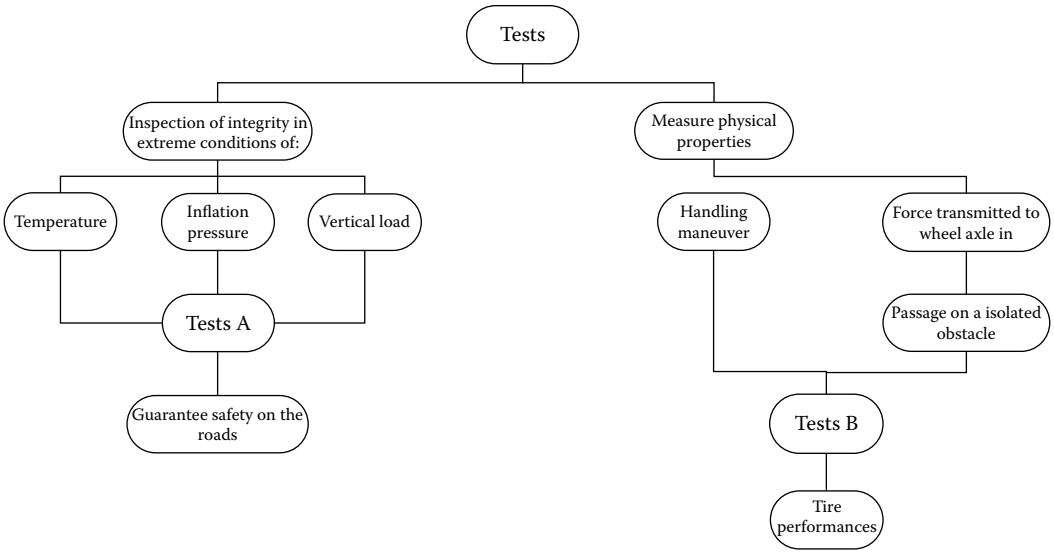

FIGURE 19.30 Typical internal experimental tests.

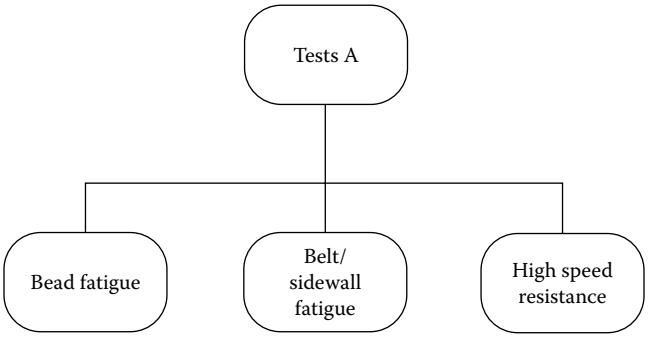

FIGURE 19.31 Type A tests.

19.5.3.2.1 Comfort Tests

A technique for determining the parameters of a rigid ring model of the tire is presented. The model can be used for studying comfort and braking issues in the 0–100 Hz.

The technique used to determine the parameters of the model includes both the direct measurements (mass, moment of inertia, stiffness) and a method to identify some parameters.

The tire is modeled as a rigid ring [28] (Figure 19.32).

The model is described by the following parameters:

a. Mass m_b and moment of inertia J_b of the rigid ring (mass and moment of the tread, belt pack, and carcass)
b. A moment of inertia J_r of the wheel, which includes a part of the tire moment of inertia (bead)
c. "Effective rolling radius" r_e of the tire, equal to radius R of the rigid ring
d. Radial c_b and torsional c_{bt} "structural stiffness": springs that represent, respectively, the pneumatic stiffness of the sidewall and the carcass, with the tire inflated
e. Vertical c_{cz}, introduced to take into account the deformations in the contact area (patch)

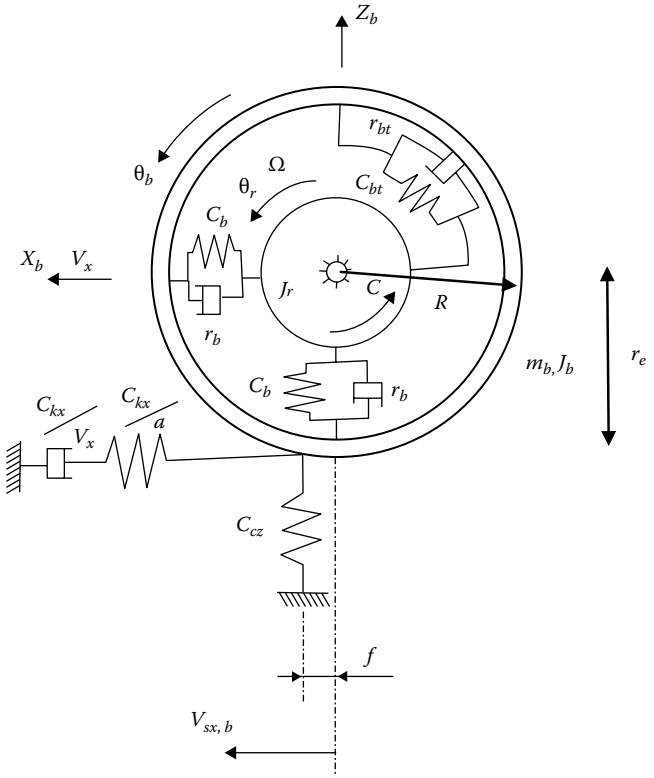

FIGURE 19.32 Rigid ring model.

f. Damping parameters corresponding to the stiffnesses indicated at points (d) and (e): r_b, r_{bt}
g. A "first-order model" (damper plus spring in series) taking into account the longitudinal slip in the contact patch. The following parameters are defined:
   - Longitudinal slip stiffness c_{kx} (= $2a^2C_p$, where C_p is the stiffness of the tread per unit length)
   - Length of the contact patch $2a$
   - Forward wheel velocity V_x
   - Slip velocity V_{sx}, b

The equations of motion concerning the model behavior are reported in [30].

The parameters to be measured directly are the following:

$$m_b;\ J_b;\ J_r;\ c_{bt};\ r_{bt};\ c_{kx};\ r_e;\ a$$

the parameters to be identified are

$$C_b,\ r_b,\ C_{cz}$$

19.5.3.2.1.1 Measuring the Length of the Contact Patch 2a Given that the contact patch of a tire varies with the forward velocity (the measurement performed with a stationary tire is much different from the measurement executed while it is rolling), the measurement is performed by photographing a tire mounted on a vehicle as it passes over a "glass plate." In particular, the camera is located underneath the road that is covered with a glass plate. Typical values of the length $2a$ (under a static load) are in the range 50–150 mm.

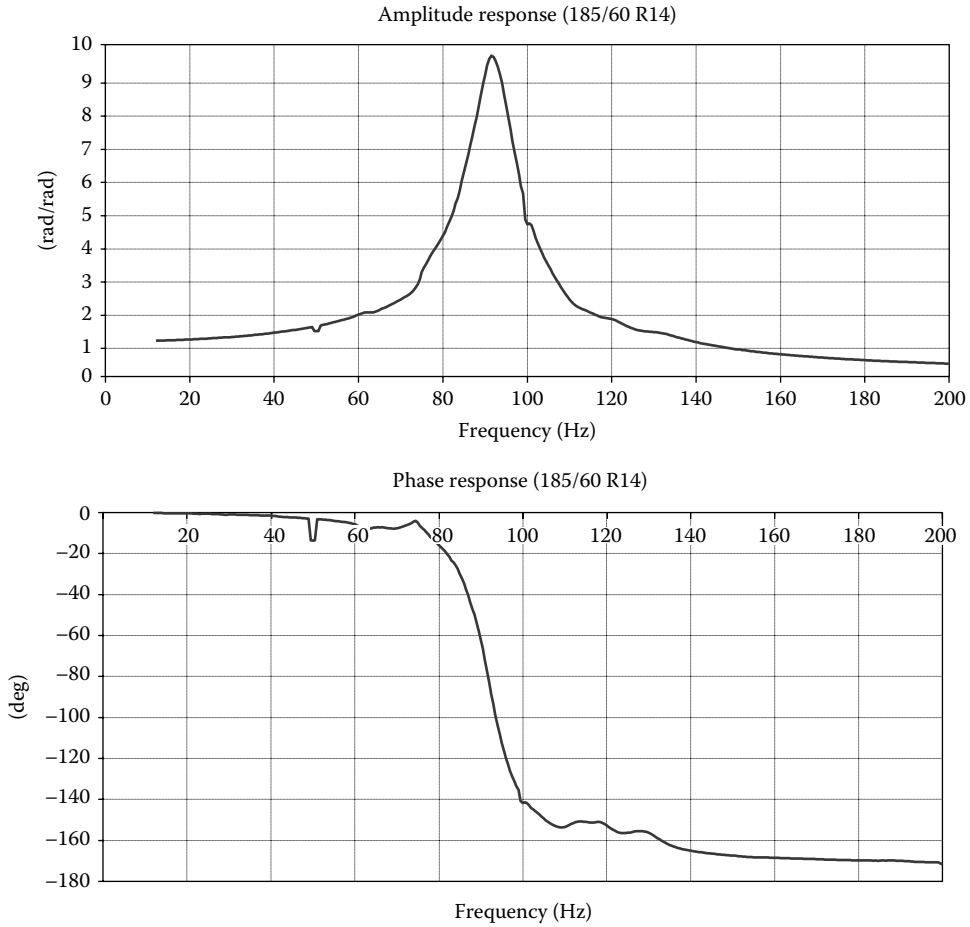

FIGURE 19.33 Experimental transfer function $H^{(s)}(\Omega)$ of a car tire.

19.5.3.2.1.2 Measuring the Mass Parameters A torsional pendulum [30] is used to measure the moment of inertia of the wheel J_{TOT} (rim plus tire). The moment of inertia of the tire J_p is determined by

$$J_p = J_{TOT} - (J_m + J_c)$$

where

J_m is the moment of inertia of the hub
J_c is the moment of inertia of the rim

Typical values of J_p and J_c (car tires) are, respectively, in the ranges 0.4–1.2 kg m^2 and 0.15–0.35 kg m^2.

The moment of inertia J_p of the tire can be divided, basically, into a moment of inertia of the tread rubber + belts + casing J_b and a moment of inertia related to the beads. Usually, $J_b = 2/3\ J_p$.

In the model in Figure 19.33, J_r has to account for the moment of inertia of the bead.

The parameter m_b (mass of the rigid ring) is $m_b = J_b/R^2$ ($r_e = R$).

19.5.3.2.1.3 Measuring the Stiffness c_{bt} and Damping r_{bt} An electric exciter is used to measure c_{bt} and r_{bt}. The exciter generates an alternated rotation of the rim on which the tire is mounted. The respective angular acceleration of the rim a_C and of the tire a_B (i.e., the tread + belts + carcass)

is measured. The ratio between the two accelerations as function of the excitation frequency Ω provides the *experimental* transfer function $H^{(s)}(\Omega)$

$$H^{(s)}(\Omega) = \frac{a_B(\Omega)}{a_C(\Omega)}$$

A typical transfer function $H^{(s)}(\Omega)$ is reported in Figure 19.33.

It should be noted that $H^{(s)}(\Omega)$ can also be expressed as

$$H^{(s)}(\Omega) = \frac{-\Omega^2 \vartheta_B}{-\Omega^2 \vartheta_C} = \frac{\vartheta_B}{\vartheta_C}$$

where ϑ_B and ϑ_C are the *measured* rotations, respectively, of the tread and the rim.

Considering the moment of inertia of the rigid ring J_b connected to the moment of inertia of the rim J_r through the torsional spring and dashpot c_{bt} and r_{bt}, the *calculated* transfer function $h^{(c)}(\Omega)$ between the calculated rotation of the tread ϑ_b and calculated rotation of the rim ϑ_r is given by

$$h^{(c)}(\Omega) = \frac{\vartheta_b}{\vartheta_r} = \frac{i\Omega r_{bt} + c_{bt}}{-\Omega^2 J_b + i\Omega r_{bt} + c_{bt}}$$

By assigning the proper value to J_b, it is possible to identify the parameters r_{bt} and c_{bt}.

Typical values of (car tire) r_{bt} and c_{bt} are found, respectively, in the ranges 18–25 N-m s/rad and 80×10^3–150×10^3 N-m/rad.

19.5.3.2.1.4 Measuring the Sliding Stiffness c_{kx} The parameter c_{kx} represents the longitudinal stiffness of the tread in the contact patch. This parameter depends on the compound and the tread pattern, as well as the extension of the tire–road contact area (and therefore the vertical load). A dynamometric trailer can be used to measure the longitudinal stiffness. Alternatively, the tire can be tested on a flat belt machine. A longitudinal slip is applied $V_{sx} = V_x - r_e\Omega$ (see Figure 19.34) and the longitudinal force F_x is measured. For small V_{sx}, $c_{kx} = \Delta F_x/\Delta V_{sx}$. This procedure is similar to the one reported in [29].

Typical values of c_{kx} are found in the range 20,000–150,000 N, and they depend strongly on the vertical load.

19.5.3.2.2 Tire Cleat Test

The natural frequencies and the damping values of the tire in the vertical plane are derived, in order to identify C_b, r_b, C_{cz}. The test involves a wheel passing over an obstacle. The wheel is mounted on a fixed measuring hub and rolls on a drum [30]. The signals—as function of time—measured at the hub refer to both the longitudinal and vertical forces, which are generated by the excitation imposed by the obstacle. By applying a proper signal analysis [30], the values of the frequencies and the damping of the main plane vibrating modes in the range 30–130 Hz are estimated. Such modes are usually four (see [29,30]) and depend on the forward velocity (Figure 19.35). Finally, the parameters C_b, r_b, and C_{cz} are computed as shown in [30] by exploiting the equations of motion of the system model in Figure 19.32.

Typical values of parameters C_b, r_b, and C_{cz} are found, respectively, in the ranges 8×10^5–20×10^5 N/m, 200–500 N s/m, and 100×10^3–300×10^3N/m.

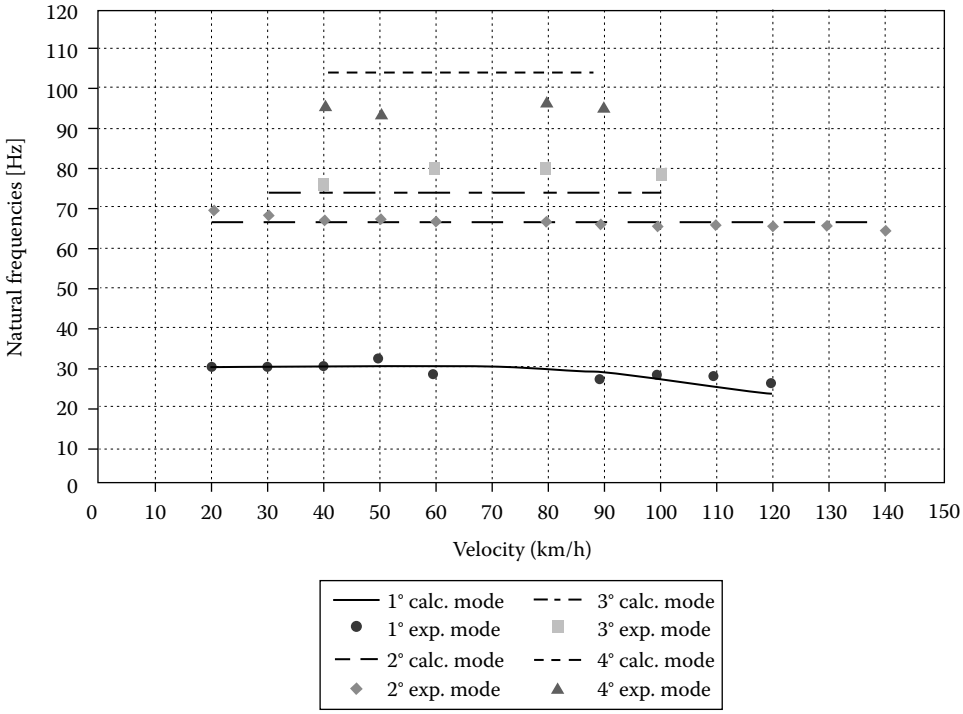

FIGURE 19.34 Measured and computed in plane natural frequencies of a rolling tire. The computations are performed by the model in Figure 19.32.

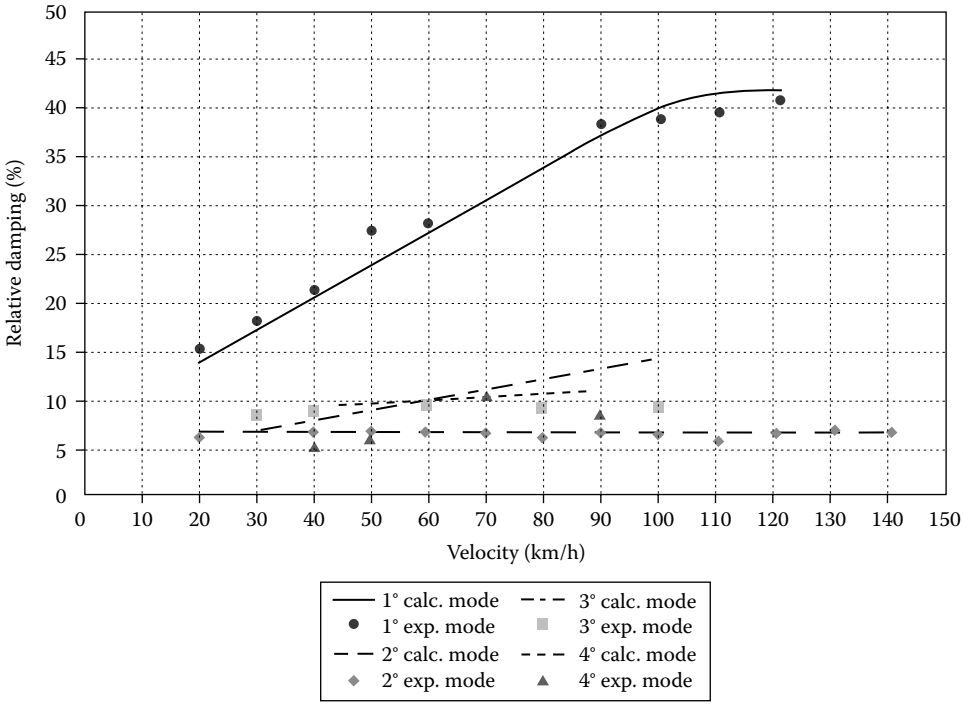

FIGURE 19.35 Measured and computed damping (r_b) of a rolling tire. The computations are performed by the model in Figure 19.32.

19.5.4 Other Standards or Regulations

Additionally, with respect to the historical regulations and standards reported in the previous sections, the following regulations or standards have been issued or are being issued at the time this chapter is written:

- ISO 4000: The standard is divided into two parts. The first part specifies the designation, dimensions, and load ratings of metric–series tires primarily intended for passenger cars. The second part refers to rims.
- ISO 28580: The standard specifies methods for measuring rolling resistance, under controlled laboratory conditions, for new pneumatic tires designed primarily for use on passenger cars, trucks, and buses. Tires intended for temporary use only are not included. The standard includes a method for correlating measurement results to allow interlaboratory comparisons. Measurement of tires using this method enables comparisons to be made between the rolling resistance of new test tires when they are free-rolling straight ahead, in a position perpendicular to the drum outer surface, and in steady-state conditions. In measuring tire rolling resistance, it is necessary to measure small forces in the presence of much larger (vertical) forces. It is, therefore, essential that equipment and instrumentation of appropriate accuracy be used.
- ISO 15222: The standard specifies the method for measuring the relative wet grip braking performance index to a reference under loaded conditions for new tires for use on commercial vehicles on a wet-paved surface.
- REGULATION EC 661/2009: The regulation concerns type-approval requirements for the general safety of motor vehicles, their trailers and systems, components, and separate technical units intended therefore. Requirements for tires with regard to wet grip, rolling resistance, and rolling noise are included. The regulation refers to E/ECE/324/Rev.2/Add.116/Rev.2, E/ECE/TRANS/505/Rev.2/Add.116/Rev.2 Regulation No. 117, where uniform provisions concerning the approval of tires with regard to rolling, to sound emissions, and to adhesion on wet surfaces and/or to rolling resistance are reported.
- ASTM 1805: The standard refers to a test method for single wheel driving traction in a straight line on snow- and ice-covered surfaces.

19.6 CONCLUSIONS

The tire is a fascinating complex device. After more than 100 years the tire has been invented, there are still huge theoretical and experimental gaps to be covered. In the future, a continuous evolution toward cheaper and more effective processes is expected. New materials could dramatically change both the tire production and the tire performance.

20.1 INTRODUCTION

While transportation over paved roadways and railways is of vital importance to the economy of a developed society, locomotion over unprepared terrain still plays a significant role in a wide range of human endeavors, including farming, construction, logging, mining, exploration, recreation, cross-country transportation, and military operations. For a long period of time in the past, owing to the lack of understanding of the behavior of the terrain and of the mechanics of vehicle–terrain interaction, the development and design of off-road vehicles have been, by and large, guided by past experience and the "cut and try" methodology. In recent years, with the increasing globalization of the economy, improving the competitiveness in the world market has become a major focus of industry.

The empirical approach to the development of off-road vehicles adopted in the past has become extremely inefficient and prohibitively expensive. This has led to the recognition of the necessity of systematic studies of the principles underlying the rational development and design of off-road vehicles. The study of the performance of off-road vehicles and machinery in relation to their operating environment, the terrain, has now become known as *terramechanics* [1–4].

In off-road operations, various types of terrain, ranging from desert sand through soft mud to fresh snow, may be encountered. The properties of the terrain quite often impose severe limitations to the mobility of off-road vehicles. An adequate knowledge of the mechanical properties of the terrain and an understanding of its response to vehicular loading are, therefore, essential to the rational development and design of off-road vehicles to meet specific operational requirements. The role of terramechanics in the development of off-road vehicles is, perhaps, analogous to that of aerodynamics in the development of aircraft or that of hydrodynamics in the design of marinecraft.

On a given terrain, the performance of an off-road vehicle is to a great extent dependent upon the manner in which the vehicle interacts with the terrain. Consequently, an understanding of the mechanics of vehicle–terrain interaction is of importance to the rational development and design of off-road vehicles. The central issue is to establish a quantitative relationship between the performance and design of an off-road vehicle for a given operating environment. In this chapter, various methods for the study of vehicle–terrain interaction are briefly reviewed.

20.2 APPLICATIONS OF THE THEORY OF ELASTICITY TO THE ANALYSIS OF STRESS DISTRIBUTION IN THE TERRAIN UNDER VEHICULAR LOADS

Certain types of terrain, such as dense soil, may be idealized as an elasto-plastic material. When the stress level in the terrain does not exceed a certain limit, it may be assumed to exhibit elastic behavior. The idealization of the terrain as an elastic medium has found applications in the prediction of stress distribution in the soil, in connection with the study of soil compaction due to vehicular loading [5].

The prediction of stress distribution in an elastic medium subject to any type of loading on the surface may be based on the analysis of the distribution of stresses under a point load. A method was developed by Boussinesq for predicting the stress distribution in a semi-infinite, homogeneous, isotropic, elastic medium subject to a vertical point load on the surface [1,3]. It gives the following expressions for the vertical stress σ_z at a point defined by the coordinates shown in Figure 20.1:

$$\sigma_z = \frac{3W}{2\pi} z^3 (x^2 + y^2 + z^2)^{-5/2} = \frac{3W}{2\pi[1 + (r/z)^2]^{5/2} z^2}$$

$$= \frac{3W}{2\pi R^2} \left(\frac{z}{R} \right)^3 = \frac{3W}{2\pi R^2} \cos^3 \theta \tag{20.1}$$

where

$R = (x^2 + y^2 + z^2)^{1/2}$

$\cos \theta = z/R$

When polar coordinates are used, the radial stress σ_r is given by

$$\sigma_r = \frac{3W}{2\pi R^2} \cos \theta \tag{20.2}$$

It is interesting to note that the stresses are independent of the modulus of elasticity of the material and that they are only functions of the load applied and the distance from the point of application of the load. It should be mentioned that Equations 20.1 and 20.2 are only valid for predicting stresses at points not too close to the point of application of the load. The material in the immediate vicinity of the point load does not behave elastically.

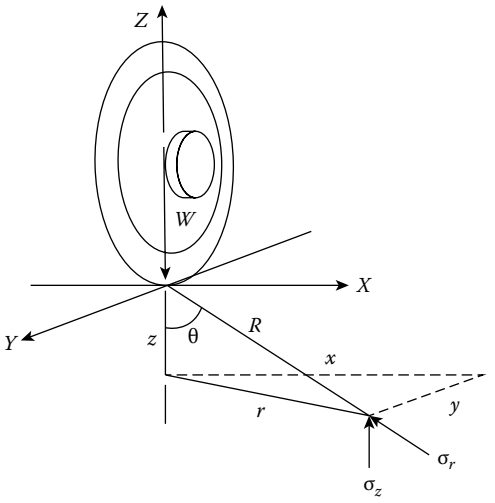

FIGURE 20.1 Stresses at a point in a semi-infinite elastic medium subject to a point load on the surface. (Reproduced from Bekker, M.G., *Theory of Land Locomotion*, University of Michigan Press, Ann Arbor, MI, 1956, with permission of the University of Michigan Press.)

