The simple suspension of Figures 21.51 through 21.54 with its parallel longitudinal links will not change its elasto-kinematic properties seriously with wheel travel. However, many suspensions—especially rear ones—show a rotation of the wheel carrier with wheel travel in side view. This is typical for a system with noticeable braking and traction-force support angles (Figure 21.56). If designed for a "neutral" reaction to lateral forces, by locating the "neutral" point of attack of forces at a distance of the pneumatic trail n_R behind the tire contact point A, this neutral point (which is "fixed" to the wheel carrier!) will move along a path g_N about the pole L with wheel travel. The point of attack of the lateral force F, however, moves along a path g_F that is parallel to the path g_M of the wheel center M. In cornering, with the outer wheel suspension compressed and the inner released, consequently with the lever of the outer force increased and that of the inner reduced, both lateral forces will generate considerable elastic toe-in angles (of course, tolerable at rear wheels).

Rear suspensions are frequently mounted on subframes that are connected to the body by bulky rubber mountings for good noise insulation. Moreover, with simple suspension systems that are not

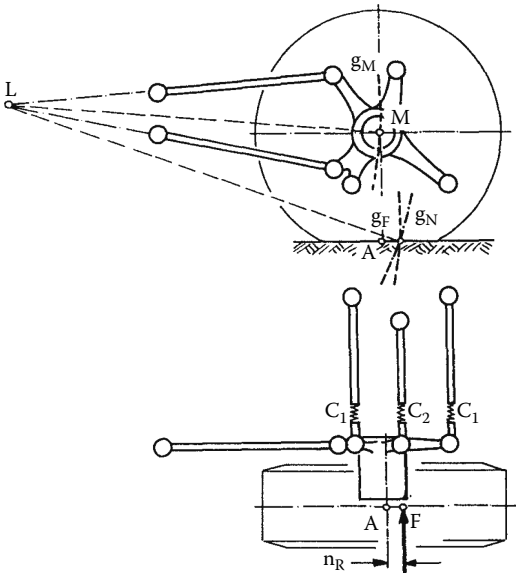

FIGURE 21.56 Variable elasto-kinematic properties caused by a rotation of the wheel carrier in side view.

suited for a deliberate elasto-kinematic harmonization, a subframe may be the only possibility to achieve elasto-kinematic effects.

Since the mountings of a subframe are normally positioned symmetrically to the medial plane of the vehicle (Figure 21.57a), the "elastic center" S_F of the system lies in the medial plane. Unilateral fore-and-aft forces therefore cause elastic steering angles of the whole assembly. On a rear axle, a unilateral braking as well as traction force generates a steering angle that counteracts the moment

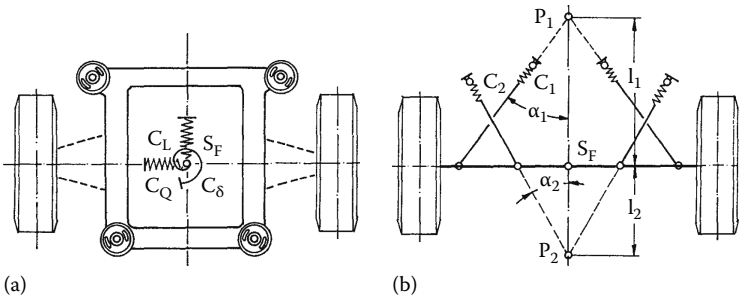

FIGURE 21.57 Subframe with elastic mountings (a) and rigid-axle suspension; (b): c = Spring rates, C_δ = angular spring rate; and S_f = elastic center.

of the unilateral force about the vehicle's center of gravity and so can be useful. On a front axle, of course, a subframe leads to a steering angle that reinforces the yaw reaction of the vehicle to the unilateral force. This is why subframes are rare on front suspensions, except for aggregates with wide-based arrangement of their mountings for maximum rotational stiffness about the vertical axis.

A rigid axle with its suspension links and their elastic joints (Figure 21.57b) shows the same basic properties as an elastically mounted subframe.

A subframe normally represents a highly overconstrained structure, the deformations of which depend on the combination of all external forces acting together. It is therefore impossible to determine a "spring rate" of a mounting point of a suspension link, with the aim to use this similarly to the spring rate of a rubber joint.

By skillful design, however, the influence of the deformations of a subframe on sensitive suspension properties can be minimized. Figure 21.58 shows a driven rear axle, its suspension being a derivative of the trapezoidal-link system fairly resistant to braking windup (see also Figure 21.9), however with two upper transverse rod links for better toe-in control. The subframe is cranked to let the propeller shaft and the exhaust pipes (not shown) pass through and, consequently, is relatively "weak" in its lower region.

Under traction torque, the forces of the front joints of the lower trapezoidal links act toward the inner side of the vehicle, and the force of the front mounting of the gearbox acts in vertical direction, both tending to bend the front transverse beam of the subframe upward. The contrary happens at the rear transverse beam. Consequently, the longitudinal beams of the subframe are subjected to a