It should be pointed out that the use of the theory of elasticity for predicting stresses in the field produces approximate results only. Measurements have shown that the stress distribution in the soil deviates from that computed using Boussinesq's equation [5]. There is a tendency for the compressive stresses in the soil to concentrate around the loading axis. This tendency becomes greater when the soil becomes more plastic due to increased moisture content. In view of this, various semiempirical equations have been proposed to account for the different characteristics of various types of soil. Frohlich introduced a concentration factor v to Boussinesq's equations. The factor v reflects the behavior of different types of soil under different conditions. Introducing the concentration factor v, the expressions for the vertical and radial stresses in the soil subject to a point load on the surface take the following forms:

$$\sigma_z = \frac{vW}{2\pi R^2}\cos^v \theta \tag{20.3}$$

$$\sigma_r = \frac{vW}{2\pi R^2}\cos^{v-2} \theta \tag{20.4}$$

The value of the concentration factor v depends on the type of soil and its moisture content. It varies from 4 for hard, dry soil to 6 for wet soil. For fairly moist and relatively dense soil, the value of v is 5. It should be noted that for an elastic medium, the value of v is 3 and that Equations 20.3 and 20.4 become identical to Equations 20.1 and 20.2, respectively.

Based on the analysis of stress distribution under a point load, the distribution of stresses in a soil under a variety of loading conditions may be predicted using the principle of superposition [1,3]. For instance, for a circular contact area with a radius r_o and a uniform contact pressure p_o shown in Figure 20.2, the vertical stress at a depth z below the center of the contact area may be determined by considering the load applied on the contact surface consisting of a number of discrete point loads. Each of these point loads is $dW = p_o\, dA = p_o\, rdrd\theta$. Hence, in accordance with Equation 20.1, for a terrain exhibiting elastic behavior with $v = 3$,

$$d\sigma_z = \frac{3p_o rdrd\theta}{2\pi[1+(r/z)^2]^{5/2}z^2} \tag{20.5}$$

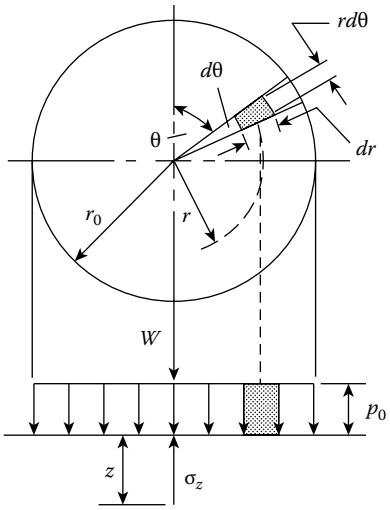

FIGURE 20.2 Vertical stresses in a semi-infinite elastic medium below the center of a circular loading area with uniform contact pressure. (Reproduced from Bekker, M.G., *Theory of Land Locomotion*, University of Michigan Press, Ann Arbor, MI, 1956, with permission of the University of Michigan Press.)

The resultant vertical stress σ_z at a depth z below the center of the circular contact area is then equal to the sum of the stresses produced by the point loads, each of which is $p_0\, rdrd\theta$. It can be computed by a double integration:

$$\sigma_z = \frac{3p_0}{2\pi}\int_0^{r_0}\int_0^{2\pi}\frac{rdrd\theta}{[1+(r/z)^2]^{5/2}z^2} = p_0\left[1-\frac{z^3}{(z^2+r_0^2)^{3/2}}\right] \tag{20.6}$$

For a terrain with value of v other than 3, the resultant vertical stress below the center of the contact area can be predicted following a similar approach to that described earlier. For instance, when $v = 4$, the resultant vertical stress σ_z at a depth z below the center of the circular contact area is expressed by [3]

$$\sigma_z = p_0\left[1-\frac{1}{\left[1+\left(r_0/z\right)^2\right]^2}\right] \tag{20.7}$$

The previously noted approach can be applied to the prediction of the stress distribution in the soil under a tire, if the contact area of the tire and the pressure distribution over the contact surface are known. Figure 20.3 shows the distributions of the major principal stress in a soil having normal field density and moisture content and with $v = 5$ under tires of different sizes and normal loads but with the same tire inflation pressure [5]. It shows that at the same tire inflation pressure, the stress can penetrate deeper with larger tires carrying heavier loads. This is because the larger tire has a larger contact area, and as a result, the stress at the same depth increases as shown in Figure 20.3, although the pressure applied on the surface of the soil remains the same. Figure 20.4 shows the effects of soil conditions on the stress distribution in the soil under a tire. In hard, dry, and dense soil with $v = 4$, the lines of equal major principal stress, commonly known as stress bulbs, are approximately circular. For wet soil with $v = 6$, the stress is more concentrated toward the center of the loading area. For tires with lugs, such as tractor tires, the pressure distribution over the contact area is dependent on soil

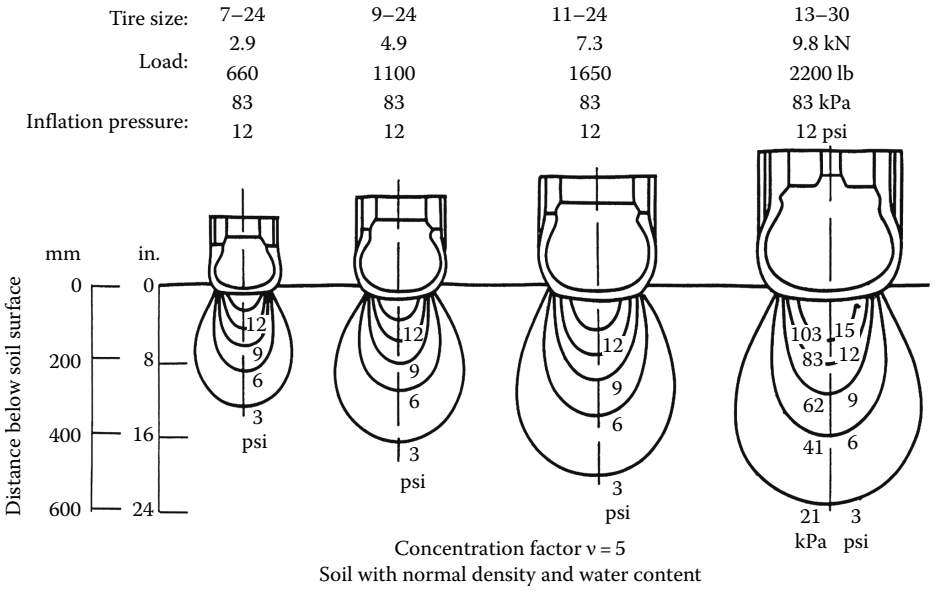

FIGURE 20.3 Distribution of major principal stresses in a soil under the loading of various tires. (Reproduced from Sohne, W., Fundamentals of pressure distribution and soil compaction under tractor tires, *Agr. Eng.*, 39(5), 276–281, 1958. conditions. In hard soil, the lugs of the tire may carry the entire load. The pressure over the contact area of the lugs may be three to four times higher than that of an equivalent tire without lugs. In wet soil, because of the sinkage of the tire, there may be hardly any difference between the contact pressure under the lugs and that under the carcass. In principle, the stress distribution in the soil under tires with lugs may be estimated following an approach similar to that described earlier.

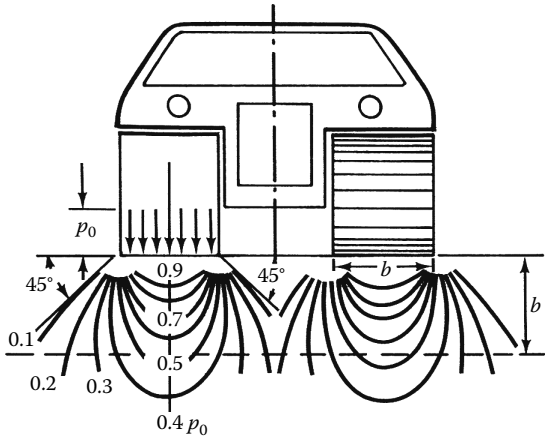

FIGURE 20.5 Distribution of vertical stresses in a semi-infinite elastic medium under a tracked vehicle. (Reproduced from Bekker, M.G., *Theory of Land Locomotion*, University of Michigan Press, Ann Arbor, MI, 1956, with permission of the University of Michigan Press.)

The stress distribution in the soil under a tracked vehicle may be predicted in a similar way. Figure 20.5 shows the distribution of vertical stress in a soil with $v = 3$ (i.e., the soil is assumed to be elastic) under the loading of a tracked vehicle [1,3]. In the analysis, the track is idealized as a rigid footing with a high ratio of track length to width and with a uniform contact pressure. It is interesting to note from Figure 20.5 that at a depth equal to the width of the track, the vertical stress under the center of the track is approximately 50% of the pressure applied on the contact surface and that it practically vanishes at a depth equal to twice the width of the track. The boundaries of the stress bulbs, for all practical purposes, may be assumed as being sloped at an angle of 45° with the horizontal, as shown in Figure 20.5. Outside the boundaries, the stress in the soil is negligible.

It should be pointed out that in practice the applications of the theory of elasticity to the analysis of vehicle–terrain interaction are limited, as it is applicable only to dense soil where soil deformation is small.

20.3 APPLICATIONS OF THE THEORY OF PLASTIC EQUILIBRIUM TO THE PREDICTION OF VEHICLE TRACTION

When the vehicular load applied to the terrain surface exceeds a certain limit, the stress level within a certain boundary of the terrain may reach a threshold that will initiate plastic flow of the terrain material. The state that precedes plastic flow is usually referred to as plastic equilibrium. The transition from the state of plastic equilibrium to that of plastic flow represents the failure of the terrain material.

There are a number of proposed criteria for the failure of soils and other similar materials. A widely used criterion is that due to Mohr–Coulomb. It postulates that the material at a point will fail if the shear stress at that point satisfies the following condition [1,3,4]:

$$\tau = c + \sigma \tan \phi \tag{20.8}$$

where

τ is the shear strength of the material
c is the apparent cohesion
σ is the normal stress
ϕ is the angle of internal shearing resistance of the material

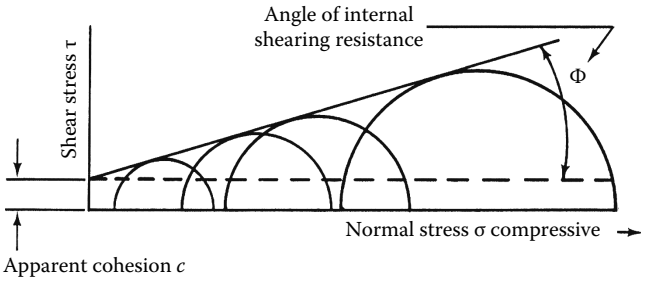

FIGURE 20.6 Mohr–Coulomb failure criterion. (Reproduced from Wong, J.Y., *Theory of Ground Vehicles*, 4th edn., John Wiley, New York, 2008.)

Cohesion of the material is the bond that cements particles together irrespective of the normal pressure exerted by one particle upon the other. On the other hand, particles of frictional material can be held together only when a normal pressure exists between them. Thus, the shear strength of saturated clay and the like does not depend on the normal load, whereas the shear strength of dry sand and the like increases with an increase in the normal pressure. For most soils, they usually exhibit both cohesive and frictional behavior.

The meaning of the Mohr–Coulomb failure criterion may be illustrated with the aid of the Mohr circle of stress, as shown in Figure 20.6. If specimens of a soil are subject to different states of stress, for each mode of failure, a Mohr circle can be constructed. If a straight line enveloping the set of Mohr circles is drawn, it will be in the form of Equation 20.8, with the cohesion of the soil being determined by the intercept of the enveloping straight line with the shear stress axis and the angle of internal shearing resistance being represented by its slope. The Mohr–Coulomb failure criterion is simply that if a Mohr circle representing the state of stress at a point in the soil touches the envelope shown in Figure 20.6, failure will take place at that point.

The shear strength parameters c and ϕ may be measured by a variety of devices [3,4]. The triaxial apparatus and the translational shear box are commonly used in civil engineering. For vehicle mobility study, however, annular shear plates (shear rings) are usually used to obtain the shear strength of terrain in the field [3,4].

The Mohr–Coulomb failure criterion can be directly applied to the prediction of the maximum thrust that an off-road vehicle can develop on a given terrain. It should be noted that the development of thrust is a result of the vehicle running gear shearing the terrain surface, as shown in Figure 20.7. For instance, if a tracked vehicle has a total track contact area A and a uniform contact pressure σ, then using Equation 20.8, the maximum thrust F_{max} of the tracked vehicle may be estimated as follows:

$$F_{max} = \tau A = (c + \sigma \tan \phi)A = cA + W \tan \phi \tag{20.9}$$

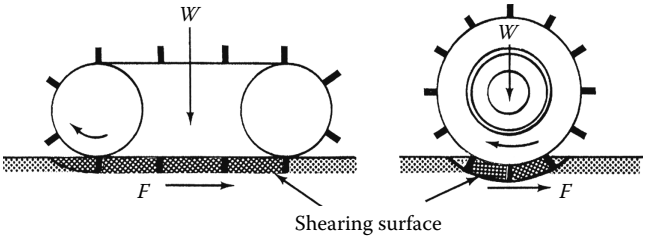

FIGURE 20.7 Shearing action of a track and a wheel. (Reproduced from Wong, J.Y., *Theory of Ground Vehicles*, 4th edn., John Wiley, New York, 2008.)

where W is the vehicle weight that is equal to the uniform normal pressure σ multiplied by the total track contact area A.

From Equation 20.9, it is seen that on a cohesive terrain with negligible angle of internal shearing resistance, such as wet clay, the maximum thrust of the vehicle is primarily dependent on the total track contact area and the cohesion of the terrain, while vehicle weight has little effect on the development of thrust. On the other hand, on dry desert sand where cohesion is negligible, the maximum thrust will be primarily dependent upon the vehicle weight and the angle of internal shearing resistance of the sand, while track contact area has little effect on the thrust.

Another important application of the theory of plastic equilibrium is the development of the theory of passive earth pressure [1,3]. It can be used in the prediction of the force acting on a bulldozer blade or of the thrust developed by a lug (grouser) of a wheel, as shown in Figure 20.8 [3]. Based on the theory of passive earth pressure, the force F_p acting on a vertical bulldozer blade with a smooth surface may be calculated as follows [3]:

$$F_p = b\int_0^{h_b} \sigma_p dz = b\int_0^{h_b} \left(\gamma_s z N_\phi + 2c\sqrt{N_\phi}\right) dz$$

$$= b\left(\frac{1}{2}\gamma_s h_b^2 N_\phi + 2ch_b\sqrt{N_\phi}\right) \tag{20.10}$$

where

b is the width of the bulldozer blade
σ_p is the passive earth pressure
γ_s is the weight density of the terrain
h_b is the cutting depth of the blade
N_ϕ is called flow value that is equal to $\tan^2(45° + \phi/2)$
c is the cohesion
ϕ is the angle of internal shearing resistance of the terrain

A similar approach may be followed to estimate the thrust developed by a lug of a cage wheel, such as that used in paddy field or that attached to a tire as a traction-aid device used in wet soil. It should be noted, however, that the lug may behave in one of two ways. If the spacing between the lugs is too small that the space between them is filled up with soil, then the shearing of the soil takes place across the lug tips. Under these circumstances, the major effect of the lugs would be the increase of the effective diameter of the wheel. On the other hand, if the spacing between the lugs is large enough that the soil fails in the manner shown in Figure 20.8, then the behavior of the lug

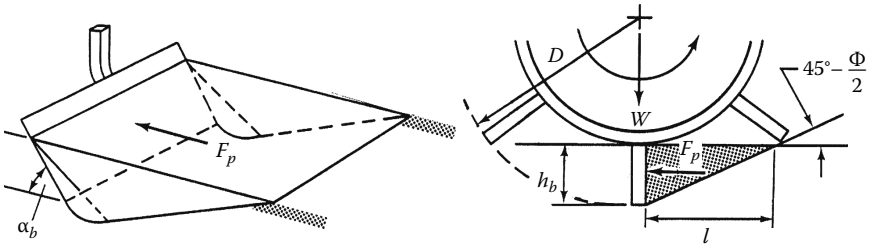

FIGURE 20.8 Interaction of a soil cutting blade and a grouser of a wheel with soil. (Reproduced from Wong, J.Y., *Theory of Ground Vehicles*, 4th edn., John Wiley, New York, 2008.)

will be similar to that of a bulldozer blade. In this case, the thrust developed by a lug with a smooth surface in the vertical position may be predicted using Equation 20.10. It should be mentioned that the shearing forces developed on the vertical surfaces on both sides of the lug may increase the total thrust and that they should be taken into account when the height of the lug is large and its penetration into the soil is significant [3,4].

It should be pointed out that in practice, a bulldozer blade is usually not vertical and the angular position of a lug on a wheel varies as it rotates. Furthermore, the bulldozer blade or the lug surface is usually not smooth and there is shear stress acting on the interface. As a result, the interaction between an inclined bulldozer blade or a lug at various angular positions and the terrain is more complicated than that described earlier, and Equation 20.10 does not provide accurate predictions of the interacting forces. Methods for predicting the forces acting on an inclined bulldozer blade with non-smooth contact surface or a lug with rough surface at various angular positions are described in Ref. [3].

It should also be noted that strictly speaking the theory of plastic equilibrium is only applicable to plastic material with little compressibility. In reality, natural terrain has varying degrees of compressibility and does not behave like a perfectly plastic material. Also, the theory of plastic equilibrium can only be used to predict the loads or forces that cause failure (or plastic flow) of the terrain material and cannot be used to estimate its deformation [3,4]. All these impose limitations to the applications of the theory of plastic equilibrium to the study of vehicle–terrain interaction [3].

20.4 EMPIRICAL METHODS FOR PREDICTING OFF-ROAD VEHICLE PERFORMANCE BASED ON THE CONE INDEX

In the past, owing to the lack of understanding of the mechanics of vehicle–terrain interaction, empirical methods have been developed for predicting off-road vehicle performance. Some of these methods are still being used today, primarily for operational planning or for preliminary evaluation of vehicle candidates for procurement purposes.

The general approach to the development of empirical methods for predicting off-road vehicle performance is to conduct tests of a select group of vehicles considered representative over a range of terrains of interest. The terrain is usually identified (or classified) by simple measurements or field observations. The results of vehicle performance testing and the terrain characteristics identified are then empirically correlated. This can lead to the development of empirical relationships for evaluating terrain trafficability on the one hand and vehicle mobility on the other.

Empirical methods based on the measurements made by a cone penetrometer shown in Figure 20.9 to identify terrain were originally developed by the U.S. Army Waterways Experiment Station (WES) (now known as the U.S. Army Engineer Research and Development Center, Vicksburg, Mississippi, United States) during World War II. The commonly used cone penetrometer has a 30° circular cone with a 0.5 in.^{2} (3.23 cm^2) base area.

These empirical methods were originally intended to provide military intelligence and reconnaissance personnel with a simple means to assess vehicle mobility on a "go/no-go" basis in fine- and coarse-grained soils. Fine-grained soils are silt or clayey soils for which 50% or more by weight of grains are smaller than 0.074 mm in diameter (or able to pass through a No. 200 sieve). Coarse-grained soils are beach or desert soils, usually containing less than 7% of the grains smaller than 0.074 mm in diameter, or soils containing 7% or more of the grains smaller than 0.074 mm in diameter but not in a wet condition, that is, they are non-remoldable. These empirical methods form the basis for the subsequent development of the NATO (North Atlantic Treaty Organization) Reference Mobility Model (NRMM).

20.4.1 Empirical Method for Predicting Tracked Vehicle Performance

In the method developed by the U.S. Army WES, an empirical equation is first used to calculate the mobility index (*MI*) of a tracked vehicle [3,6]. The *MI* for tracked vehicles is expressed by

$$\text{Mobility index} = \left(\frac{\text{contact pressure factor} \times \text{weight factor}}{\text{track factor} \times \text{grouser factor}} + \text{bogie factor} - \text{clearance factor} \right) \times \text{engine factor} \times \text{transmission factor} \tag{20.11}$$

where

$$\text{Contact pressure factor} = \frac{\text{gross weight, lb}}{\text{area of tracks in contact with ground, in.}^2}$$

Weight factor: less than 50,000 lb (222.4 kN) = 1.0
50,000 – 69,999 lb (222.4 – 311.4 kN) = 1.2
70,000 – 99,999 lb (311.4 – 444.8 kN) = 1.4
100,000 lb (444.8 kN) or greater = 1.8

Track factor = track width, in./100

Grouser factor: grouser less than 1.5 in. (3.8 cm) high = 1.0
grouser more than 1.5 in. (3.8 cm) high = 1.1

$$\text{Bogie factor} = \frac{\text{gross weight, lb, divided by 10}}{\text{total number of bogies} \times \text{area of one track shoe, in.}^2}$$

Clearance factor = clearance, in./10
Engine factor: ≥10 hp/ton of vehicle weight = 1.0
<10 hp/ton of vehicle weight = 1.05
Transmission factor: automatic = 1.0; manual = 1.05

Based on the *MI,* a parameter called the vehicle cone index (*VCI*) is calculated. The *VCI* represents the minimum strength of a soil in the critical layer that permits a given vehicle to successfully make a specific number of passes, usually one pass or 50 passes. For instance, the values of *VCI* for one pass and 50 passes, VCI_1 and VCI_{50}, for fine-grained soils may be calculated from the *MI* using the following empirical equations:

$$VCI_1 = 7.0 + 0.2MI - \left(\frac{39.2}{MI + 5.6} \right) \tag{20.12}$$

$$VCI_{50} = 19.27 + 0.43MI - \left(\frac{125.79}{MI + 7.08} \right) \tag{20.13}$$

The soil strength is described in terms of either the rating cone index (*RCI*) for fine-grained soils or the cone index (*CI*) for coarse-grained soils. The *CI* is the force per unit cone base area measured by the cone penetrometer. While the *CI* is commonly used as a parameter with no dimensions attached, it is in fact the penetration force in pounds divided by the area of the cone base in square inches, and thus, it has the unit of pressure. The *RCI* is the *CI* of the soil after being remolded following a recommended procedure [6]. The critical layer referred to earlier varies with the type and weight of the vehicle and soil strength profile. For freely draining or clean sand, it is usually the 0–6 in. (0–15 cm) layer. For fine-grained soils and poorly drained sands with fines, the critical layer is usually the 0–6 in. (0–15 cm) layer for one pass and the 6–12 in. (15–30 cm) layer for 50 passes.

After the *VCI* and soil strength have been determined, the values of the performance parameters of a tracked vehicle, such as the net maximum drawbar pull coefficient (the ratio of maximum drawbar pull to vehicle weight), maximum slope negotiable, and towed motion resistance coefficient (the ratio of towed motion resistance to vehicle weight), are then empirically determined as functions of vehicle type, number of passes to be completed, and the excess of *RCI* over *VCI* (i.e., *RCI* − *VCI*) for fine-grained soils or *CI* for coarse-grained soils [6]. For instance, Figure 20.10 shows the empirical relations between the net maximum drawbar pull coefficient (or maximum slope negotiable) and *RCI* − *VCI* for tracked vehicles with different grouser heights and for wheeled vehicles over

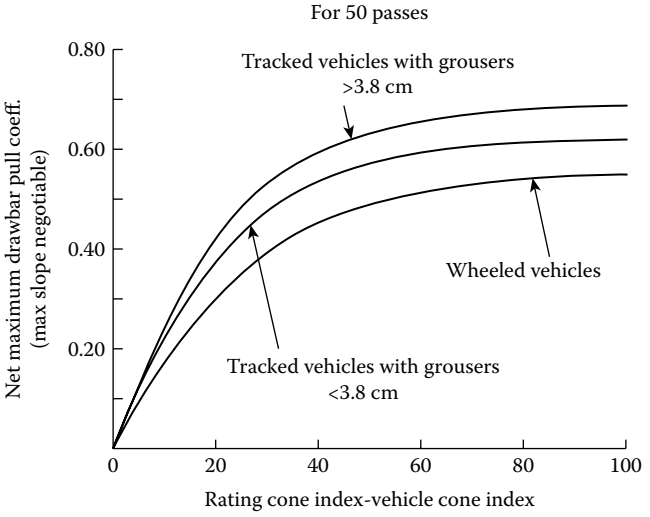

FIGURE 20.10 Variations of net maximum drawbar pull coefficient with the excess of *RCI* over *VCI* on level, fine-grained soil. (Reproduced from Rula, A.A. and Nuttall, C.J., An analysis of ground mobility models (ANAMOB), Technical Report No. M-71-4, U.S. Army Corps of Engineers Waterways Experiment Station, Vicksburg, MS, 1971.)

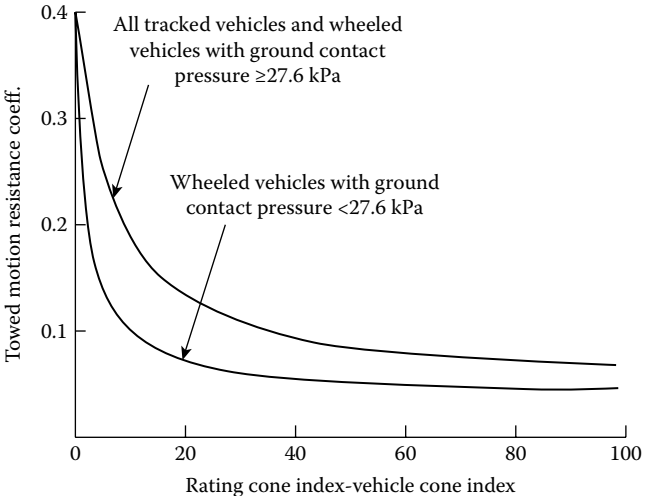

FIGURE 20.11 Variations of the first-pass towed motion resistance with the excess of *RCI* over *VCI* on level, fine-grained soil. (Reproduced from Rula, A.A. and Nuttall, C.J., An analysis of ground mobility models (ANAMOB), Technical Report No. M-71-4, U.S. Army Corps of Engineers Waterways Experiment Station, Vicksburg, MS, 1971.)

fine-grained soils. The empirical relations between the first-pass towed motion resistance coefficient and the excess of *RCI* over *VCI* for tracked and wheeled vehicles operating on fine-grained soils are shown in Figure 20.11.

20.4.2 Empirical Method for Predicting Wheeled Vehicle Performance

Similar to the empirical method developed by WES for predicting tracked vehicle performance, in this method an empirical equation is first used to calculate the *MI* of an off-road wheeled vehicle [3,6]. The *MI* for wheeled vehicles is expressed by

$$\text{Mobility index} = \left(\frac{\text{contact pressure factor} \times \text{weight factor}}{\text{tire factor} \times \text{grouser factor}} + \text{wheel load factor} - \text{clearance factor} \right) \times \text{engine factor} \times \text{transmission factor} \tag{20.14}$$

where

$$\text{Contact pressure factor} = \frac{\text{gross weight, lb}}{\text{tire width} \times \text{tire radius} \times \text{no. of tires, in.}^2}$$

Weight Factor	Weight Range (lb)	Weight Factor (Y)
	<2,000 (8.9 kN)	$Y = 0.553X$
	2,000–13,500 (8.9–60 kN)	$Y = 0.033X + 1.050$
	13,501–20,000 (60–88.9 kN)	$Y = 0.142X - 0.420$
	>20,000 (88.9 kN)	$Y = 0.278X - 3.115$

where X = gross weight, kips/no. of axles

Tire factor = (10 + tire width, in.)/100
Grouser factor: with chains = 1.05
without chains = 1.0
Wheel load factor = gross weight, kips/(no. of axles × 2)
Clearance factor = clearance, in./10
Engine factor: ≥ 10 hp/ton of vehicle weight = 1.0
< 10 hp/ton of vehicle weight = 1.05
Transmission factor: automatic = 1.0; manual = 1.05

Similar to the empirical method for predicting tracked vehicle performance, the *MI* of wheeled vehicles is used to determine a *VCI*. For a self-propelled, wheeled vehicle, the *VCI* for fine-grained soils is related to the *MI* by the following empirical equations:

For one pass, if $MI \leq 115$,

$$VCI_1 = 11.48 + 0.2MI - \left(\frac{39.2}{MI + 3.74}\right) \tag{20.15}$$

and if $MI > 115$,

$$VCI_1 = 4.1MI^{0.446} \tag{20.16}$$

For 50 passes,

$$VCI_{50} = 28.23 + 0.43MI - \left(\frac{92.67}{MI + 3.67}\right) \tag{20.17}$$

Lately, a correction factor (*CF*), taking into account the effect of tire deflection, has been introduced into the calculations of *VCI*. The *CF* is expressed by

$$CF = \left(\frac{0.15}{\delta/h}\right)^{0.25} \tag{20.18}$$

where
δ is the tire deflection
h is the unloaded section height of the tire

The corrected value of *VCI* is obtained by multiplying Equation 20.15, 20.16, or 20.17 by the *CF* given by Equation 20.18.

After the *VCI* of a wheeled vehicle and the strength of the soil have been determined, the net maximum drawbar pull coefficient (maximum slope negotiable) and the towed motion resistance coefficient of the wheeled vehicle can then be predicted using empirical relations shown in Figures 20.10 and 20.11, respectively. The values of the performance parameters are related to the excess of the *RCI* over the *VCI* for fine-grained soils.

20.5 EMPIRICAL METHODS FOR PREDICTING VEHICLE MOBILITY BASED ON THE MEAN MAXIMUM PRESSURE

Another type of empirical method for predicting the mobility of off-road vehicles is based on the concept of mean maximum pressure (*MMP*) proposed by Rowland [7,8]. *MMP* is defined as the mean value of the maxima occurring under all of the road wheel stations.

Empirical equations for predicting the value of *MMP* of track systems with different design features are given in the succeeding text.

For link and belt tracks on rigid road wheels,

$$MMP = \frac{1.26W}{2n_r A_l b\sqrt{t_t D}}, \text{kPa} \tag{20.19}$$

For belt tracks on pneumatic tired road wheels,

$$MMP = \frac{0.5W}{2n_r b\sqrt{D\delta}}, \text{kPa} \tag{20.20}$$

where

W is the vehicle weight in kN
n_r is the number of wheel stations in one track
A_l is the rigid area of link (or belt track cleat) as a proportion of $b \times t_t$
b is the width of the track or pneumatic tire in m
t_t is the track pitch in m
D is the outer diameter of the road wheel or pneumatic tire in m
δ is the radial deflection of the pneumatic tire under load in m

Table 20.1 shows the values of *MMP* for various tracked vehicles calculated using the empirical formulas described earlier [8].

To evaluate whether a particular vehicle with a specific value of *MMP* will have adequate mobility over a given terrain, a set of desirable values of the *MMP* for different levels of mobility on various types of terrain is proposed by Rowland, as shown in Table 20.2.

It should be pointed out that in the empirical Equations 20.19 and 20.20, terrain characteristics are not explicitly taken into account in the calculations of *MMP*. Thus, the values of *MMP* calculated are independent of terrain conditions. In reality, the pressure distribution under a tracked vehicle, and hence the actual value of *MMP*, is strongly influenced by terrain characteristics [3,4,9].

TABLE 20.1
Values of the Mean Maximum Pressure (*MMP*) of Some Tracked Vehicles

Vehicle	Track Configuration	Weight (kN)	Mean Maximum Pressure (kPa)
All Terrain Vehicle Bv206	Belt track	62	34
Armored Personnel Carrier M113	Link track	114	121
Caterpillar D4 tractor	Link track	59	82
Caterpillar D7 tractor	Link track	131	80

It has been shown that the values of *MMP* calculated using Rowland's empirical formulas are significantly different from those measured and that the effects of vehicle design parameters on the values of *MMP* are not accurately represented by the empirical formulas on many types of terrain [9]. Furthermore, Equation 20.19 or 20.20, together with Table 20.2, can only be employed to predict vehicle performance qualitatively on a "go/no-go" basis and cannot be used to quantitatively predict the performance of the vehicle, such as its motion resistance, thrust, drawbar pull, and tractive efficiency.

In summary, empirical methods are simple to use and may be useful in estimating the performance of vehicles with design features similar to those that have been tested under similar operating conditions. It should be pointed out, however, that empirical relations should not normally be extrapolated beyond the conditions upon which they were derived. Consequently, empirical methods have inherent limitations. For instance, it is uncertain that they can play a useful role in the evaluation of vehicles with new design features or in new operating environments.

20.6 SEMIEMPIRICAL METHODS FOR PREDICTING THE PERFORMANCE OF TRACKED VEHICLES

20.6.1 Bevameter Techniques

One of the widely known semiempirical methods for predicting the performance of off-road vehicles is that due to M.G. Bekker [2–4]. This method is based on terrain data measured using an instrument conceived by Bekker, which has now become known as the bevameter (Bekker value meter). The bevameter was developed on the premise that terrain properties should be measured under loading conditions similar to that of the vehicle running gear. The vehicle running gear exerts normal load to the terrain surface resulting in sinkage and causing motion resistance. It also applies shear load to the terrain surface resulting in the development of thrust and the associated slip, as shown in Figure 20.12. To simulate these, the bevameter is designed to perform two sets of tests: one is a set of penetration tests and the other is a set of shear tests. In the penetration tests, a plate of suitable size is used to simulate the contact area of the vehicle running gear, and the pressure–sinkage (p–z) relationship of the terrain is measured, as shown in Figure 20.12. This relationship is used to predict the normal pressure distribution on the vehicle–terrain interface, as well as vehicle sinkage. To minimize the uncertainty

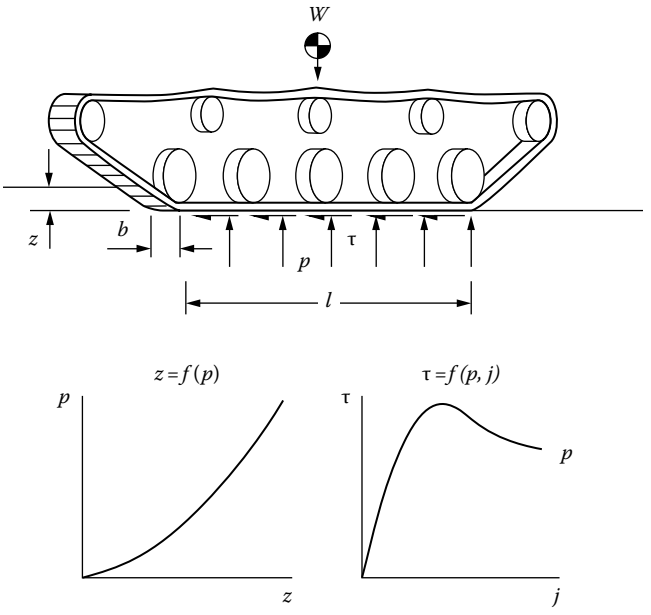

FIGURE 20.12 The interaction between a vehicle running gear and terrain. (Reproduced from Wong, J.Y., *Theory of Ground Vehicles*, 4th edn., John Wiley, New York, 2008.)

in applying the measured data to the prediction of the performance of full-size vehicles, it is preferable that the size of the plate used in the penetration tests be comparable to that of the contact area of a track link or a tire. In the shear tests, a shear ring or a rectangular shear plate is used to simulate the shearing action of the vehicle running gear. The shear stress–shear displacement relationship (τ–j), as shown in Figure 20.12, and the shear strength of the terrain (as described in Section 20.3) are measured. This provides the necessary data for predicting the shear stress distribution on the vehicle–terrain interface and the thrust–slip relationship of the vehicle [2–4].

After terrain data have been collected by the bevameter, they should be properly processed and characterized so that they may be integrated into a framework for predicting the performance of off-road vehicles [3,4].

20.6.1.1 Pressure–Sinkage Relationships

A set of pressure–sinkage curves measured in a sandy loam is shown in Figure 20.13. For most mineral terrain, Bekker proposed the following equation for characterizing the pressure–sinkage relationship:

$$p = \left(\frac{k_c}{b} + k_\phi \right) z^n \tag{20.21}$$

where

p is the pressure
b is the characteristic dimension of the plate, for a rectangular plate it is the width and for a circular plate it is the radius
z is the sinkage
n, k_c, and k_ϕ are pressure–sinkage parameters

For organic terrain (muskeg), snow-covered terrain with ice layers, and others, the pressure–sinkage relationships are different from that for mineral terrain described by Equation 20.21.

Detailed analysis of the pressure–sinkage characteristics of organic terrain (muskeg) and snow-covered terrain with ice layers may be found in Refs. [3,4,10,11]. The procedure for deriving the pressure–sinkage parameters from test data is described in Refs. [2–4]. Table 20.3 gives the values of n, k_c, and k_ϕ of a sample of terrains. More terrain data may be found in Refs. [2–4,10,12].

20.6.1.2 Shear Stress–Shear Displacement Relationships

A shear curve measured in a mineral terrain is shown in Figure 20.14. This type of shear curve can be characterized by an exponential equation of the following form:

$$\tau = \tau_{max}(1 - e^{-j/k}) = (c + \sigma \tan \phi)(1 - e^{-j/k}) \tag{20.22}$$

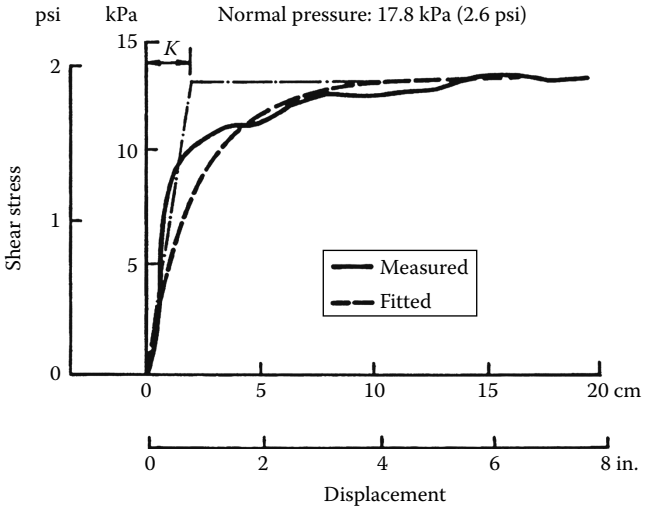

FIGURE 20.14 A shear curve of a simple exponential form. (Reproduced from Wong, J.Y., *Theory of Ground Vehicles*, 4th edn., John Wiley, New York, 2008.)

where

τ is the shear stress

τ_{max} is the maximum shear stress or shear strength of the terrain

c and ø are the cohesion and angle of internal shearing resistance of the terrain, respectively

j is the shear displacement

K is referred to as the shear deformation modulus

K may be considered as a measure of the magnitude of shear displacement required to develop the maximum shear stress. The value of K determines the shape of the shear curve. Its value may be represented by the distance between the vertical axis and the point of intersection of the straight line tangent to the shear curve at the origin and the horizontal line representing the maximum shear stress, as shown in Figure 20.14. The slope of the shear curve at the origin can be obtained by differentiating τ with respect to j in Equation 20.22:

$$\frac{d\tau}{dj} = \frac{\tau_{max}}{K} e^{-j/k}; \quad \text{when} \quad j = 0, \quad \frac{d\tau}{dj} = \frac{\tau_{max}}{K} \tag{20.23}$$

Thus, the value of K can be determined from the slope of the shear curve at the origin and the maximum shear stress τ_{max}. The value of K may also be taken as 1/3 of the shear displacement where the shear stress τ is 95% of the maximum shear stress τ_{max}.

For organic terrain (muskeg), brittle soil, frozen snow, etc., the shear stress–shear displacement relationships usually cannot be characterized by Equation 20.22. Detailed analysis of the shearing characteristics of organic terrain (muskeg), brittle soil, and frozen snow may be found in Refs. [3,4,13].

20.6.1.3 Response of Terrain to Repetitive Loading

When an off-road vehicle is in a straight line motion, an element of the terrain under the running gear is first subject to the load applied by the front wheel (or the leading road wheel in a track system). When the front wheel has passed, the load on the terrain element is released. Load is reapplied as the succeeding wheel rolls over it. A terrain element is thus subject to the repetitive loading of the consecutive wheels of a multi-axle wheeled vehicle or the road wheels of a tracked vehicle.

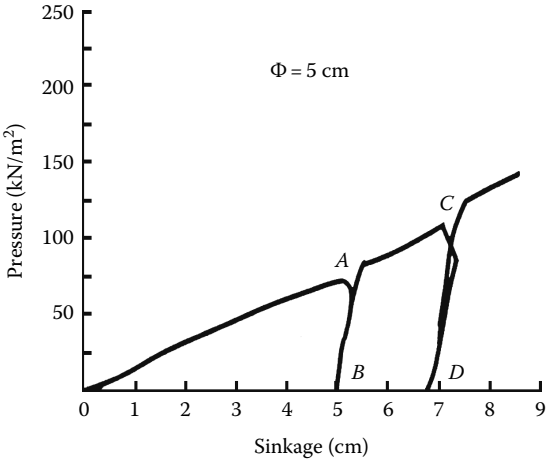

FIGURE 20.15 Response to repetitive normal load of a mineral terrain. (Reproduced from Wong, J.Y., *Theory of Ground Vehicles*, 4th edn., John Wiley, New York, 2008.)

The loading–unloading–reloading cycle continues until the rear wheel of the vehicle has passed over it. To realistically predict the normal pressure distribution under a moving vehicle and hence its performance, the response of the terrain to repetitive loading must be measured. The response of a mineral terrain to repetitive normal load is shown in Figure 20.15. It can be seen that the pressure initially increases with sinkage along *OA*. However, when the load applied to the terrain is reduced at *A*, the pressure–sinkage relationship during unloading follows line *AB*. When the load is reapplied at *B,* the pressure–sinkage relationship follows, more or less, the same path as that during unloading. When the reapplied load exceeds that at which the preceding unloading begins (point *A* in Figure 20.15), additional sinkage results. With the further increase of pressure, the pressure–sinkage relationship appears to follow the continuous loading path as *AC* shown in the figure. The characteristics of the second unloading–reloading cycle that begins at *C* are similar to those of the first one. For organic terrain (muskeg) or snow-covered terrain, the response to repetitive loading is different from that shown in Figure 20.15. Further information may be found in Refs. [3,4].

It should be emphasized that to realistically predict the performance of off-road vehicles, the response of terrain to repetitive loading must be taken into consideration, in addition to the pressure–sinkage and shearing characteristics described in previous sections.

20.6.2 Motion Resistance of a Track

In the semiempirical method proposed by Bekker, it is assumed that a track is equivalent to a rigid footing and that the normal reaction exerted on the track by the terrain can be equated to that beneath a sinkage plate at the same depth in a pressure–sinkage test, as described in Section 20.6.1.1. If the center of gravity of the vehicle is located at the midpoint of the track contact length, the normal pressure distribution may be assumed to be uniform. Using the pressure–sinkage relationship given by Equation 20.21, the sinkage z_0 of the track is expressed by

$$z_0 = \left(\frac{p}{k_c/b + k_\phi} \right)^{1/n} = \left(\frac{W/bl}{k_c/b + k_\phi} \right)^{1/n} \tag{20.24}$$

where

p is the normal pressure

W is the normal load on a track

b and l are the width and length of the track in contact with the terrain, respectively

The work done in compacting the terrain and making a rut of width b, length l, and depth z_0 is given by

$$\text{Work} = bl\int_0^{z_o} pdz = bl\int_0^{z_o}\left(\frac{k_c}{b}+k_\phi\right) z^n\, dz = bl\left(\frac{k_c}{b}+k_\phi\right)\left(\frac{z_0{}^{n+1}}{n+1}\right) \tag{20.25}$$

Substituting for z_0 from Equation 20.24 yields

$$\text{Work} = \frac{bl}{(n+1)(k_c/b+k_\phi)^{1/n}}\left(\frac{W}{bl}\right)^{(n+1)/n} \tag{20.26}$$

If the track is pulled a distance l in the horizontal direction, the work done by the pulling force, which is equal to the magnitude of the motion resistance due to terrain compaction R_c, can be equated to the vertical work done in making a rut of length l, as expressed by Equation 20.26:

$$R_c l = \frac{bl}{(n+1)(k_c/b+k_\phi)^{1/n}}\left(\frac{W}{bl}\right)^{(n+1)/n} \tag{20.27}$$

and

$$R_c = \frac{1}{(n+1)b^{1/n}(k_c/b+k_\phi)^{1/n}}\left(\frac{W}{l}\right)^{(n+1)/n} \tag{20.28}$$

Equation 20.28 is for predicting the motion resistance due to compacting the terrain by a track with uniform pressure distribution based on Bekker's pressure–sinkage equation (Equation 20.21). Expressions for motion resistance based on other pressure–sinkage relations may be derived in a similar way.

As the semiempirical method proposed by Bekker is based on a number of simplifying assumptions, it can only provide a preliminary assessment of the motion resistance of a track. For instance, the idealization of a track as a rigid footing is not realistic, particularly for tracked vehicles designed for high-speed operations, such as military vehicles with relatively short track pitch. For this type of tracked vehicle, the normal pressure distribution under the track is far from uniform [3,4]. To improve the accuracy of prediction, more realistic and comprehensive methods have been developed and will be discussed in the Chapter 34.

20.6.3 Thrust–Slip Relationship of a Track

While Equation 20.9 can be used to estimate the maximum thrust developed by a track at high slips (i.e., the track spins without the corresponding forward movement), it is desirable to determine the relationship between the thrust and slip over the full operating range. This is because tracked vehicles usually operate at relatively low slips in order to achieve high operating efficiency. To predict the relation between thrust and slip, it is necessary to examine the development of shear displacement beneath the track, since shear stress is a function of shear displacement, as described in Section 20.6.1.2. The shear displacement at various points under the track is shown schematically in Figure 20.16. At point 1 at the front of the track, the grouser just comes into contact with the terrain. It cannot develop the same shear displacement as the other grousers behind it, since they have been shearing the terrain surface for varying periods of time. The amount of shear displacement j

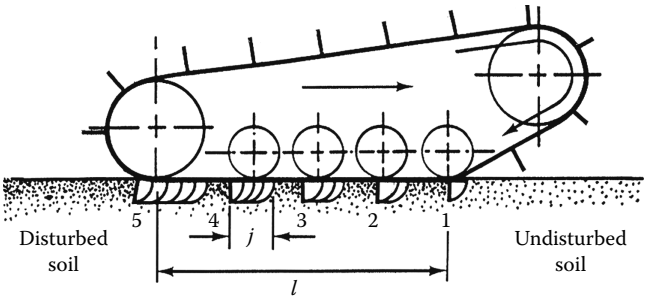

FIGURE 20.16 Development of shear displacement under a track. (Reproduced from Bekker, M.G., *Theory of Land Locomotion*, University of Michigan Press, Ann Arbor, MI, 1956, with permission of the University of Michigan Press.)

increases along the track contact length and reaches its maximum value at the rear of the contact area. To examine the development of shear displacement beneath a track quantitatively, the slip i is defined first [1,3]:

$$i = 1 - \frac{V}{r\omega} = 1 - \frac{V}{V_t} = \frac{V_t - V}{V_t} = \frac{V_j}{V_t} \tag{20.29}$$

where

V is the actual forward speed of the track

V_t is the theoretical speed of the track that is equa1 to the product of the angular speed ω and the pitch radius r of the sprocket

V_j is the speed of slip of the track with respect to the terrain

When the track is slipping, V_j will be in the direction opposite to that of vehicle motion. Since the track is assumed to be inextensible, the speed of slip V_j is the same for every point on the track in contact with the terrain. The shear displacement j at the point located at a distance x from the front of the contact length can be determined by

$$j = V_j t \tag{20.30}$$

where t is the contact time of the point in question and is equal to x/V_t.

Rearranging Equation 20.30, the expression for shear displacement j becomes

$$j = \frac{V_j x}{V_t} = ix \tag{20.31}$$

This indicates that the shear displacement beneath a flat track increases linearly from the front to the rear of the contact length. Since the shear stress is related to shear displacement as discussed in Section 20.6.1.2, the shear stress distribution on the track contact area can be found. For a flat track with uniform normal pressure and with the shear stress–shear displacement relationship described by Equation 20.22, the thrust–slip relationship for a track is given by

$$F = b\int_0^l \left(c + \frac{W}{bl}\tan\phi\right)(1 - e^{-ix/K})dx = (Ac + W\tan\phi)\left[1 - \frac{K}{il}(1 - e^{-il/k})\right] \tag{20.32}$$

Equation 20.32 gives the functional relationship among thrust F; vehicle design parameters A, b, l, and W; terrain parameters, c, ø, and K; and track slip i. If the slip is 100%, Equations 20.9 and 20.32 are practically identical.

It should be pointed out that the thrust–slip relationship for a track given by Equation 20.32 is based on a number of simplifying assumptions. In practice, the track usually does not behave like a rigid footing and the normal pressure is not uniformly distributed over the contact area. Consequently, Equation 20.32 gives approximate results only [3,4]. Improved methods for predicting thrust–slip relationship of tracked vehicles will be discussed in the Chapter 34.

20.7 SEMIEMPIRICAL METHODS FOR PREDICTING THE PERFORMANCE OF WHEELED VEHICLES

20.7.1 Motion Resistance of a Rigid Wheel

While pneumatic tires have been widely used in off-road wheeled vehicles, the mechanics of rigid wheels operating over unprepared terrain is still of interest as a pneumatic tire at high inflation pressure may behave like a rigid wheel in soft soil. Furthermore, rigid wheels are still used in special circumstances, such as in paddy field or as traction-aided devices for pneumatic tires on wet terrain. One of the earlier methods for predicting the motion resistance of a rigid wheel is that proposed by Bekker [1,3]. In developing this method, it is assumed that the terrain reaction at all points on the contact area is purely radial and is equa1 to the normal pressure beneath a horizontal plate in a pressure–sinkage test described in Section 20.6.1.1 (Figure 20.17). The shear stress on the wheel–terrain interface is neglected. In the absence of shear stress, the equilibrium equations of a rigid wheel in the horizontal and vertical directions can be written as

$$R_c = b\int_0^{\theta_0} \sigma r \sin\theta \, d\theta \tag{20.33}$$

$$W = b\int_0^{\theta_0} \sigma r \cos\theta \, d\theta \tag{20.34}$$

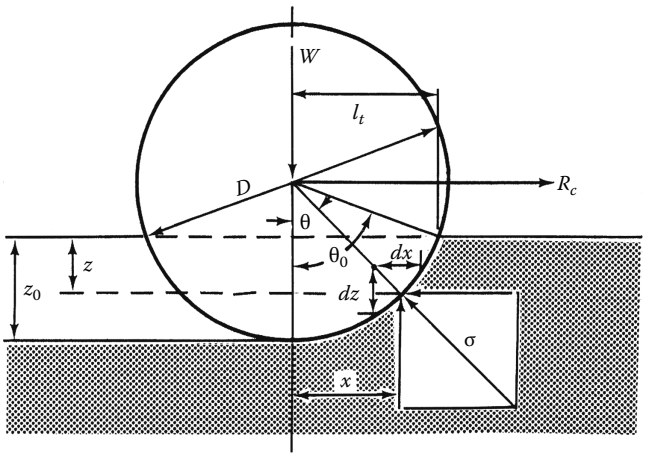

FIGURE 20.17 A simplified wheel–soil interaction model. (Reproduced from Bekker, M.G., *Theory of Land Locomotion*, University of Michigan Press, Ann Arbor, MI, 1956, with permission of the University of Michigan Press.)

where
R_c is the motion resistance
W is the load on the wheel
σ is the normal pressure exerted on the wheel rim by the terrain
b and r are width and radius of the wheel, respectively

Since it is assumed that the normal pressure σ acting on the wheel rim is equal to the normal pressure p beneath a plate at the same depth z in a pressure–sinkage test, then $\sigma\, r \sin\theta\, d\theta = p\, dz$ and $\sigma\, r \cos\theta\, d\theta = p\, dx$. Using the pressure–sinkage relationship defined by Equation 20.21, Equation 20.33 becomes

$$R_c = b\int_0^{Z_0}\left(\frac{k_c}{b}+k_\phi\right)z^n dz = b\left[\left(\frac{k_c}{b}+k_\phi\right)\frac{z_0^{n+1}}{n+1}\right] \tag{20.35}$$

The value of R_c determined by Equation 20.35 is equivalent to the vertical work done per unit length in pressing a plate of width b into the terrain to a depth of z_0. The assumption for the stress distribution made by Bekker implies that the motion resistance of a rigid wheel is due to the vertical work done in making a rut of depth z_0. The rut depth z_0 can be derived by considering the equilibrium of the wheel in the vertical direction using Equation 20.34 and is expressed by [1,3]

$$z_0 = \left[\frac{3W}{b(3-n)(k_c/b+k_\phi)\sqrt{D}}\right]^{2/(2n+1)} \tag{20.36}$$

Substituting Equation 20.36 into Equation 20.35, the compaction resistance R_c is expressed by

$$R_c = \left[\frac{1}{(3-n)^{(2n+2)/(2n+1)}(n+1)b^{1/(2n+1)}(k_c/b+k_\phi)^{1/(2n+1)}}\right]\left[\frac{3W}{\sqrt{D}}\right]^{(2n+2)/(2n+1)} \tag{20.37}$$

It can be seen from Equation 20.37 that to reduce the motion resistance, it seems more effective to increase the wheel diameter D than the width b, as D enters the equation in higher power than b.

20.7.2 Motion Resistance of a Pneumatic Tire

The motion resistance of a pneumatic tire depends on its mode of operation. If the ground is sufficiently soft and the sum of the inflation pressure p_i and the pressure produced by the stiffness of the carcass p_c is greater than the maximum pressure that the terrain can support at the lowest point of the tire circumference, the tire will remain round like a rigid rim. This is referred to as the rigid mode of operation. On the other hand, if the terrain is firm and the tire inflation pressure is low, a portion of the circumference of the tire will be flattened. This is referred to as the elastic mode of operation. To predict the motion resistance of a tire, it is necessary, first of all, to determine the operating mode of the tire. If the tire behaves like a rigid rim, using Equation 20.21, the normal pressure p_g at the lowest point of contact at sinkage z_0 (i.e., the bottom dead center) is given by

$$p_g = \left(\frac{k_c}{b}+k_\phi\right)z_0^n \tag{20.38}$$

Substituting Equation 20.36 into Equation 20.38, the expression for p_g becomes

$$p_g = \left(\frac{k_c}{b} + k_\phi\right)^{1/(2n+1)} \left[\frac{3W}{(3-n)b\sqrt{D}}\right]^{2n/(2n+1)} \tag{20.39}$$

If the sum of the inflation pressure p_i and the pressure due to carcass stiffness p_c is greater than the pressure defined by Equation 20.39, which may be called the critical pressure p_{gcr}, the tire will remain round like a rigid wheel [3]. Under this condition, the motion resistance due to compacting the terrain can be predicted using Equation 20.37. On the other hand, if it is less than the critical pressure p_{gcr}, the tire is in the elastic mode of operation and a portion of the tire circumference will be flattened. The contact pressure on the flattened portion will be equa1 to $p_i + p_c$. In this case, the sinkage of the tire z_0 can be predicted using Equation 20.21:

$$z_0 = \left[\frac{p_i + p_c}{k_c/b + k_\phi}\right]^{1/n} \tag{20.40}$$

Substituting Equation 20.40 into Equation 20.35, the motion resistance of a tire in the elastic mode of operation is given by

$$R_c = b\left(\frac{k_c}{b} + k_\phi\right)\left(\frac{z_0^{n+1}}{n+1}\right) = \frac{b(p_i + p_c)^{(n+1)/n}}{(n+1)(k_c/b + k_\phi)^{1/n}} \tag{20.41}$$

Recent studies show that the sum of the inflation pressure and the pressure produced by carcass stiffness, $p_i + p_c$, can be represented by the average ground pressure p_{gr} of the tire on hard ground [2–4]. The average ground pressure p_{gr} may be calculated from the normal load and the gross contact area of the tire on hard surface given in the generalized deflection chart of the tire provided by the tire manufacturer [2–4].

20.7.3 Thrust–Slip Relationship of a Wheel

In the wheel–terrain interaction model proposed by Bekker and described in Section 20.7.1, only the normal pressure on the interface is considered and the shear stress is completely neglected. As a result, the semiempirical method developed by Bekker is unable to predict the tractive performance of a driven wheel. Later, a method was developed by Wong and Reece to predict the shear stress distribution on the wheel–terrain interface and the thrust–slip relationship of a wheel [3,4,14].

To predict the thrust–slip relationship of a wheel, the development of shear displacement along the wheel–terrain interface has to be examined first. The shear displacement developed along the contact area of a wheel may be determined by analyzing the slip velocity V_j on the wheel–terrain interface. For a rigid wheel, the slip velocity V_j of a point on the rim relative to the terrain is the tangential component of the absolute velocity at that point, as illustrated in Figure 20.18. The magnitude of the slip velocity V_j of a point on the rim defined by angle θ can be expressed by

$$V_j = r\omega[1-(1-i)\cos\theta] \tag{20.42}$$

The shear displacement j at a point defined by angle θ on the wheel–terrain interface is given by

$$j = \int_0^t V_j dt = \int_\theta^{\theta_0} r\omega[1-(1-i)\cos\theta]\frac{d\theta}{\omega} = r[(\theta_0 - \theta) - (1-i)(\sin\theta_0 - \sin\theta)] \tag{20.43}$$

where θ_0 is the entry angle where a point on the rim first comes into contact with the terrain (Figure 20.18).

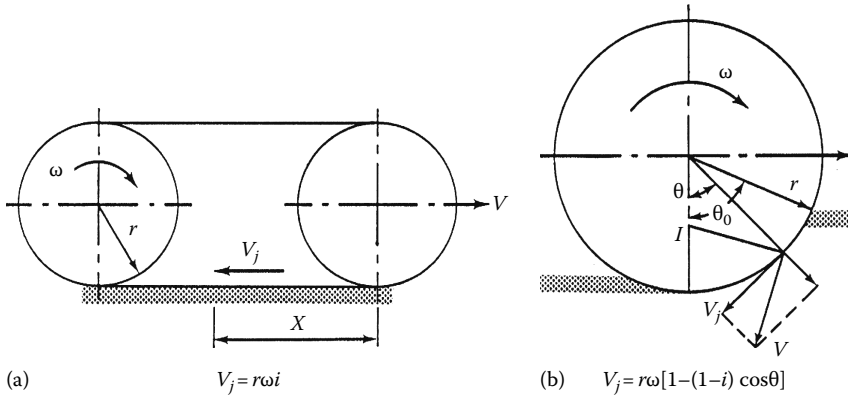

FIGURE 20.18 Slip velocity on (a) track–terrain and (b) wheel–terrain interface. (Reproduced from Wong, J.Y., *Theory of Ground Vehicles*, 4th edn., John Wiley, New York, 2008.)

Based on the relationship between the shear stress and shear displacement discussed previously in Section 20.6.1.2, the shear stress distribution along the contact area of a rigid wheel can be determined. For instance, using Equation 20.22, the shear stress distribution along the wheel–terrain interface is expressed by

$$\tau(\theta) = [c + p(\theta)\tan\phi](1 - e^{-j/K}) = \tau_{max}[1 - e^{-(r/K)[\theta_0 - \theta - (1-i)(\sin\theta_0 - \sin\theta)]}] \tag{20.44}$$

The normal pressure distribution along a rigid wheel $p(\theta)$ may be predicted by a variety of methods, including the simplified method proposed by Bekker and described in Section 20.7.1. By integrating the horizontal component of shear (tangential) stress over the entire contact area, the thrust F developed by the wheel is expressed by

$$F = rb\int_0^{\theta_0} \tau(\theta)\cos\theta\, d\theta \tag{20.45}$$

It should be mentioned that taking into account the presence of shear stress on the wheel–terrain interface, the vertical load on the wheel is partly supported by its vertical component. This fact has been neglected in the original wheel–terrain interaction model proposed by Bekker. In a more complete analysis of wheel–terrain interaction, the effects of shear stress on supporting vertical load and on the development of thrust should be taken into consideration. The equations for predicting the performance of a rigid wheel are given by [3,4]

For vertical load,

$$W = rb\left[\int_0^{\theta_0} p(\theta)\cos\theta\, d\theta + \int_0^{\theta_0} \tau(\theta)\sin\theta\, d\theta\right] \tag{20.46}$$

for drawbar pull,

$$F_d = rb\left[\int_0^{\theta_0} \tau(\theta)\cos\theta\, d\theta - \int_0^{\theta_0} p(\theta)\sin\theta\, d\theta\right] \tag{20.47}$$

and for driving torque,

$$M_w = r^2 b \int_0^{\theta_0} \tau(\theta)\, d\theta \tag{20.48}$$

Following a similar approach, the thrust–slip relationship and the overall performance of a tire in the elastic operating mode may be predicted [3,4].

20.8 CLOSING REMARKS

Different methods are available for evaluating different aspects of off-road vehicle–terrain interaction. The theory of elasticity may be used to predict the stress distribution in dense soil under vehicular loads. The theory of plastic equilibrium may be applied to estimating the maximum thrust that an off-road vehicle may develop, as well as the force developed by the lug of a wheel. Empirical methods may be employed to predict the performance of vehicles with design features similar to those that have been tested under similar operating conditions. However, empirical relations should not be extrapolated beyond the conditions upon which they were derived. Consequently, it is uncertain that empirical methods can play a useful role in the prediction of the performance of off-road vehicles with new design features or in new operating environment. The semiempirical methods for predicting the performance of tracked and wheeled vehicles developed by Bekker are useful in providing a basic understanding of the physical nature of off-road vehicle–terrain interaction. They also identify the vehicle and terrain parameters that would significantly affect the performance of off-road vehicles. It should be pointed out, however, that some of the assumptions used in the development of these semiempirical methods are unrealistic or oversimplified. For instance, the assumption that a track may be idealized as a rigid footing with uniform contact pressure is unrealistic in many cases. The assumption that only normal reaction (pressure) is present on the wheel–terrain interface is oversimplified. Comprehensive and realistic computer-aided methods for predicting the performance of off-road vehicles have emerged recently and will be presented in the Chapter 34 [15–32].

Notations

A	contact area

21.1 INTRODUCTION

For the first motor vehicles, rigid axles with leaf springs were adopted from horse-drawn carriages. With growing knowledge of vehicle-dynamic laws, and of the vibrational behavior of the vehicle, kinematic suspension mechanisms were introduced that enabled additional properties like, for instance, traction and braking anti-pitch arrangements. Improved measuring methods and computer programs allow the deliberate elasto-kinematic harmonization of suspensions to achieve optimum driving stability along with optimum ride comfort.

Figure 21.1 shows a steerable independent front suspension with typical elements of construction: "a" is the wheel with the tire and "b" the wheel carrier that determines the attitude of the wheel in relation to the vehicle body. The brake "c" is arranged between the wheel and the wheel carrier. The lower transverse link "d" is triangulated by a tension link "e" to the vehicle body; "e" is here the arm of a stabilizer bar or "antiroll bar" (MacPherson principle). The damper "f" is fixed to the wheel carrier, and its piston rod represents another link of the suspension. The track rod "g" connects the steering arm of the wheel carrier with the rack-and-pinion steering "h" and so completes the suspension mechanism. The spring "i" can be regarded as a "highly compliant" suspension link, together with which the suspension becomes a "statically determinate system." The driveshaft "k" connects the wheel axle with the inboard final-drive gearbox (not shown).

The kinematic laws of the mechanisms of wheel suspensions and methods for the analysis of suspension geometry as well as suspension characteristics will be covered in this treatise.

Since the wheel and the suspension links move inside the vehicle body, and since clearance is one of the most important problems during design, every wheel suspension is usually designed on the assumption that the vehicle body is the "fixed" system (Figure 21.2). In the vehicle-fixed coordinate system used in the following, the x-axis is directed forward, the y-axis to the left, and the z-axis upward. The pitch angle ϑ, the roll angle φ, and the yaw angle ψ are also defined in this illustration. The steering angle δ on the left wheel is defined as greater than zero for a left-hand corner (this means, of course, that a positive "toe-in" angle δ_v corresponds to a negative steering angle δ).

Suspension systems are mostly represented in the following without showing the spring elements, because normally any type of spring can be used in any suspension design.

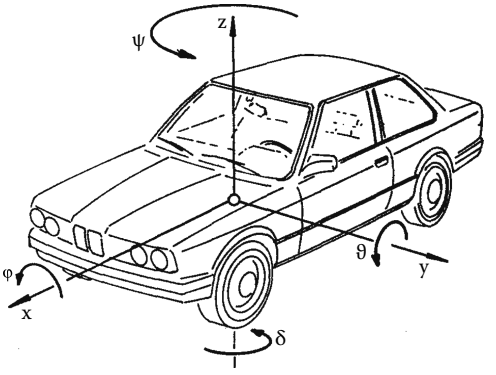

FIGURE 21.2 Coordinate system.

Suspension design is a very special topic, and the relatively small number of suspension design experts is concentrated in the companies of motorcar producers—the number of which is not very great. The special knowledge about suspensions is handed down by the more experienced to the junior designer according to the principle of "learning by doing." Theoretical treatment in publications is often simplifying, and even a book cannot mention all the special tricks applied in everyday design work. Nevertheless, an attempt will be made here to elucidate the most important considerations and methods for suspension design. This treatise closely takes pattern from the author's books on suspensions [1,6], which may be recommended for a more detailed information.

21.2 ANALYSIS OF SUSPENSIONS

To respond to road irregularities, every wheel of a fast road vehicle needs a possibility of mainly vertically directed motion, one "degree of freedom," the wheel's path following a defined and reproducible function.

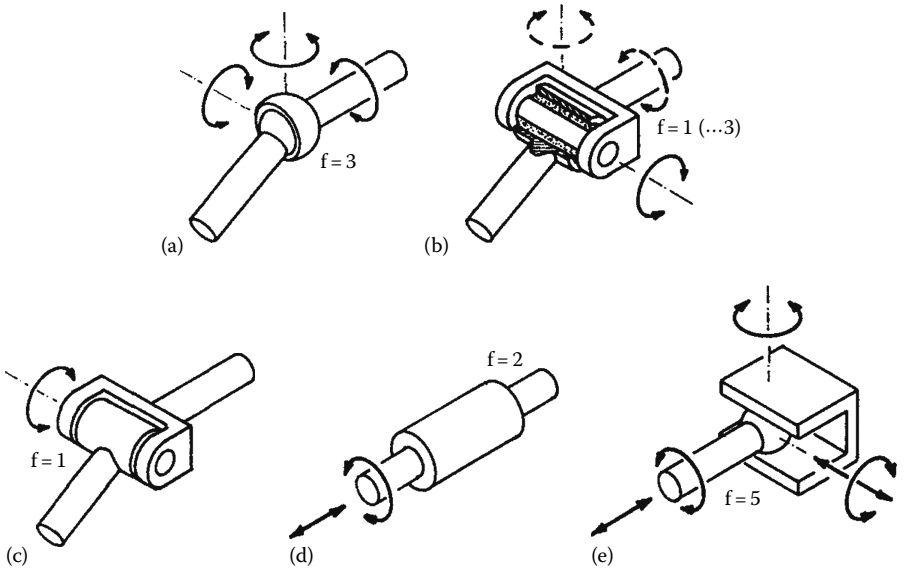

FIGURE 21.3 Joint types: (a) ball joint, (b) rubber joint, (c) turning joint, (d) turning-and-sliding joint, and (e) ball-and-surface joint.

In space, a freely movable body has six degrees of freedom. The degree of freedom of a complete mechanism is designated in the following by an uppercase "F" and that of a joint by a lowercase "f."

Figure 21.3 shows the most important types of joints used in suspensions: (a) is the ball joint that allows free motion about three independent axes of rotation, thus providing three degrees of freedom, f = 3. Since with many ball joints mainly only one rotational axis is utilized, the angular displacements about the two other axes being relatively small, a rubber joint (b) may be employed; the rubber joint, however, introduces restoring moments into the connected parts. The turning joint (c) provides f = 1 and the turning-and-sliding joint (d) f = 2. The ball-and-surface joint (e) is rare in wheel suspensions (f = 5).

These joints serve to connect the suspension links (Figure 21.4) to the body and the wheel carrier. The rod link (a) that has two ball joints, each with three degrees of freedom, provides six degrees of freedom for the mechanism. One of them, however, is the free rotation "r" of the link about its own axis. So the rod link provides five degrees of freedom for the suspension. The triangular link or "A arm" (b) provides f = 4, and the trapezoidal link (c) f = 2. The turning-and-sliding link (d) is represented in suspensions by a telescopic damper, consequently, in the special form shown here with the ball joint on the axis of the turning-and-sliding joint, enabling the rod to rotate freely (r = 1), and therefore provides f = 4 for the suspension.

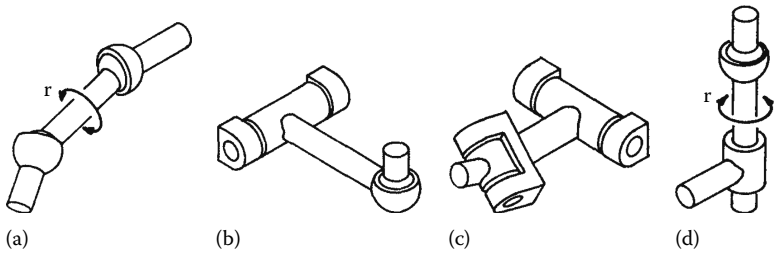

FIGURE 21.4 Types of wheel-suspension links: (a) rod link, (b) triangular link or "A arm", (c) trapezoidal link, and (d) turning-and-sliding link (r = ability of free rotation).

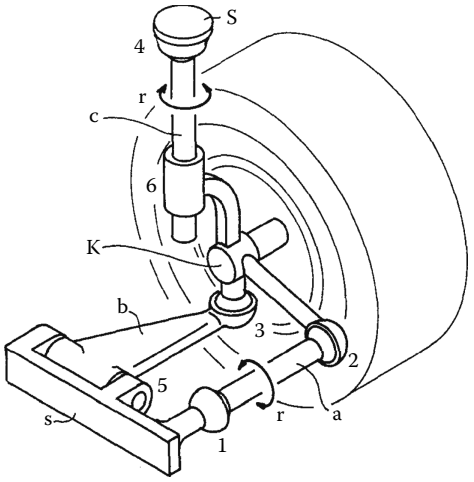

FIGURE 21.5 Schematic of an independent suspension.

Figure 21.5 shows a suspension mechanism where the most important types of joints and links are utilized. The degree of freedom of a suspension mechanism is

$$F = 6(k + l - g) - r + \sum_{1}^{g} f_i \tag{21.1}$$

where
k is the number of wheel carriers
l is the number of links
g is the number of joints
r is the number of free rotations of links
f_i is the degree of freedom of joint i

With k = 1, l = 3, g = 6, and the sum of the degrees of freedom of four ball joints, one turning joint and one turning-and-sliding joint $\Sigma f_i = 4 \times 3 + 1 + 2 = 15$ and two rotations (r = 2), the degree of freedom of the mechanism becomes F = 1, as is necessary for an independent wheel suspension.

Suspension types as used on fast vehicles are mainly classified into independent suspensions (Figure 21.6) (represented here by a simple semitrailing link system (a) and a sophisticated five-link

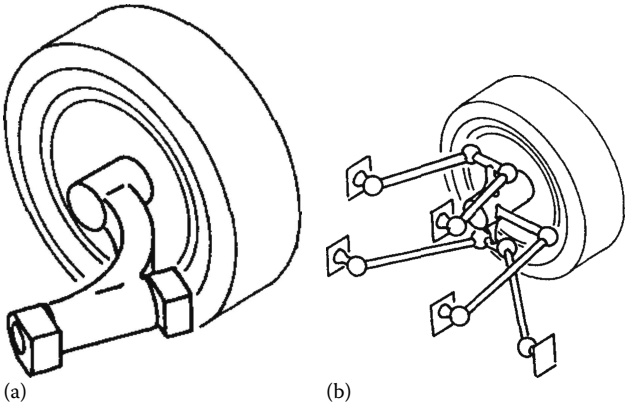

FIGURE 21.6 Examples of independent wheel suspensions: (a) Semitrailing link and (b) five-link system.

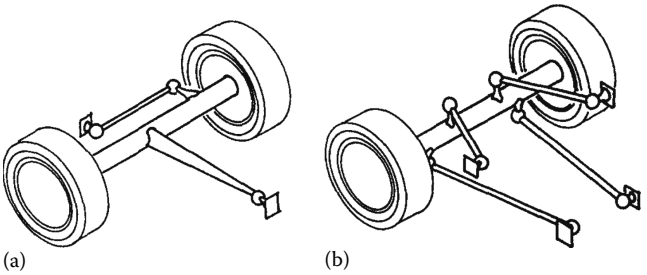

FIGURE 21.7 Examples of rigid-axle systems: (a) thrust-ball axle and (b) four-link system.

suspension (b)) or rigid-axle suspensions (Figure 21.7) (where (a) is the "thrust-ball axle" with a "Panhard rod" and (b) a four-link system). An independent suspension features one wheel and requires one degree of freedom, while a rigid axle is a wheel carrier with two wheels and, consequently, needs two degrees of freedom. Since one rod link reduces the degree of freedom of a mechanism by one, the basic model of an independent suspension is a five-link mechanism and that of a rigid-axle suspension is a system with four links.

However, there are also suspension mechanisms with two wheel carriers for two wheels but of neither the independent nor the rigid-axle type. These are the "compound suspensions" (Figure 21.8). In Figure 21.8a, the upper transverse link of each wheel of a five-link suspension is connected to the wheel carrier of the respective opposite wheel. In Figure 21.8b, the axle beam of a four-rod rigid-axle suspension has been split, and its halves have been connected by a turning-and-sliding joint; the superfluous two degrees of freedom introduced by the latter have been offset by two additional (transverse) rod links. This compound system forms the basic type of the worldwide spread family of "torsion-beam suspensions" for the rear wheels of front-drive cars (see also Figure 21.27).

For kinematic analysis of suspensions, it is popular to define "poles" and "instantaneous axes" of the mechanism and to use these for the definition of suspension properties or "suspension characteristics" like the roll center and the scrub radius or for the establishment of the balance of forces and moments at the suspension. However, this method is not generally applicable, as will be discussed in the following.

Figure 21.9 shows three variants of a simple "trapezoidal-link suspension." In Figure 21.9a, the axes of the turning joints of the trapezoidal link are parallel, and together with the upper rod link, they define an instantaneous axis of rotation m that is also parallel to the axes of the turning joints. The geometry of this suspension can be analyzed perfectly in a plane of projection that is rectangular to the joint axes. The system in Figure 21.9a represents a "planar mechanism." In Figure 21.9b, the axes of the joints at the trapezoidal link are inclined with respect to each other and intersect at a point Z. Since Z is a fixed point to the wheel carrier as well as to the vehicle body, all points of the wheel carrier rotate in space on concentric spheres about Z. The suspension in Figure 21.9b is a "spherical mechanism," and the planar mechanism of Figure 21.9a is clearly a special case of the

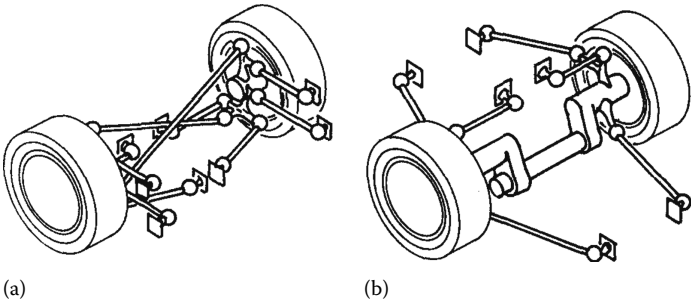

FIGURE 21.8 Examples of compound suspensions: System derivable from (a) an independant suspension and (b) a rigid axle.

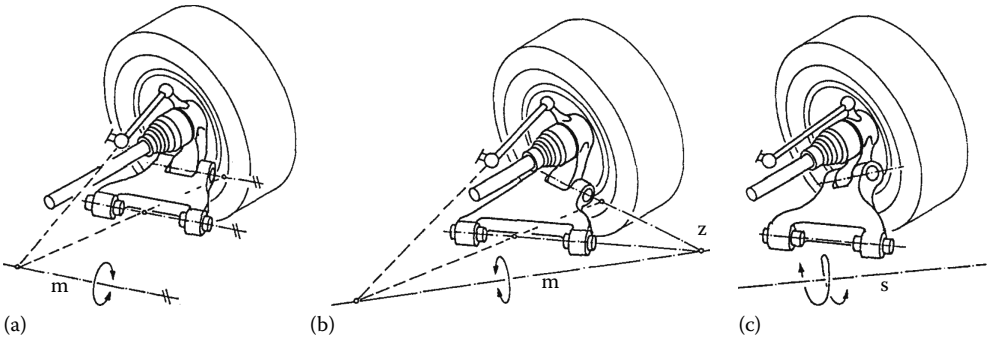

FIGURE 21.9 Three variants of trapezoidal-link suspensions: (a) Planar, (b) Spherical, and (c) Spatial Mechanism, (m = instantaneous axis, s = screw axis, z = spherical center).

spherical one, with the spherical center Z shifted to infinity. The suspension in Figure 21.9c shows skew axes of the turning joints that no longer intersect; the motion of this system can no longer be reduced to a rotation about an instantaneous axis m but is to be characterized by an instantaneous rotation about an axis s together with an overlaid axial shift along that axis. The result is an "instantaneous screw," and the mechanism is of the "spatial" type.

In suspension design, a number of "suspension characteristics" have been introduced that give information about essential properties of the suspension in connection with typical load cases or driving maneuvers. The five most important characteristics are the roll center, the braking-force support angle, the traction-force support angle, the camber change with wheel travel, and the toe-in change with wheel travel. For all these characteristics to be freely dimensioned, the suspension must be based on a mechanism defined by five parameters. An instantaneous axis of a planar or spherical mechanism is defined by four parameters (for instance, by the, respectively, two coordinates of its points of intersection with two planes), while a fifth parameter—the axial pitch—is required for an instantaneous screw.

Kinematic analysis of suspensions has, therefore, to be based on the assumption of an instantaneous screw. The axis of a screw, however, is not generally applicable for defining levers of forces or establishing the static balance of forces, in contrast to an instantaneous axis of rotation: forces that are not directed rectangularly to the screw axis generate a torque even if they intersect with that axis. Points of intersection of planes with the screw axis cannot normally serve as "poles" for kinematic or static investigations.

A very suitable and simple method for kinematic analysis of the suspension mechanism is indicated in Figure 21.10. A suspension shows five rod links and one spring element, all connected to the vehicle chassis as well as to the wheel carrier by ball joints. The (wanted) state of motion of the wheel carrier K may be characterized by the "velocity" vector $\mathbf{v}_M$ of the wheel center M as the reference point and the angular-velocity vector $\boldsymbol{\omega}_K$ of the wheel carrier. The velocity vector of any point i at the wheel carrier follows as

$$\mathbf{v}_i = \mathbf{v}_M + \boldsymbol{\omega}_K \times \mathbf{r}_i \tag{21.2}$$

For a constant length of the link $\mathbf{a}_i$, the components of the velocity $\mathbf{v}_i$ and a possible velocity $\mathbf{v}_{i'}$ at the inner joint in the direction of the link vector must be equal:

$$\mathbf{v}_i \cdot \mathbf{a}_i = \mathbf{v}_{i'} \cdot \mathbf{a}_i \tag{21.3}$$

There follows from (21.2) and (21.3)

$$(\mathbf{v}_M + \boldsymbol{\omega}_k \times \mathbf{r}_i) \times \mathbf{a}_i = \mathbf{v}_{i'} \times \mathbf{a}_i \tag{21.4}$$

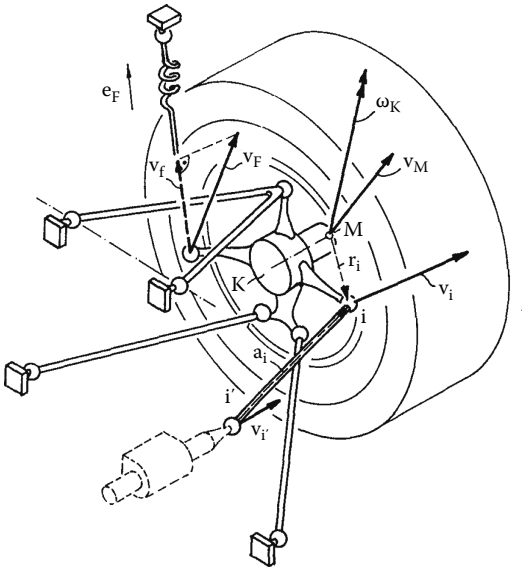

FIGURE 21.10 Motion analysis of a wheel suspension.

and—written in components—this is a linear equation. Similar equations can be established for all five rod links. The terms $\mathbf{v}_i \cdot a_i$ can represent elastic displacements of the link or also the input of a steering gear (e.g., if a_i is the track rod of a steered suspension). In all other cases, the right-hand side of Equation 21.4 is zero. The spring is a "highly compliant" rod and completes the system to a "statically determinate" structure. If compressed, its "spring compression velocity" v_f replaces the term $\mathbf{v}_i \cdot \mathbf{a}_i$ in Equation 21.4.

Six linear equations of the (21.4) type, generated by the five rod links and the spring, form a system to determine the respective three components of the vectors $\mathbf{v}_M$ and $\boldsymbol{\omega}_K$.

The "velocities" can, of course, also be regarded as "virtual displacements" if multiplied with a time differential dt.

An essential advantage of this method is that the equations serving for kinematic analysis can be also be applied to the analysis of forces and that equations for static analysis no longer need to be established. Since the "suspension characteristics" mentioned earlier are mostly derivatives of forces or displacements, the method may easily be applied to define those characteristics, as demonstrated with a simple front-wheel suspension subjected to a braking force F_{xB} (Figure 21.11).

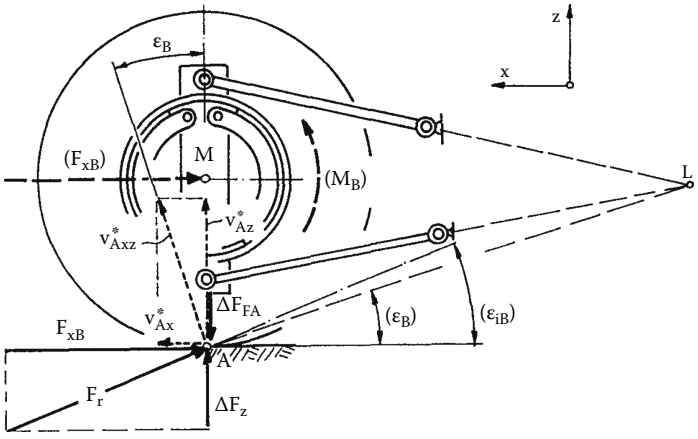

FIGURE 21.11 Balance of power (braking event).

The deceleration force causes a pitching moment, depending on the height of the vehicle's center of gravity and its wheelbase. This moment increases the front-wheel load by ΔF_Z at the expense of the rear wheel. The front-wheel brake acts between wheel and wheel carrier and represents the "torque support" that transfers the braking torque M_B to the wheel. The spring-force change (reduced to the tire contact point A) is indicated by ΔF_{FA}.

The diagram of forces is independent of the vehicle's forward velocity, so the latter can be "subtracted" from all of the "velocities" at the suspension, or, so to speak, the diagram is also valid under the assumption of a "locked" brake. Under this condition, the tire contact point A is "fixed" to the wheel carrier during braking, and, for a virtual spring compression, point A moves with a virtual "velocity" $\mathbf{v}_A^*$ rectangularly to the "polar ray" connecting it with the pole L. With the forces, and the components of the vector $\mathbf{v}_A^*$, the balance of "power" can be established: $(\Delta F_Z - \Delta F_{FA})v_{AZ}^* - F_{XB}v_{AX}^* = 0$, or with $\tan\varepsilon_B = \pm v_{AX}^*/v_{AZ}^*$ (upper sign for front wheels), we get

$$\Delta F_{FA} = \Delta F_Z - F_B \tan\varepsilon_B \tag{21.5}$$

ε_B is the "braking-force support angle" [3], a suspension characteristic, and permits the actual "anti-dive" property of the suspension to be evaluated. The spring-force change obviously diminishes as the support angle increases.

On a spatial suspension, of course, the virtual velocity vector $\mathbf{v}_A^*$ has to be determined according to Equation 21.2 assuming the torque support to be "locked."

In the rare case of inboard brakes and transmission of the braking torque via driveshafts, or in the normal case of an independent suspension with the final-drive gearbox fixed to the vehicle body, the method described earlier can be applied analogously, namely, by integrating the driveshafts into the kinematic suspension model and assuming the "torque support" (e.g., the engine) to be locked.

On a universal joint, the two shaft halves can rotate with respect to each other only about an axis that lies in the plane of symmetry Π_S (Figure 21.12). The vector of the relative angular velocity of the shaft halves therefore has to be rectangular to the "normal vector" **n** of the plane of symmetry.

For a given state of motion of a wheel carrier K of a suspension—type is immaterial—characterized by the vectors $\mathbf{v}_M$ and $\boldsymbol{\omega}_K$ in Figure 21.13, the velocity $\mathbf{v}_2$ of the outboard universal joint 2 of the driveshaft W can be determined by Equation 21.2. With $\mathbf{v}_2$, and regarding the conditions of movement at the universal joints, and assuming the inboard shaft end to be "locked," the state of motion of the driveshaft can be derived and, consequently, the relative angular velocity of the outboard

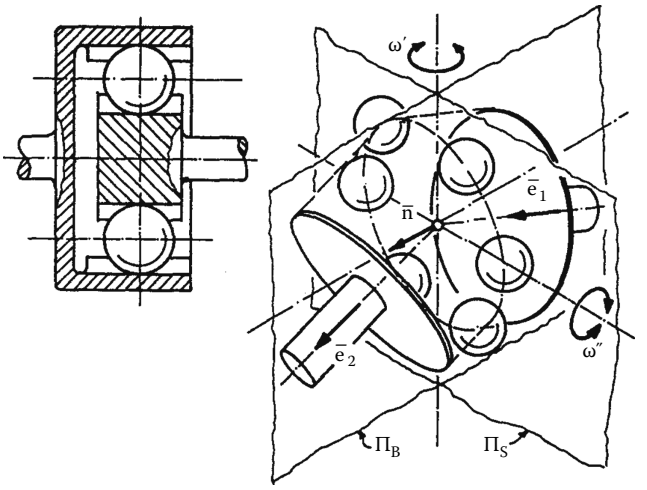

FIGURE 21.12 Homokinetic universal joint.

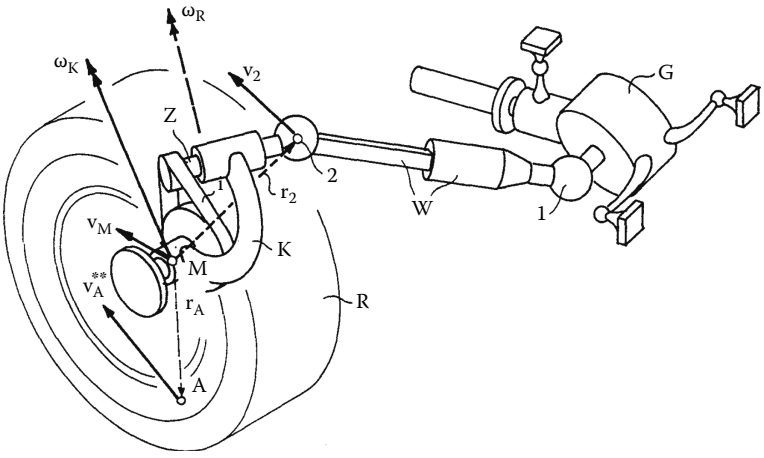

FIGURE 21.13 Wheel carrier with driveshaft and hub reduction gear.

shaft end Z of the driveshaft with respect to the wheel carrier. With this, possibly reduced by a hub reduction gear (symbolized here by a belt drive with a reduction ratio i, where i > 0 for equal direction of rotation of shaft Z and the wheel), we get the relative angular velocity of wheel and wheel carrier and so the absolute angular velocity $\boldsymbol{\omega}_R$ of the wheel. A virtual velocity vector $\mathbf{v}_A^{**}$ can be derived in analogy to Equation 21.2:

$$\mathbf{v}_A^{**} = \mathbf{v}_M + \boldsymbol{\omega}_R \times \mathbf{r}_A \tag{21.6}$$

21.3 TRACTION AND BRAKING

During acceleration or braking, the force of inertia m_{ax} acts at the center of gravity S of the vehicle (Figure 21.14) and causes the wheel-load transfer ΔF_{ZV} and ΔF_{zh} at the front (v) and rear (h) wheels. The distribution of the longitudinal traction or braking forces F_{xv} and F_{xh} at the tire contact points is determined by the design of the system, for instance, for optimum use of the friction coefficient between road and tire. The resulting forces F_r at the wheels intersect at the height of the center of gravity at a point called the "braking" or "accelerating" center E [4]. The angles ε_{iv}^* and ε_{ih}^* between the front and rear tire contact points and the center E are the "ideal" support angles; suspensions that provide these angles will achieve "100%" anti-dive or anti-squat effect upon accelerating or braking.

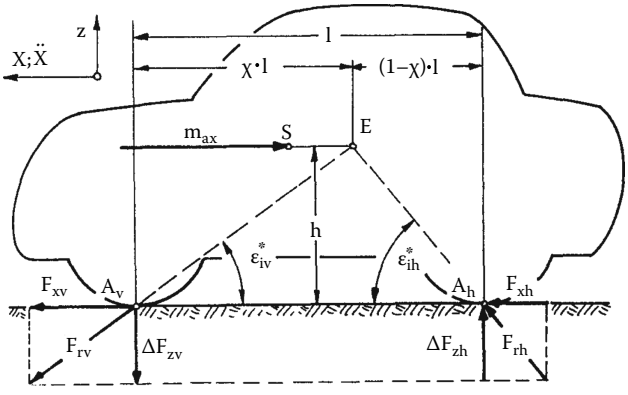

FIGURE 21.14 Diagram of forces upon accelerating.

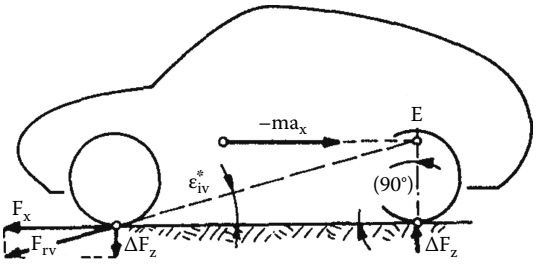

FIGURE 21.15 Single-axle drive.

With single-axle drive or braking (Figure 21.15), the accelerating or braking center E is located above the nonaffected wheel. At the latter, the "ideal" support angle is 90° that means that anti-dive or anti-squat measures are not possible. The ideal support angle of the driven or braked suspension then follows simply from the center-of-gravity height and the wheelbase of the vehicle.

As already demonstrated with Figure 21.11, the support angles follow from virtual velocity vectors at the tire contact points with virtual wheel travel, assuming the torque support (brake or engine) to be locked, and can be determined in the case of a torque support at the wheel carrier (wheel brake, or also hub engine) by

$$\tan \varepsilon^* = \frac{\pm v^*_{Ax}}{v^*_{Az}} \tag{21.7}$$

and in the case of torque transmission via driveshafts and possible hub reduction gears by

$$\tan \varepsilon^{**} = \frac{\pm v^{**}_{Ax}}{v^{**}_{Az}} \tag{21.8}$$

(upper sign valid for front wheels).

Typical cases of a torque support mounted at the wheel carrier are shown in Figure 21.16: a wheel-carrier drive unit (a) as used on light motorcycles, a "live" rigid axle with the final-drive gearbox integrated into the axle beam (b) and a brake mounted to the wheel carrier of an independent suspension (c). The torque support at the vehicle body, combined with transverse driveshafts, is typical for an independent suspension (Figure 21.17a) and for a de Dion rigid axle (b).

On steerable suspensions, it is difficult to achieve large braking-force support angles, since this is mostly coupled with a "pole" close to the wheel (like the pole in Figure 21.11), and may cause

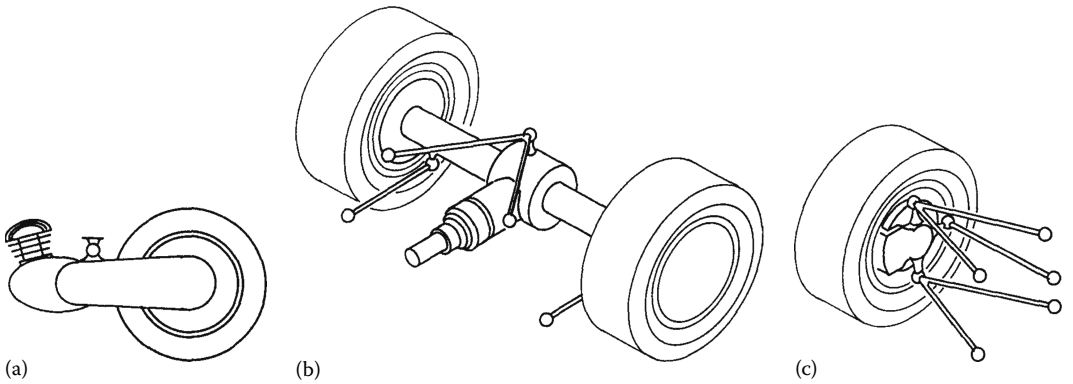

FIGURE 21.16 Torque support mounted to the wheel carrier: (a) wheel-carrier drive unit, (b) rigid axle with final drive ("live axle"), (c) brake calliper mounted to the wheel carrier of an independent suspension.

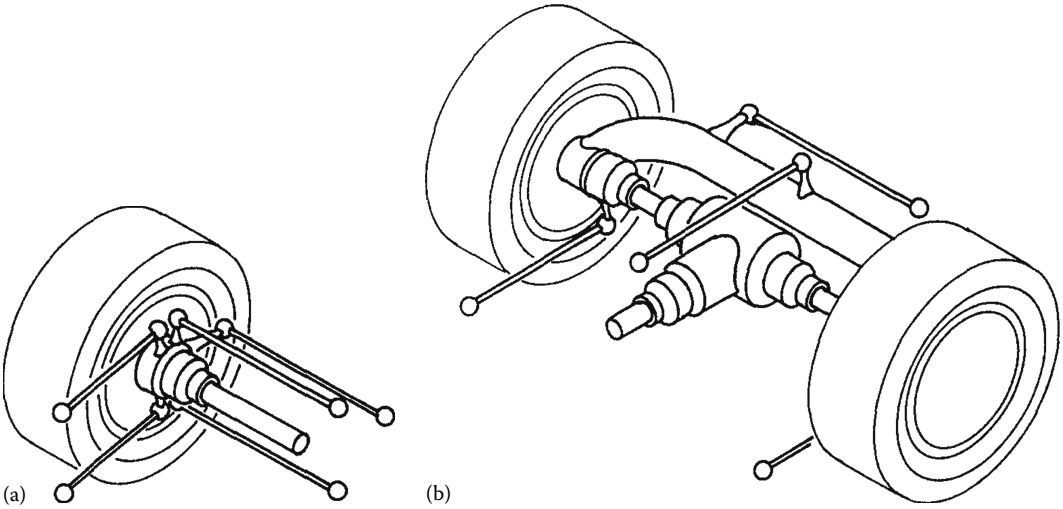

FIGURE 21.17 Torque support mounted to the vehicle body: (a) independant suspension with drive shaft and (b) De-Dion rigid axle.

undesirable change in the "castor" angle and offset with wheel travel (see Section 21.5). However, a steerable suspension with the "kingpin" arranged between the suspension and the chassis, as usual on motorcycle forks (Figure 21.18), may enable a large support angle ε^* with minimized castor change, by arranging a "leading link" K approximately at a right angle to the kingpin and controlling a rotatably mounted brake support BA by a torque reaction rod BS. The same applies to the (historical) Dubonnet suspension for passenger cars.

On an independent suspension with driveshafts, the tire contact point A will approximately copy the path of the wheel center M with wheel travel, even if the inner shaft end is assumed to be locked (Figure 21.19). Therefore, the support angle in the case of traction is comparatively low and approximately equal to the "wheel-travel angle" (see Section 21.6).

A hub reduction gear, however, may have a considerable influence on the support angle if the wheel carrier shows a rotation in side view with wheel travel. The suspension in Figure 21.20 has a

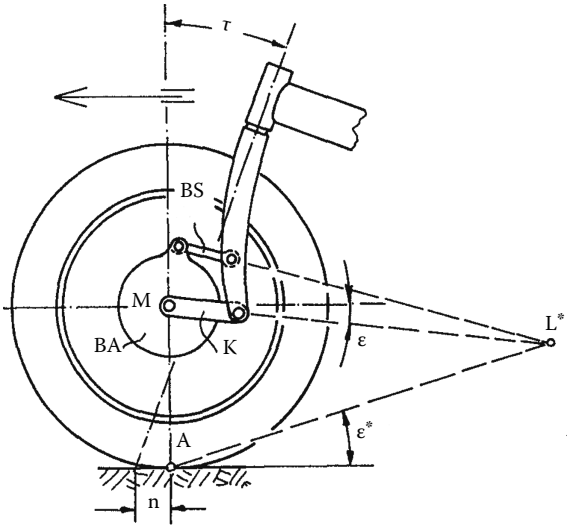

FIGURE 21.18 Rotatably mounted brake support.

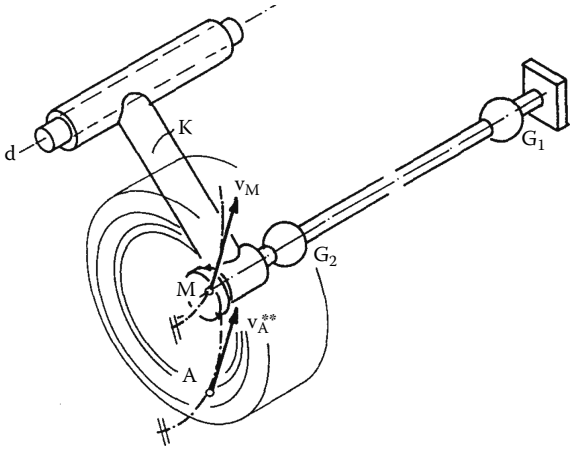

FIGURE 21.19 Independent suspension with driveshaft.

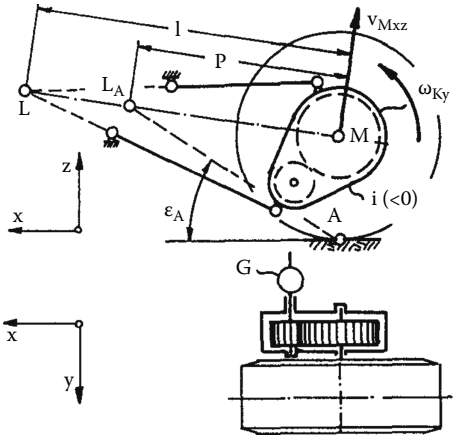

FIGURE 21.20 Suspension with hub reduction gear.

"longitudinal pole" L close to the wheel and is driven via a transverse driveshaft and a hub reduction gear. The distance of the "traction pole" L_A can be approximated by

$$p = \frac{li}{(i-1)} \tag{21.9}$$

and in the case of reversed rotation ($i < 0$), L_A is located between the suspension pole L and the wheel center M.

Overcompensation of traction or braking pitching will normally cause discomfort and will at any rate lead to increased tire wear, caused by longitudinal slip on bad road surface.

A special case of driven-independent suspension, without any universal joint in the driveline, is the rare swing-axle system with a "swinging" bevel gear (Figure 21.21). Assuming the engine to be locked, the pinion of the final drive will be locked, too. With virtual wheel travel, the swing arm will rotate about the axis d, while the wheel (as a spatial body) is fixed firstly at the point T of intersection of its axis with the axis d and secondly at the contact point E of the gears. So the virtual axis of wheel movement is the line m^{**} running through T and E and generates a pole L^{**} in the plane of the wheel and thus a considerable support angle ε^{**} (however, with suspensions of this type, the pinion at the other wheel will usually be *behind* it and create a support angle of inverted sign).

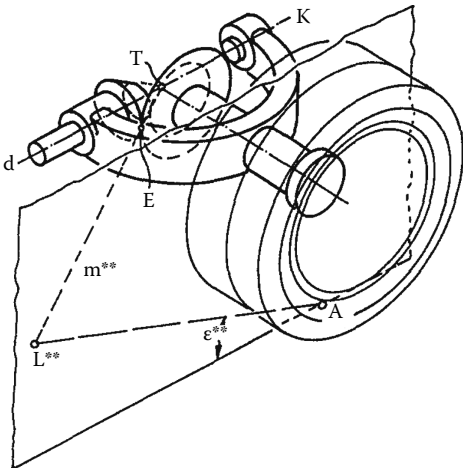

FIGURE 21.21 Swing axle with swinging bevel gear.

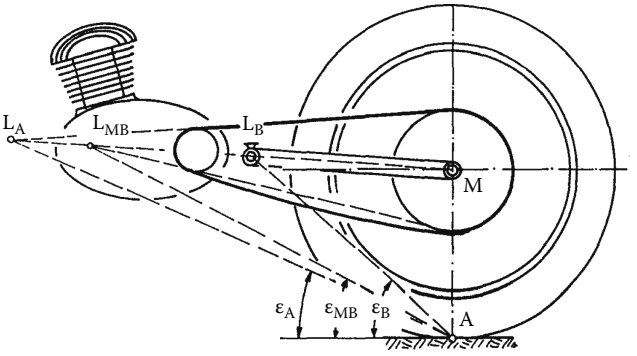

FIGURE 21.22 Support angles on a chain drive suspension.

A chain drive rear suspension with a longitudinal swing arm, as used for motorcycles (Figure 21.22), features three support angles: one angle ε_B for the brake fixed to the swing arm (the wheel carrier) and support angles ε_A and ε_{MB} for the cases of traction and engine braking that follow from the points of intersection of the swing arm and the respective chain run under tension [5].

For tandem-axle aggregates as usual on trucks and trailers, careful harmonization of the support angles is needed to avoid excessive axle-load difference upon braking or accelerating and, with that, premature slip of the axle with reduced load [1,6].

On vehicles with variable braking or traction-force distribution (for instance, motorcycles with independently operated brakes or also vehicles with the braking or traction antilock system in action), the support angles should better not exceed the "ideal" angles for the "worst case"—that is, single-axle traction or braking.

A braking power control device influenced by spring loading (monitoring the deflection of a mechanical spring or the pressure of a gas spring) cannot perceive a dynamic load change if the suspension is designed for 100% anti-pitch geometry. In such a case, the use of sensors for longitudinal accelerations will be preferable.

21.4 CORNERING

In steady-state cornering, the centrifugal force at the vehicle's center of gravity generates a roll moment that increases the outer wheel loading and decreases the inner. Figure 21.23 shows a simplified model of a vehicle, the suspensions being represented by rigid axles with "slot guidances"

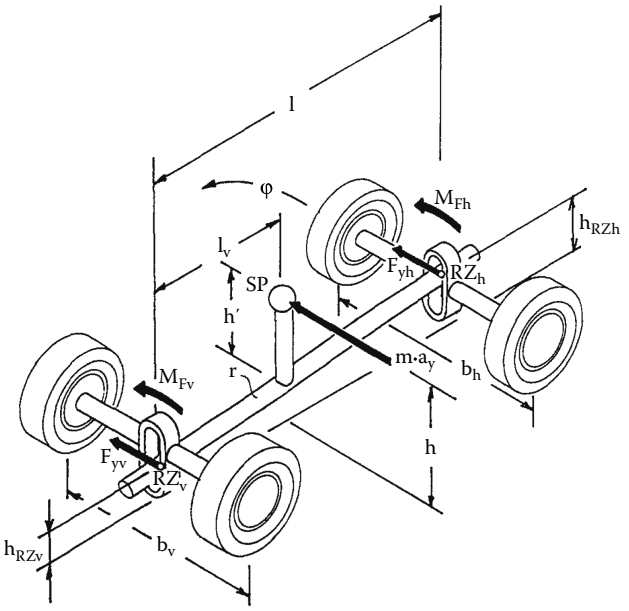

FIGURE 21.23 Forces and moments in cornering.

that allow the vehicle body to move up and down and to roll. The springs are not depicted but are represented by their restoring moments M_{Fv} and M_{Fh}. The lateral forces F_{yv} and F_{yh} are transmitted to the vehicle body via the contact points RZ_v and RZ_h. Since the center of gravity SP is located above the line r connecting the contact points, by the distance h′, the centrifugal force causes a roll moment that loads the system of springs and generates a roll angle φ. The line r is therefore called the "roll axis," and the contact points RZ are the "roll centers."

On independent and on compound suspensions, the "unsprung masses" also generate a roll moment that has to be taken up by the system of springs, depending on the gradient of camber change with wheel travel in relation to the vehicle body.

The roll moment of the vehicle body that acts on the springs is distributed to the front and rear axle according to their "roll spring rates" and causes the moments M_{Fv} and M_{Fh}. With respect to pitch oscillations of the vehicle excited by single obstacles (e.g., a railway crossing), the "natural frequency" of the front suspension is usually chosen lower than that of the rear one (see Section 21.6). Consequently, the contribution of the front springs to the "roll rate" is normally lower than that of the rear springs—which is undesirable because it results in a reduced wheel-load difference at the front wheels at the expense of the rear wheels. To compensate for this, "stabilizer" or "anti-roll" bars are used on front suspensions to reinforce the front roll rate (Figure 21.24a), and possible "transverse compound springs" (b) may additionally lower the rear roll rate in order to secure an understeering behavior of the vehicle. Within certain limits, the roll-center heights above the road surface can also serve for influencing the roll moment distribution.

Front-wheel suspensions with a significant braking-force support angle may have a further effect on wheel-load transfer because the longitudinal component of the lateral force increases with the steering angle and promotes understeering [7].

Determination of the roll center is easy at a rigid-axle suspension. In Figure 21.25, the fulcrum of the slot guidance is clearly the point of lateral-force transmission between vehicle body and axle. Determination of the roll center by application of "virtual power" (as already used in Section 21.3) has, of course, to take into consideration that the rigid axle has two degrees of freedom, one of them catering for the bounce motion and certainly not being suited for body roll analysis, firstly because it does not show horizontal velocity components at the contact points and so is unable to generate

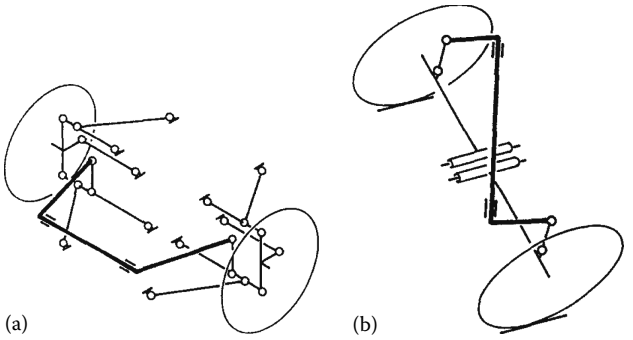

FIGURE 21.24 Stabilizer bar (a) and transverse compound spring (b).

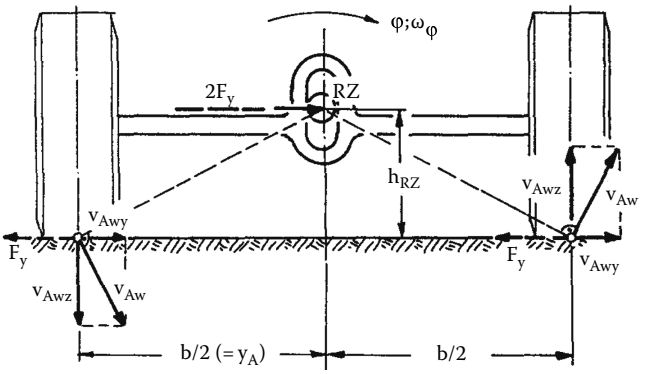

FIGURE 21.25 Roll center of a rigid axle.

"virtual power" with lateral forces and secondly—and decisive—because it is part of a "symmetrical" state of motion, while vehicle roll is an "antimetric" event. With antimetric motion of the axle, however, we get antimetric velocity vectors $\mathbf{v_{Aw}}$ at the tire contact points rectangular to the connecting lines of the contact points A and the fulcrum. The "power" of the lateral forces F_y and the velocity components v_{Awy} must be equal to the "power" of the rolling moment $2F_y h_{RZ}$ and the angular roll velocity ω_φ: $2F_y h_{RZ}\omega_\varphi = 2F_y v_{Awy}$, and since $v_{Awz} = \omega_\varphi y_A$, the roll-center height follows as

$$h_{RZ} = y_A\left(\frac{v_{Awy}}{v_{Awz}}\right) \tag{21.10}$$

With an independent suspension, there is only one form of wheel motion in relation to the vehicle body (Figure 21.26), while a compound suspension like the well-known "torsion-beam" or "H-frame" suspension in Figure 21.27 normally, of course, shows different forms of symmetrical and antimetric motion. With symmetrical up-and-down travel of both wheels, the whole "frame" rotates about the connecting line of the pivot points L and L′, that is, the axis m_p of parallel motion. With antimetric motion, however, the transverse beam is twisted about the connecting line of the shear centers T of its "open profile section," the medial point M of this line remaining "fixed" for reasons of antimetry. So the axis of antimetric motion m_w of each wheel runs through M and the respective pivot point L (or L′) and thus defines a respective "pole" Q_w in the cross-sectional plane. The antimetric velocity vector (not shown) at the contact point A in the cross-sectional plane is rectangular to the connecting line between A and Q_w and defines the roll center RZ.

The preceding considerations are valid only for very small lateral accelerations, where the lateral forces are approximately equal at both wheels and where the roll angle of the vehicle is negligible.

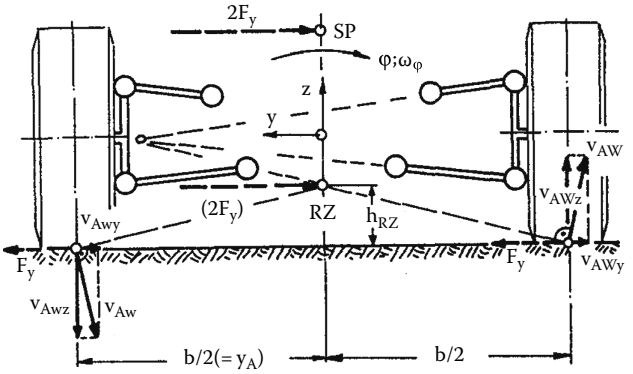

FIGURE 21.26 Roll center of an independent suspension.

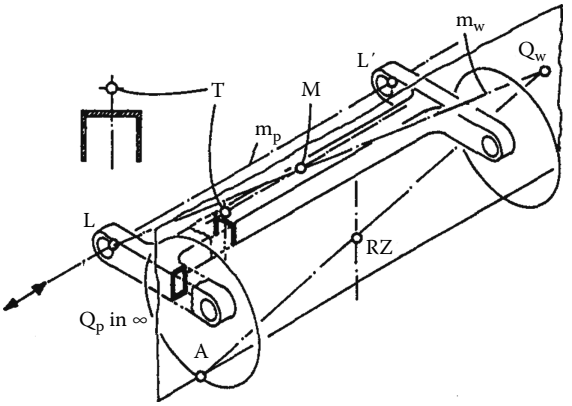

FIGURE 21.27 Roll center of a compound suspension.

With increasing lateral acceleration and roll angle, the positions of the suspensions of both wheels of an "axle" become nonsymmetrical (Figure 21.28). Here, the simple definition of a "roll center" hits up against its limits. Above all, it cannot be expected that the problem of high lateral acceleration would be solved by simple geometrical considerations, since the diagram of forces in Figure 21.28 is statically "overconstrained": the lateral forces F_{qa} and F_{qi} act in-line and result from a combination of nonlinear tire properties like the slip angle diagrams, camber forces, and toe-in or toe-out forces.

The suspension in Figure 21.28 is designed for a straightened path of the contact point A—which means "constant roll-center height above the road" and can be achieved by transverse links of unequal length, the length being approximately inversely proportional to the distance from the road [8]; see the upper sketch of Figure 21.28. The suspension is planar, so the poles can be used for the analysis of forces. Obviously, the "polar ray" A_a–P_{qa} of the outer wheel ascends considerably from the road, while the polar ray of the inner wheel is by far closer to the horizontal line. So the outer suspension can react to the vector sum of the axle-load transfer ΔF_{Ra} and the lateral force F_{qa} by a "kinematic" force K_a that reduces the necessary spring-force change ΔF_{FRa} to almost half the value of the required spring-force change at the inner wheel. The travel of the outer wheel toward bump is remarkably lower than the inner travel toward rebound; the vehicle is "jacked up."

Obviously, the jacking-up effect can be reduced by adapting the inclinations of the polar rays of both wheels to the respective forces acting so that the spring-force changes become equal on both wheels. This, of course, requires a suspension with a curved path of the tire contact

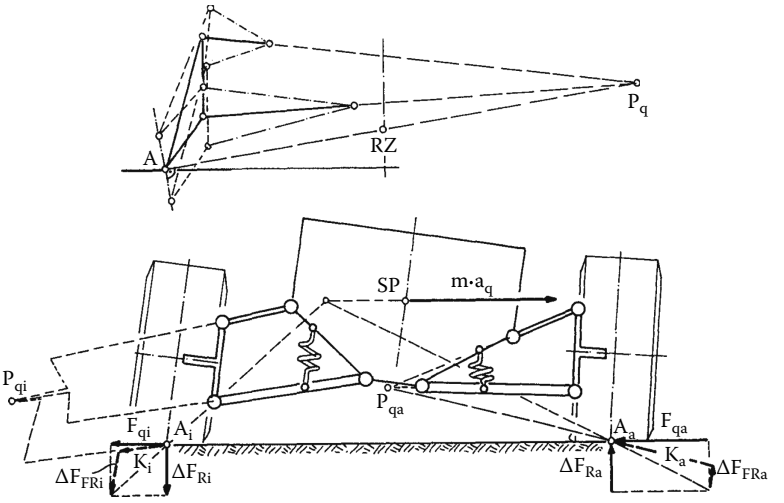

FIGURE 21.28 Independent suspension with high lateral acceleration.

point—consequently with a roll center sinking down to the road with bump. Modern independent suspensions preferably show a geometry where the roll center sinks downward with bump quicker than the vehicle body.

On rigid axles, jacking up is avoided for a roll center that appears "fixed" to the vehicle body, that is, that sinks toward the road with bump as quickly as the vehicle (this is true, for instance, for the axle shown in Figure 21.25).

Driving stability of the vehicle and its behavior in cornering can also be influenced by kinematic self-steering ("bump steer") of the suspension. The rise of a steering angle from vehicle roll can be easily explained with a rigid-axle suspension (Figure 21.29). The four-link mechanism can rotate in relation to the body only about the line connecting the points of intersection P_v and P_h of the links. Consequently, the line P_vP_h is the instantaneous axis m_w of antimetric motion and, of course, defines the roll center RZ. The "roll axis" r of the vehicle runs through RZ (see Figure 21.23). With vehicle roll angle φ and an angle κ between m_w and r, the rigid-axle beam will in plan view assume a steering angle

$$\delta = \kappa\varphi \tag{21.11}$$

similar to the axles of the well-known steerable roller skate (which employs distinctly skew axes m_w).

A positive steering angle δ on a rear axle increases the cornering radius in a left-hand corner and, consequently, promotes understeering; the contrary applies to a front axle.

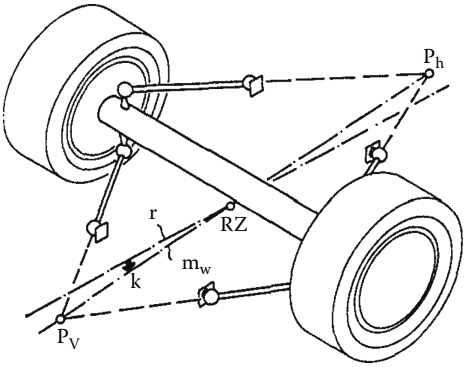

FIGURE 21.29 Four-link rigid-axle suspension.

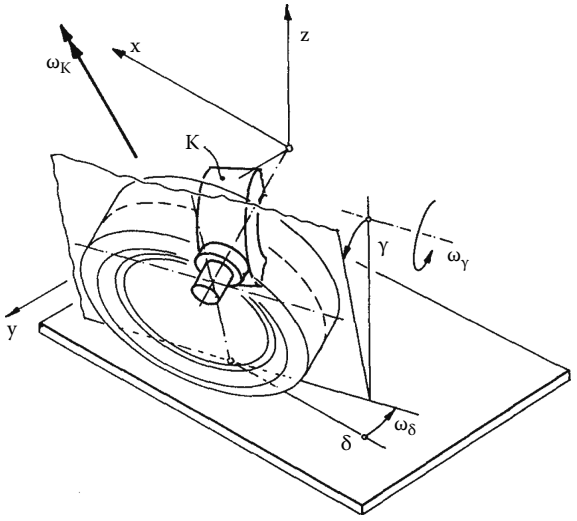

FIGURE 21.30 Angular interdependences at a wheel carrier.

With independent or compound suspensions, the definition of an angle κ is difficult and of little use because the two wheels may assume different steering angles that have to be divided into resulting toe-in angles and steering angles.

In general, a wheel carrier K with given steering angle δ, wheel camber angle γ, and angular velocity $\boldsymbol{\omega}_K$, as shown in Figure 21.30, generates a wheel camber velocity [1,6]

$$\omega_\gamma = -\omega_{Kx}\cos\delta - \omega_{Ky}\sin\delta \tag{21.12}$$

and a steering velocity

$$\omega_\delta = -\omega_{Kx}\tan\gamma\sin\delta + \omega_{Ky}\tan\gamma\cos\delta + \omega_{Kz} \tag{21.13}$$

(note that the steering velocity is not necessarily equal to the vertical component of ω_K!).

With a vertical component v_{Az} resulting from a virtual spring deflection (or, because of the same value, velocities v^*_{Az} or v^{**}_{Az}), the camber change and the steering angle with wheel travel become

$$\frac{d\gamma}{ds} = \frac{\omega\gamma}{v_{Az}} \tag{21.14}$$

$$\frac{d\delta}{ds} = \frac{\omega\delta}{v_{Az}} \tag{21.15}$$

Typical steering effects of an independent suspension are discussed using Figure 21.31. The double-wishbone suspension with a rod link (e.g., the track rod of a steerable system) behind the wheel may be designed so that the inboard joint of the rod is in the center of curvature of the path of the rod's outboard joint (position 0). The toe-in curve $\delta_v(s)$ has, therefore, a vertical tangent in the normal position (s = 0)—which means that dδ/ds is zero. With bump, however, toe-in increases slightly while, with rebound, the wheel moves progressively toward toe-out.

This "s shape" of the curve is typical for multi-link suspensions and is caused by the deviation of the theoretical path of the outboard joint of the rod, as given by the wheel-carrier motion (here with a variable radius of curvature), from the real path that is a circle about the inner joint of the rod.

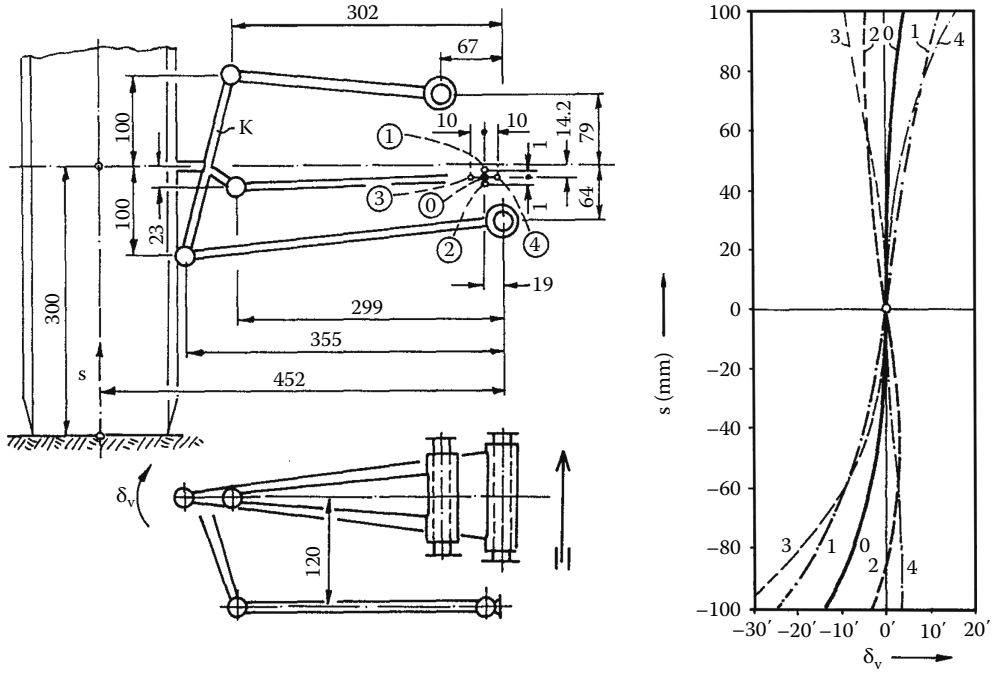

FIGURE 21.31 Toe-in against wheel travel for an independent suspension.

Displacement of the inner joint of the rod by merely 1 mm up or down (positions 1 and 2) leads to a considerable change in the toe-in gradient, the curve, however, retaining its s shape. On the other hand, lengthening or shortening the rod (positions 3 and 4) by ±10 mm without changing the height does not affect the gradient but deforms the curve by an overlaid circular shape.

These tendencies will be inverted with the rod link before instead of behind the wheel.

The diagram shows up two important things: Firstly, careful control of especially the vertical positions of joints (in production and by suitable design) is wanted to avoid undesirable tolerances of steering angles; secondly, deliberate deviation from the "kinematically correct" layout may serve for desirable steering effects or for compensation of elastic steering angles (Section 21.7).

21.5 STEERING GEOMETRY

Front wheels of fast vehicles are steered by axle-pivot (or "kingpin") steering that makes for very small lever arms of disturbing forces, saves space in the vehicle, and causes only negligible loss of embraced ground space (so secures stability against upset).

As for suspension geometry, special "steering characteristics" have also been established for steering geometry. The conventional definitions of most of these characteristics are shown in Figure 21.32.

The kingpin axis d is normally defined by two ball joints at the wheel carrier and is therefore "fixed" to the latter. It is inclined in cross section of the vehicle by the "kingpin inclination" σ and in side view by the "castor angle" τ. The horizontal distance between the intersection point D of the kingpin with the road surface and the center plane of the wheel is the "scrub radius" or "kingpin offset" r_S, while the corresponding distance at wheel-center height is the "wheel-center offset" r_C. In side view to the wheel, the horizontal distance between point D and the tire contact point A is the "castor offset" n, and the corresponding characteristic at the height of the wheel center is the "castor offset at wheel center" n_τ.

While these characteristics have already been standardized worldwide, this is not true for another, less visualized characteristic that is also of very great importance with respect to the relevant amount of the wheel load: the "wheel-load lever arm" p [1,6,7].

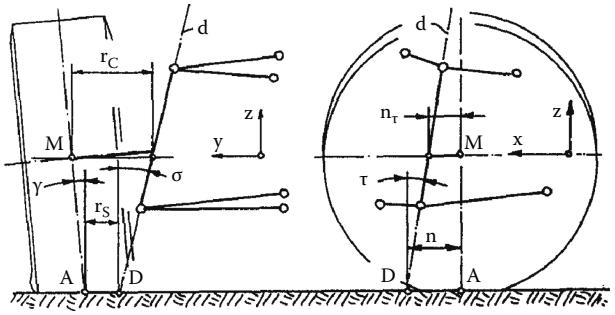

FIGURE 21.32 Conventional definitions of steering characteristics.

On a suspension with the kingpin fixed to the wheel carrier, as in Figure 21.32, the wheel-load lever arm can be calculated by

$$p = r_S \tan\tau + n \tan\sigma \tag{21.16}$$

At the end of the 1970s, steerable suspensions appeared with a "kingpin" defined by an instantaneous axis or even an instantaneous screw, to achieve more freedom in kinematic layout especially with respect to antilock braking systems and the space available in the wheels for brake disks. Figure 21.33 shows how a suspension with conventional "fixed" kingpin axis (d) can be transformed into one with a "virtual" kingpin axis (i) by splitting the triangular links into separate rod links. An early example of such a suspension is depicted in Figure 21.34. The triangular link of the strut-type design is split into a transverse and a tension link, both coupled with the wheel carrier by separate ball joints.

With such a design, the kingpin is normally variable with respect to the suspension links as well as to the wheel carrier, and several of the conventional definitions discussed with Figure 21.32 are no longer valid. Moreover, the virtual kingpin axis may become an instantaneous screw and, consequently, no longer be applicable for the definition of lever arms for forces.

For this reason, there is a need for improved definitions of the steering-geometry characteristics but, of course, in full compatibility with those hitherto. The method will be the same as used in the preceding considerations, namely, application of "virtual power balance" (Figure 21.35).

Since angular interdependences are not affected by the question of whether the kingpin axis is a screw axis or not, the definitions of the kingpin inclination σ and the castor angle τ can be retained:

$$\sigma = -\text{atn}\left(\frac{\omega_{Ky}}{\omega_{Kz}}\right) \tag{21.17}$$

$$\tau = -\text{atn}\left(\frac{\omega_{Kx}}{\omega_{Kz}}\right) \tag{21.18}$$

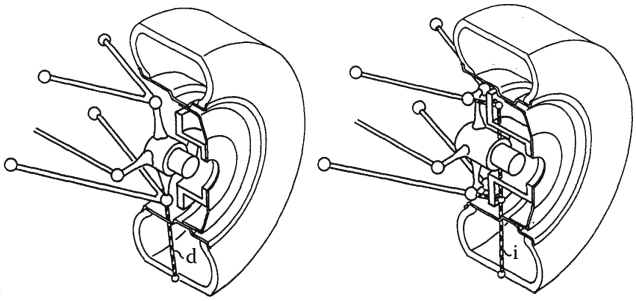

FIGURE 21.33 Suspensions with fixed (d) and virtual (i) kingpin axes.

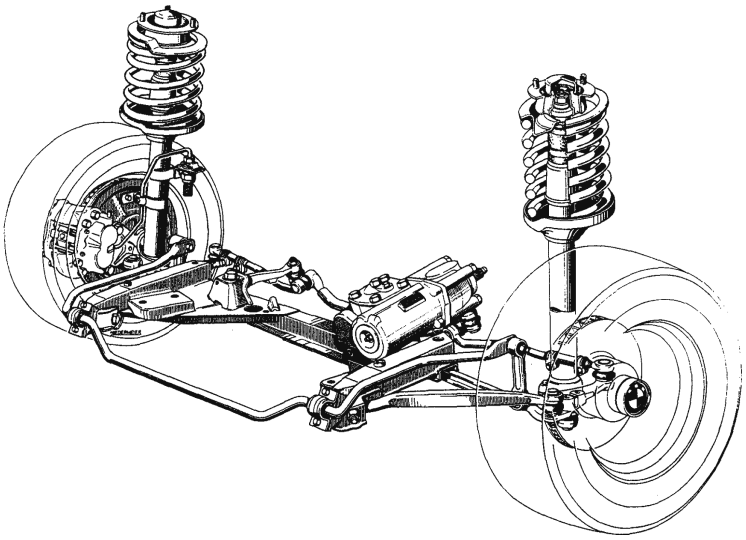

FIGURE 21.34 Strut suspension with virtual kingpin axis. (Courtesy of BMW AG, Munich, Germany, 1977.)

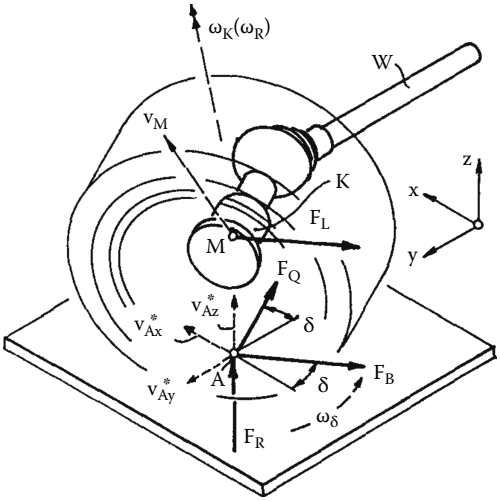

FIGURE 21.35 Velocities and forces with a steered wheel.

The scrub radius r_S is known as the lever arm of a braking force if the brake is mounted to the wheel carrier. To secure compatibility with the conventional definition, a scrub radius r_S derived from Figure 21.35, together with a braking force F_B, must give a moment $F_B r_S$ and generate a "power" $F_B r_S \omega_\delta$ with ω_δ according to Equation 21.13. With a virtual vector $\mathbf{v}^*_A$—which stems from a virtual *steering input* assuming the *spring* to be *incompressible*—the virtual "power" of a braking-force vector $\mathbf{F}_B$ is its scalar product with $\mathbf{v}^*_A$; so we get $F_B r_S \omega_\delta = \mathbf{F}_B \cdot \mathbf{v}^*_A$, and with the components $F_{Bx} = -F_B \cos\delta$, $F_{By} = -F_B \sin\delta$, and $F_{Bz} = 0$, the scrub radius is

$$r_S = \frac{-\left(v^*_{Ax} \cos\delta + v^*_{Ay} \sin\delta\right)}{\omega_\delta} \tag{21.19}$$

The wheel-center offset r_C, the castor offset n, the castor offset at wheel center n_τ, and the wheel-load lever arm p follow by similar considerations:

$$r_C = \frac{-\left(v_{Mx}\cos\delta + v_{My}\sin\delta\right)}{\omega_\delta} \tag{21.20}$$

$$n = \frac{-\left(v^*_{Ax}\sin\delta - v^*_{Ay}\cos\delta\right)}{\omega_\delta} \tag{21.21}$$

$$n_\tau = \frac{\left(v_{Mx}\sin\delta - v_{My}\cos\delta\right)}{\omega_\delta} \tag{21.22}$$

$$p = -\frac{v^*_{Az}}{\omega_\delta} \tag{21.23}$$

By multiplication with the time differential dt, Equation 21.23 changes to

$$p = -\frac{dz}{d\delta} \tag{21.24}$$

or the wheel-load lever arm is the derivative of the vehicle lift over the steering angle (with the spring assumed to be incompressible).

Typical curves of the steering characteristics γ, n, and p for suspensions with "fixed" kingpin axes and different geometrical layouts are shown in Figure 21.36.

It is clearly seen that the gradient of wheel camber γ in straight-ahead position (δ = 0) is approximately proportional to the castor angle.

The castor offset n increases with inner steering angle and decreases with outer, finally becoming negative.

The gradient of the wheel-load lever arm p for δ = 0 is the "restoring-force lever due to vehicle weight" dp/dδ, the most important prerequisite for self-centering of the steering in straight-ahead driving. On a suspension with "fixed" kingpin during a steering event with "incompressible" spring, increasing dp/dδ obviously goes along with increasing castor-offset change dn/dδ (which latter is disadvantageous for steering returnability in cornering).

This problem can be bypassed by separating the spring from the suspension links (Figure 21.37). However, the wheel-load lever arm can be influenced widely on a suspension with a "virtual kingpin."

In analogy to the generalized definitions of the steering characteristics according to Figure 21.35, but using a virtual velocity v_A^{**} for a virtual steering input with "locked" engine and shaft drive, a "traction-force radius" r_T [1,6] can be calculated as

$$r_T = \frac{-\left(v^{**}_{Ax}\cos\delta + v^{**}_{Ay}\sin\delta\right)}{\omega_\delta} \tag{21.25}$$

that is plotted against the wheel travel s in Figure 21.38 in comparison with the scrub radius r_S and the wheel-center offset r_C of a normal wheel suspension. In contrast to r_S and r_C, r_T decreases with bump and increases with rebound, thus immediately explaining the behavior of a front-drive car in

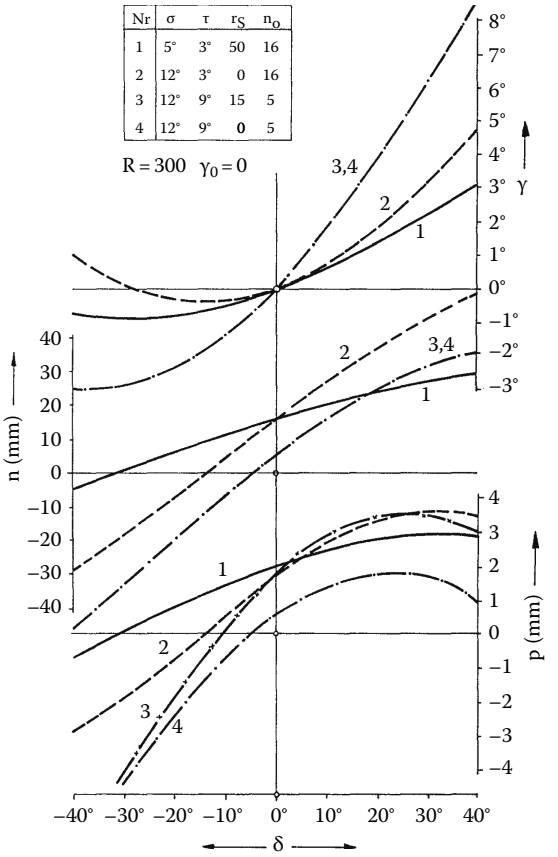

FIGURE 21.36 Camber, castor offset, and wheel-load lever arm plotted against steering angle.

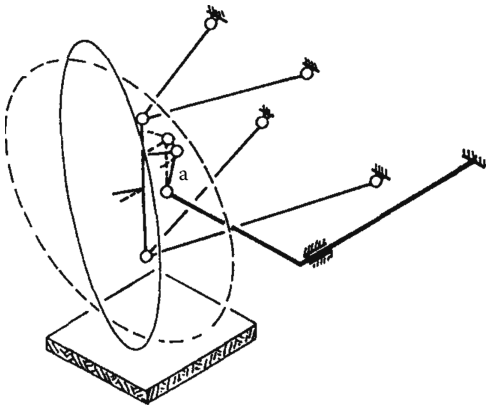

FIGURE 21.37 Free choice of restoring torque due to vehicle weight.

cornering, with the outer suspension deflected toward bump and the inner toward rebound: due to the different radii r_T, accelerating forces try to straighten the steering.

On a suspension with transverse driveshaft, but without a hub reduction gear, the radius r_T is easily determined according to Figure 21.39: the bisecting line d* of the wheel and shaft axes (or also a line parallel to it) through the intersection point H of wheel axis (a) and kingpin axis (d) intersects the road surface in a distance r_T from the tire contact point A.

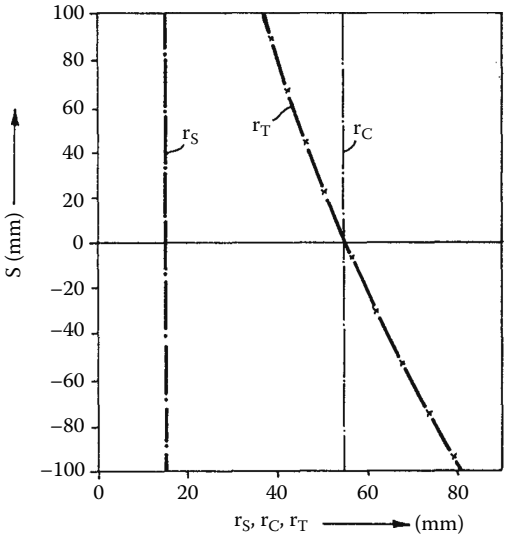

FIGURE 21.38 Traction-force radius, wheel-center offset, and scrub radius against wheel travel.

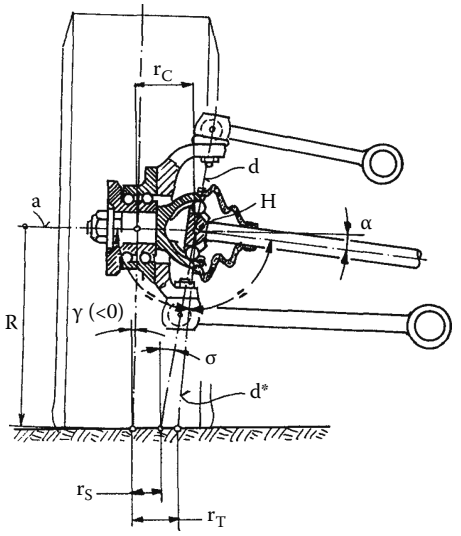

FIGURE 21.39 Graphical approximation of the traction-force radius.

With a hub reduction gear, the radius r_T can be considerably reduced, provided the kingpin inclination σ is other than zero and especially if the reduction ratio is negative (inversed rotation). With the angles in radians, r_T can be approximated [6] by

$$r_T \approx r_S + \left(\frac{R}{i}\right)\left(\frac{\sigma+\gamma-\alpha}{2}\right) \tag{21.26}$$

where

R is the wheel radius
i is the reduction ratio
σ is the kingpin inclination
γ is the wheel camber
α is the angle of the shaft deflection

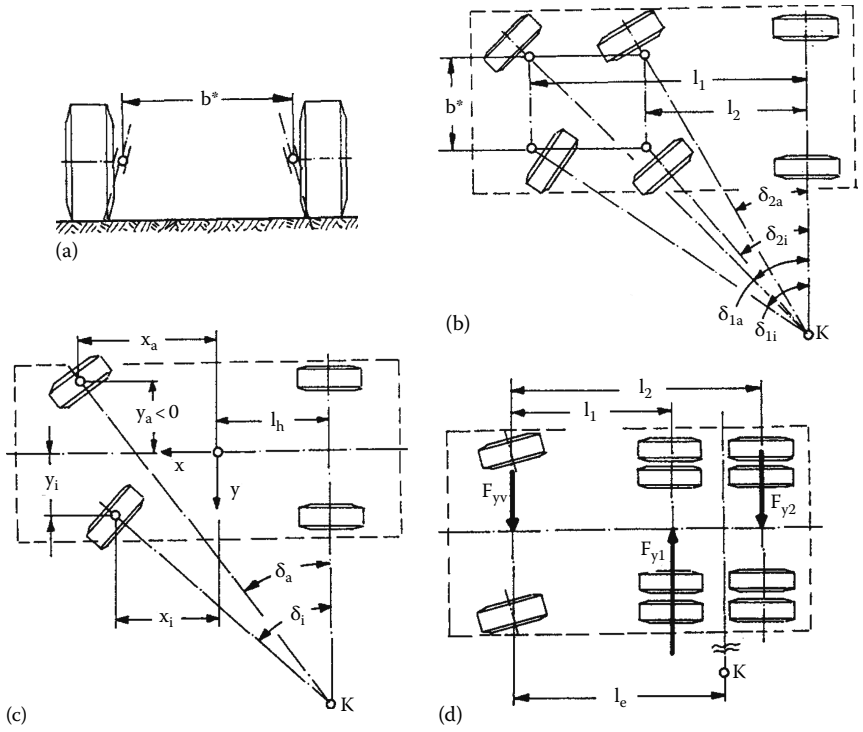

FIGURE 21.40 Ackermann condition: (a), (b) Simplifying consideration, (c) generalized and exact consideration, and (d) non-steerable tandem rear axle.

The steering linkage, consisting of levers and track rods, connects the two wheels of a steerable "axle" to the steering box and has to ensure a certain relationship of the outer and inner steering angles δ_a and δ_i. For instance, these angles may be wanted to fulfill the condition that all wheel axes of the vehicle intersect in plan view (Figure 21.40). Such a layout provides exact rolling of all wheels about a center of cornering K and is called the "Ackermann condition." The corresponding steering angles are the "Ackermann angles" (note that in vehicle dynamics, this term is applied to the medial steering angle of two wheels and is thus of quite different interpretation). The well-known simplifying "Ackermann equations"

$$\cot \delta_a = \frac{\cot \delta_i + b^*}{l} \tag{21.27}$$

for the relationship of steering angles at one axle and

$$l_1 \cot \delta_1 = l_2 \cot \delta_2 \tag{21.28}$$

for the relationship of steering angles between two axles (Figure 21.40b) are not sufficiently exact for modern suspensions with large kingpin inclinations (or even "virtual" kingpin axes) where they may lead to errors up to two angular degrees at full lock and, consequently, to serious errors in the steering-returnability layout. In such a case, it is preferable to consider the real positions of the wheels (Figure 21.40c) [1,6].

On trucks or trailers with tandem axles, the effective "wheelbase" follows from an approximation as

$$l_e = \frac{l_1^2 + l_2^2}{l_1 + l_2} \tag{21.29}$$

and is slightly longer than the medial wheelbase of the two axles (Figure 21.40d).

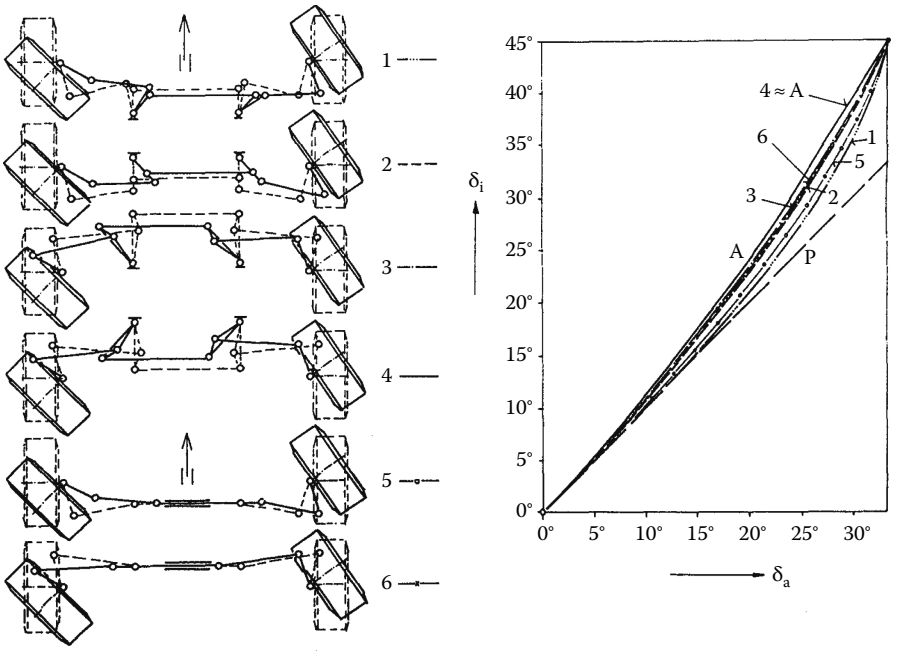

FIGURE 21.41 Typical properties of steering-linkage arrangements.

A comparison of typical properties of steering linkages for independent suspensions is shown in Figure 21.41. With respect to modern suspensions with soft longitudinal compliance (see Chapter 21.7), track rods are preferably arranged in transverse direction to avoid induced steering angles with fore-and-aft compliance.

The Ackermann curve A is not curved steadily in the same sense but tends toward a point of inflection. Only the linkage 4 is able to provide such a behavior [9] but this, however, at the expense of an extreme forward position of the steering box. The linkage 1 shows the greatest deviation of the Ackermann curve and close approximation to the curve P of parallel steering of both wheels over a wide range.

Steering returnability with high lateral accelerations is mainly secured by the lateral forces of the tires in connection with the steering-geometry characteristics.

When rolling forward, and loaded with a lateral force (Figure 21.42), a tire shows an angular deflection of its contact patch by the slip angle α, caused by the trapezoidal diagram of lateral shear τ. The resulting force of this diagram is therefore displaced behind the wheel center by the "pneumatic trail" n_R.

Consequently, the lateral force of the tire acts on a steerable suspension by an effective lever that is the sum of the (geometrical) castor offset n and the pneumatic trail n_R.

With increasing lateral force (and increasing slip angle α), however, the shear diagram (τ) begins to collapse at its rear end, and the pneumatic trail n_R decreases toward zero.

Moreover, with increasing steering angle, the castor offset n of the (dominant) outer wheel decreases and may in the end assume a negative value; see Figure 21.36.

For this reason, the restoring torque at the steering wheel usually shows a "degressive" curve with respect to steering angle and lateral acceleration. This has the advantage of avoiding high steering-wheel forces and cramped muscles of the driver's arms, securing better sensitivity for steering corrections that may be needed at the vehicle's dynamic limits. At any event, a restoring torque greater than zero is necessary to provide correct information about the actual state of forces.

The increased wheel load of the outer wheel acts on the corresponding wheel-load lever arm p and contributes to returnability if p is negative—which is true only for greater steering angles (see Figure 21.36).

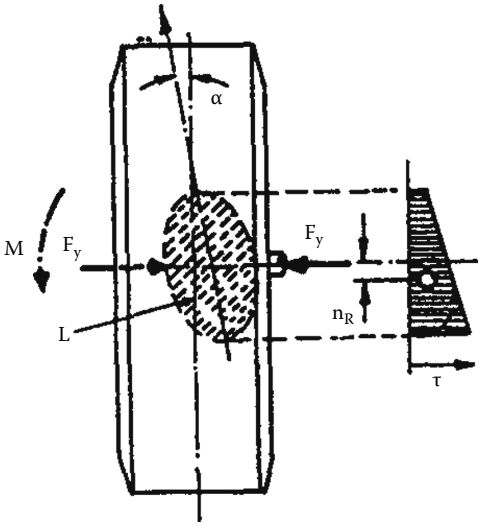

FIGURE 21.42 Tire slip angle α and pneumatic trail n_R.

A strong braking-force support angle, especially if progressive with bump, causes a "stabilizer" effect at the front axle that may lead to self-reinforcing understeer and so may impair the returnability, as already mentioned in Section 21.4.

In contrast with cornering at high lateral accelerations, the steering returnability at very low speed, with a lateral acceleration near zero—for example, during a parking maneuver—is influenced by a considerably greater number of parameters. In the extreme case, wheel-load transfer and dynamic lateral forces vanish.

If the steering geometry shows a deviation from Ackermann, for instance, because of the special property of the steering linkage (see Figure 21.36) or also because of deliberate approximation to the parallel steering curve (P) for better use of the sideslip potential of the two wheels (as very usual in the past), the angles of deviation act like considerable "toe-in" angles and generate lateral forces directed toward the medial plane of the vehicle on *both* wheels. Due to the decrease in the outer castor offset n with respect to the inner, with increasing steering angle (see Figure 21.36), these "toe-in forces" cause a moment that tends to increase the steering angle and so to impair the return of the steering. The vehicle load, of course, acts on the wheel-load lever arm in a restoring sense, but it is usually too small to counteract the "toe-in" moment.

However, with great steering angle and small cornering radius, the tire generates a "scrub torque" that tries to resist the circular path of the contact patch on the road, and this torque will in many cases "save" the returnability.

The returnability of the steering at low speed obviously depends on the difference between two large moments that, moreover, are affected by considerable tolerances caused by tire wear, pressure, temperature, manufacturer, etc. (a worn tire with abrased tread shows significantly higher sideslip forces than a well-grooved one). For this reason, good approximation of the steering geometry to Ackermann may be recommendable on suspensions with great castor-offset change, and road tests should cover the whole field of possible conditions like worn tires, high and low friction coefficients, and wrong tire pressure.

21.6 SPRINGS AND SUSPENSION

The primary purpose of springing and damping is to protect the vehicle body from impact forces resulting from road irregularities. Upon being compressed or extended, the spring stores or releases energy, the vehicle body experiencing only the spring-force fluctuation.

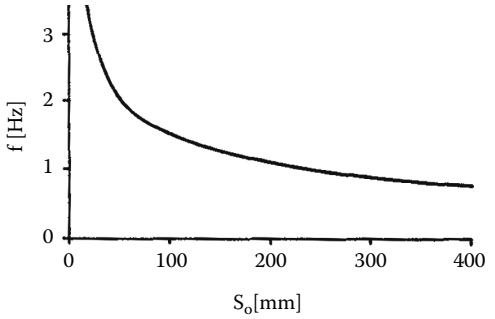

FIGURE 21.43 Natural frequency versus static deflection for a linear spring.

Most acceptable frequencies for a human being range between f = 0. 7 and 2.0 Hz that correspond to static compressions s_o of a linear spring of about 500–60 mm (Figure 21.43). Since the wheel travel of a suspension is limited to about ±100–120 mm, a soft spring cannot store much energy. A progressive spring characteristic is achieved by the superimposition of a basic and an auxiliary spring (preferably of the rubber-elastic type).

For a comfortable vehicle, the pitching frequency should not be higher than the bounce frequency. On a vehicle with long wheelbase or low pitching moment of inertia, this may require application of a "longitudinal compound springing system" in order to reduce the pitching frequency (this is typical, e.g., for light front-drive cars).

Long-wave obstacles like railway crossings excite pitching oscillations due to the delay of time between the impacts on the front and on the rear wheels. For quick fading of the pitch angle, it is usual to give the rear suspension a chance to "catch up" on the oscillation of the front suspension by providing the bounce frequencies at the front axle lower than at the rear axle. This measure, on the other hand, is contradictory to the desire for a "front roll rate" higher than the rear rate (see Section 21.4) and is the reason for the application of antiroll bars at the front suspensions.

Several features that concern the interaction of springs and suspension are taken into consideration in the following.

Even today, leaf springs are in use also still for suspension purposes. A nonsymmetrical leaf spring (Figure 21.44) shows a rotation of the axle beam connected to it about a "pole" p, with a polar distance

$$p = \frac{l_1 l_2}{(l_2 - l_1)} \tag{21.30}$$

This pole corresponds absolutely to the "kinematic" pole of a suspension mechanism and is therefore applicable in the same sense, for example, for the determination of a support angle.

Under traction or braking torque M, a leaf-sprung axle "winds up" by an angle α' (Figure 21.45); the windup spring rate is

$$c_{\alpha'} = \frac{dM}{d\alpha} = c l_1 l_2 \tag{21.31}$$

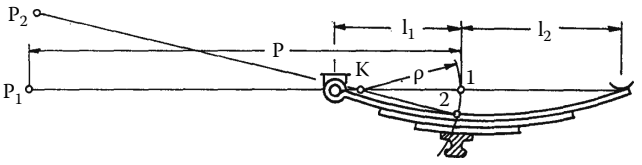

FIGURE 21.44 Nonsymmetrical leaf spring with its pole.

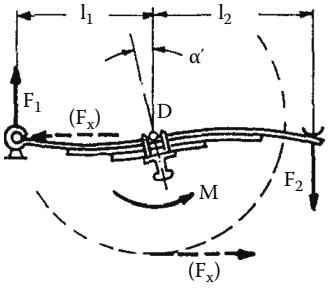

FIGURE 21.45 Windup of a leaf spring under torque.

or $c_{\alpha'} = cl^2$ for a symmetrical spring with $l_1 = l_2 = l$—which means that the resistance to windup increases proportionally to the square of the length (a decisive reason for the application of long leaf springs).

A coil spring is usually mounted between the body and a suspension link and is thus subjected to bending with wheel travel (Figure 21.46). Minimum bending moments, optimum security against buckling, and minimum height of installation can be achieved by a symmetrical deformation of the spring at both ends (Figure 21.46b).

In a suspension, the spring is usually displaced from the wheel load line, and so shows a "spring ratio" between its deflection and the wheel travel (Figure 21.47). The effective spring force F_{FA} "reduced" to the tire contact point A follows from the spring force F_F by the balance of power: $F_F v_f = F_{FA} \cdot V_{Az}$, or with the spring ratio

$$i_F = \frac{v_f}{v_{Az}} \tag{21.32}$$

we get

$$F_{FA} = F_F \cdot i_F \tag{21.33}$$

The effective "spring rate" $c_{FA} = dF_{FA}/ds = d(F_F i_F)/ds$ reduced to the tire contact point A depends on the variable spring force F_F and on the spring ratio i_F that is also variable in most cases. Therefore, the effective spring rate has to be calculated [10] by

$$c_{FA} = c_F i_F^2 + F_F \left(\frac{di_F}{ds} \right) \tag{21.34}$$

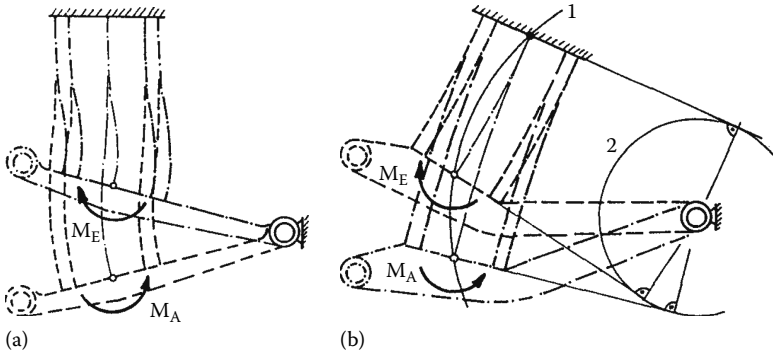

FIGURE 21.46 Coil springs and suspension links.

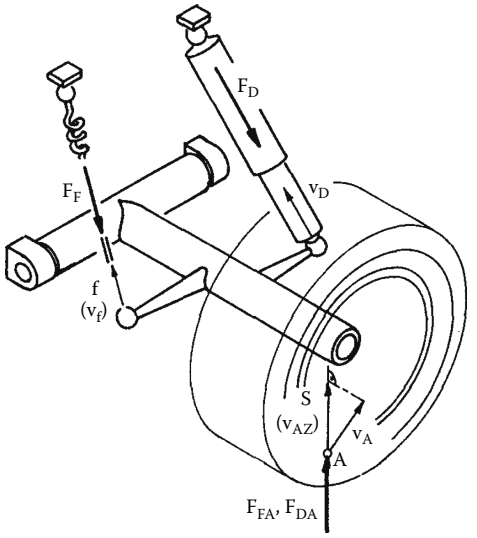

FIGURE 21.47 Spring ratio.

The second term of this equation is the "kinematic spring rate," and its application is conspicuous especially at the rear suspensions of motorcycles in order to achieve a highly progressive spring characteristic using a linear spring element.

Variable spring ratio, however, is closely coupled with variable levers and varying directions of forces. Modern wheel suspensions are designed for elasto-kinematic function—see Section 21.7—and especially for soft longitudinal compliance. To avoid fluctuating horizontal components of forces on such a suspension, kinematic tricks to influence the spring characteristic are not recommendable. The spring and the damper should preferably retain an approximately vertical position in the vehicle.

On a suspension with traction or braking anti-pitch design, and with the support angle variable with wheel travel, the longitudinal force influences the temporary spring rate during a braking or accelerating event [1,6].

Finally, another "suspension characteristic" may be mentioned, which, however, is of subordinate importance on wheel suspensions for motorcars, namely, the "wheel-travel angle" ε (Figure 21.48), by which the path of the wheel center M is inclined with respect to the vertical line in side view:

$$\varepsilon = -\text{atn}\left(\frac{v_{Mx}}{v_{Mz}}\right) \tag{21.35}$$

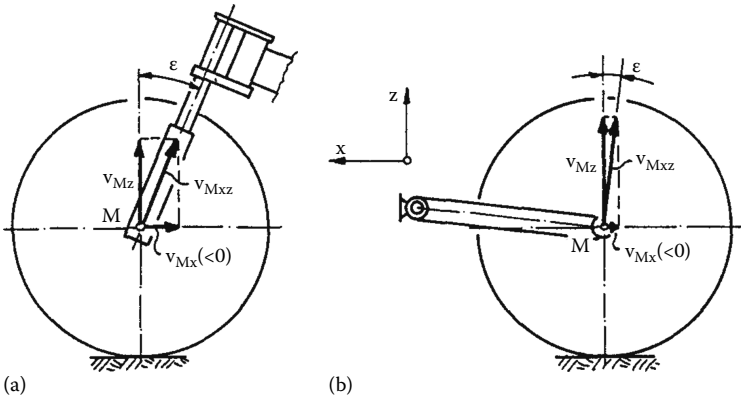

FIGURE 21.48 Wheel-travel angle at a telescopic fork (a) and a trailing link (b).

It is conspicuous for a telescopic front fork of a motorcycle (a)—and may there be useful for off-road riding—but is of minor interest on a motorcar suspension (b) having regard to the rubber-elastic mountings of the latter. It has already been mentioned in Section 21.4 that there is a relationship to the traction-force support angle of a suspension with driveshaft.

21.7 ELASTO-KINEMATICS

Road irregularities as well as tire nonuniformity excite suspension vibrations that are softened by rubber mountings. These also serve for noise insulation and have the additional advantages of being maintenance-free, friction-free, capable of recovering after temporary overload, and cost saving.

In former times, rubber mountings normally worsened the driving behavior, since they provoked undesirable elastic properties at the suspension mechanism, so it was usual to replace them by stiff (e.g., metallic) joints for motor sport purpose.

On comfortable vehicles, longitudinal compliance of a suspension may achieve as much as 15 mm. Suitable countermeasures are required to avoid unfavorable steering angles on such a suspension.

The term "elasto-kinematics" means a conscious harmonization of the spring rates of the suspension joints (and possible elastic rates of any chassis elements) and of the spatial arrangement of the suspension links to compensate for the elastic displacements that occur under external loads or even to convert them into "wanted" displacements.

A historical solution of a longitudinally compliant suspension, first applied as early as in 1933, is shown in Figure 21.49. The double-wishbone system can rotate about an axis d at the chassis against the restoring force of a rubber mounting G. The track rod Sp runs roughly parallel to the plane defined by the axis d and the kingpin axis, thus allowing longitudinal displacement without noticeable toe-in change.

This is, of course, not yet an "elasto-kinematic" assembly in the modern sense, but there is already an intention to be seen of avoiding elastic "windup" of the wheel carrier under braking force.

On a rubber joint, different spring rates in different directions are easy to achieve (Figure 21.50). A skew force F leads to a displacement f that is deflected toward the softer spring in direction "1" (the drawing also shows the—exact—graphical design according to the Mohr/Land method to determine the displacement $f = F/c^*$). These properties of rubber springs are frequently utilized especially for subframe mountings.

Elasto-kinematic investigations can be divided into two main fields: the suspension mechanism and the structure of subframes or the vehicle body. While suspensions are generally statically

determinate systems and therefore easier to survey, the deformations of spatial structures can normally be evaluated only by establishment of finite-element models.

In the first place, typical measures of elasto-kinematic harmonization of the suspension mechanism may be demonstrated using an example of a five-link system with very clear and symmetrical dimensions (on a realistic suspension, all the effects discussed here will appear in superimposition).

The wheel load F_R (Figure 21.51) is caught up by the outboard joint of the upper transverse link that supports the spring. The moment $F_R b_R$ loads the upper transverse link by compression and the two lower transverse links by tension, while the two longitudinal links are not involved.

For the vehicle's driving stability, preferably an elastic steering angle (toe-in change) $\Delta\delta_v$ is of interest and occasionally an elastic camber change $\Delta\gamma$, too. On the simple mechanism of Figure 21.51, the elastic toe-in change and camber change follow from the deformations f_1 and f_2 of the two lower transverse links and f_3 of the upper one as

$$\Delta\delta_v = \frac{(f_1 - f_2)}{2l} \quad \text{and} \quad \Delta\gamma = \frac{\left[f_3 - (f_1 + f_2)/2\right]}{2h}$$

where $f_1 = F_1/c_1$, etc. (>0 for tension force). With the elastic deformations $f_1 \ldots f_3$ we get an elastic chamber angle (here negative) $\Delta\gamma_R$ and an elastic toe-in-charge $\Delta\delta_{vR}$ caused by the wheel load force F_R.

While F_R causes a negative camber change, the toe-in angle will be negative (i.e., toe-out) for $c_1 > c_2$. Based on the "kinematic" toe-in curve δ_{v0} of the (rigid) suspension mechanism (Figure 21.51d), the "elastic" curve under wheel load δ_{vR} is displaced in normal position (s = 0) by $\Delta\delta_{vR}$ and, since the wheel load increases with bump, will show increasing offset from the curve δ_{vo}.

If undesired, the offset $\Delta\delta_{vR}$ can be compensated for by adjusting one of the lower transverse-link joints. To correct the changed gradient of the curve δ_{vR}, a deliberately "wrong" kinematic adjustment of the vertical coordinate of one of the joints of the lower transverse links is useful (see Figure 21.31), and a variation of the length of one of the links may help to correct a possibly unfavorable change in the radius of curvature of δ_{vR}.

These elasto-kinematic measures obviously allow to achieve any desired function of the suspension under wheel load. With this state of the system, the next case to be investigated may be that of lateral force (e.g., cornering) (Figure 21.52).

The lateral force F_Q loads the suspension at a point displaced behind the tire contact point A by the "pneumatic trail" n_R (see Figures 21.42, 21.52b and d) and, consequently, the lower transverse rear link by a considerably greater reaction force than the lower tansverse front link, and causes elastic compression of these two links and deformations f_1 and f_2. The upper transverse link is loaded by a tension

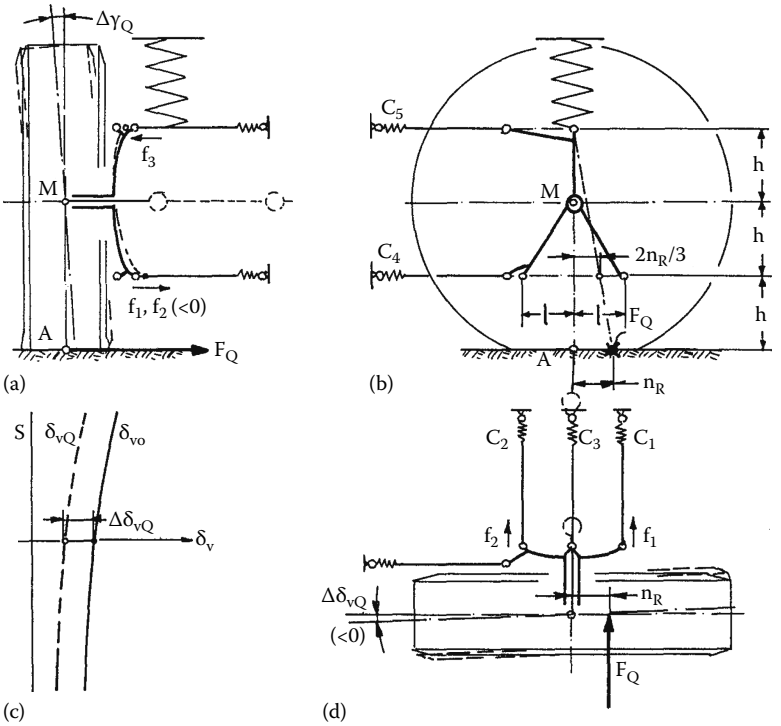

FIGURE 21.52 Suspension of Figure 21.51 loaded with a lateral force F_Q.

force and, therefore, elongated by f_3. The deformations f_1 and f_2 lead to a toe in change $\Delta\delta_{vQ}$ (positive or negative, depending on the spring rates of the lower transverse links) caused by the lateral force, and, together with the elongation f_3 of the upper transverse link, to a (positive) elastic camber change $\Delta\gamma_Q$.

On a front wheel, toe-out will be welcomed because this will improve the vehicle's behavior by an understeering reaction to a steering input (important for the driver's safe "feeling"), while on a rear wheel, toe-out means oversteering and is at any event undesirable. To compensate for undesired toe-out, there are obviously two imaginable measures: firstly, a reinforcing of the spring rate c_1 (or reduction of c_2) without affecting the suspension geometry and, secondly, a shift of the lower transverse links in fore-and-aft direction to provide more suitable reaction forces of the links. These measures, of course, require repeat of the investigations into wheel-load elasto-kinematics as discussed with Figure 21.51.

As already noted in Section 21.5, the pneumatic trail n_R decreases as the lateral acceleration increases. For this reason, any compliant front suspension will show a tendency toward elastic oversteering and any rear suspension a tendency toward elastic understeering with increasing lateral acceleration.

With the brake arranged between wheel and wheel carrier, as usual, a braking force F_B acts at the tire contact point A (Figure 21.53) and causes reaction forces at the longitudinal links, namely a tension force at the lower link and a compression force at the upper one, and elastic deformations f_4 and f_5 of them. Moreover, due to the lateral offset b_B of the longitudinal links from the central plane

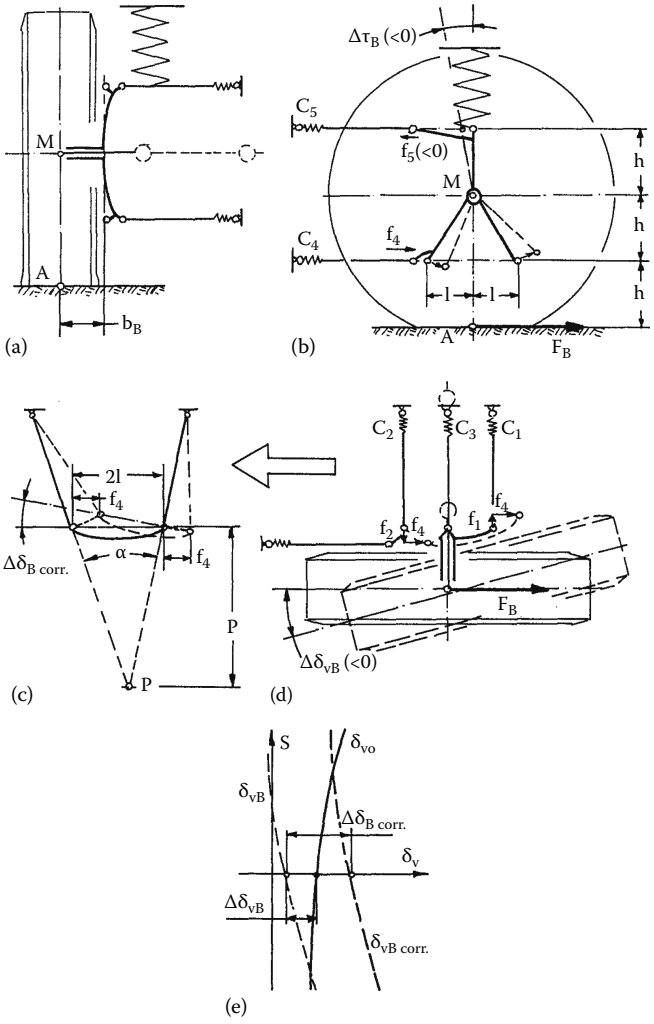

FIGURE 21.53 Suspension of Figure 21.51 loaded with a braking force F_B: τ = windup angle of wheel carrier.

of the wheel (Figure 21.53a), the lower transverse rear link is compressed by f_1, while the front one is elongated by f_2. This causes an elastic steering angle $\Delta\delta_{vB}$ that shifts the "kinematic" toe-in curve δ_{v0} in toe-out sense. While elastic camber change is here of little interest, a negative toe-in change will, of course, be favourable at a front suspension since, in cornering, the (dominant) outer wheel will promote an understeering reaction during braking. On a rear wheel, however, a toe-in increase during braking when cornering is urgently desired in order to counteract the oversteering "power-off effect" that occurs especially in emergency situations.

With the spring rates of the transverse suspension links already adapted to the preceding load cases ofwheel load and lateral force, the inversion from toe-out into toe-in requires application of a new trick (Figure 21.53c): the inclination of the two lower transverse links toward each other in plan view by an angle α to create a "kinematic" steering angle about the "pole" P under the influence of the longitudinal deflection f_4 of the lower longitudinal link (for toe-in under lateral force, this pole has of course to be displaced behind the wheel center by at least $2n_R/3$, see Figure 21.52). It may, for instance, be desired to invert the toe-out angle $\Delta\delta_{vB}$ into a toe-in angle by superimposing a correcting angle $\Delta\delta_{Bcorr}$ greater than $\Delta\delta_{vB}$. The required pole distance follows then from $p : f_4/\Delta\delta_{Bcorr}$.

The toe-in change is, however, not the only serious effect that occurs during braking. Another deformation is a considerable "windup" $\Delta\tau_B$ caused by the lengthening of the lower longitudinal and the compression of the upper link. It is obvious that the outboard joints of the two lower transverse links are displaced vertically in opposite directions, causing a remarkable change in the gradient of the toe-in curve (see the considerations with Figure 21.31). So the resulting toe-in curve δ_{vB} is determined by a toe-out displacement $\Delta\delta_{vB}$ in normal position, compensated for, of course, by a toe-in angle $\Delta\delta_{Bcorr}$, and an inclination of the curve toward toe-out with bump. The latter is tolerable at front and rear wheels, since in cornering, it promotes understeering at front as well as at rear wheels under the influence of a braking force.

Assuming the suspension to be driven by a transverse driveshaft, a fourth case of external load remains, the traction force, that normally loads the wheel carrier at the wheel center M (Figure 21.54). Due to the simplified geometry of the suspension chosen for the examples, the traction force F_T compresses the two longitudinal links by equal forces, and elastic "windup" will be negligible. With the lateral distance b_T between M and the longitudinal links in cross view, the traction force causes an elongation f_1 of the lower transverse rear link and a compression f_2 of the front one, and these deformations result in an elastic toe-in angle change $\Delta\delta_{vT}$.

With respect to the "power-off effect" in cornering, this will be welcomed at a front wheel, since the outer front wheel will generate an understeering toe-out angle with released accelerator pedal.

On a rear wheel, however, toe-out under traction force is desirable to achieve an understeering toe-in effect with power change at least at the outer wheel. The option of installing an angle α between the two lower transverse links has already been used up by the braking-force layout, and it will normally be improbable that the same angle is suited to generate the necessary correcting angle $\Delta\delta_{Tcorr}$. There is, however, an ultimate measure left, namely the mutual adaptation of the effective levers b_B and b_T in such a manner that both cases of load can be solved by using the same angle α of inclination [11], see Figures 21.54a and c.

On a steerable suspension, of course, the levers b_B and b_T correspond to the scrub radius r_S and the wheel-center offset r_C, and the elasto-kinematic requirements may clearly become conflicting with those of steering geometry.

If there is a hub reduction gear, the wheel carrier is loaded—in addition to the force F_T at the wheel center—by the clockwise reaction torque of the gear $F_TR(i - 1)/i$ with the tire radius R and the reduction ratio i.

Nonetheless, the preceding considerations should have made it plausible that the elasto-kinematic harmonization of a wheel suspension can—at least theoretically—be done covering all of the relevant cases of external load, like wheel load, lateral force, braking, and possible traction force, by suitable choice of the spring rates of the suspension joints and of the positions and inclinations of the links (clearly, this in reality would, of course, require that the investigations be iterated). On the other hand,

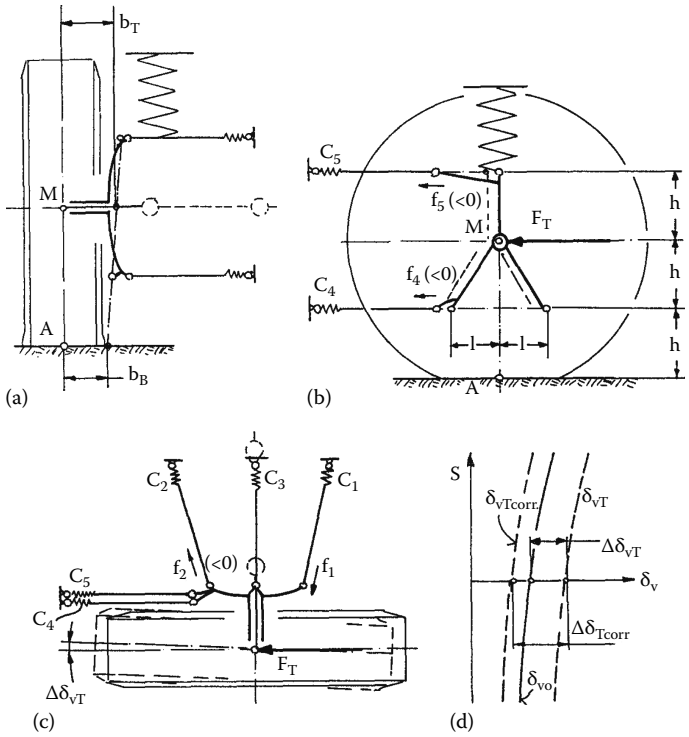

FIGURE 21.54 Suspension of Figure 21.51 loaded with a traction force F_T.

it may have shown up that the more promising elasto-kinematic harmonization is, the more suspension links are available. This is the main reason for the increasing application of multi-link suspensions.

A driven five-link rear axle of a production car, which reveals application of all of the measures discussed earlier, is depicted in Figure 21.55. Upper and lower diagonal links provide lateral and longitudinal guidance of the wheel carrier, also supporting the braking torque (of course with elastic "windup"). All the links have different angles of inclination in space. The elongated axes of the two lower links intersect outside their outboard joints while the two upper ones cross. In contrast to the right-hand side of Figure 21.33, this leads to a "virtual axis" i that is inclined upward—inside in the vehicle—clearly a measure of harmonization of braking and traction-force levers, as discussed with Figure 21.54. Such a position of the axis i could, of course, also have been achieved by using an upper triangular link; however, this (shorter) transverse link would reduce the roll-center height change with wheel travel (see Figure 21.28) and reinforce the disadvantageous jacking-up effect in cornering.
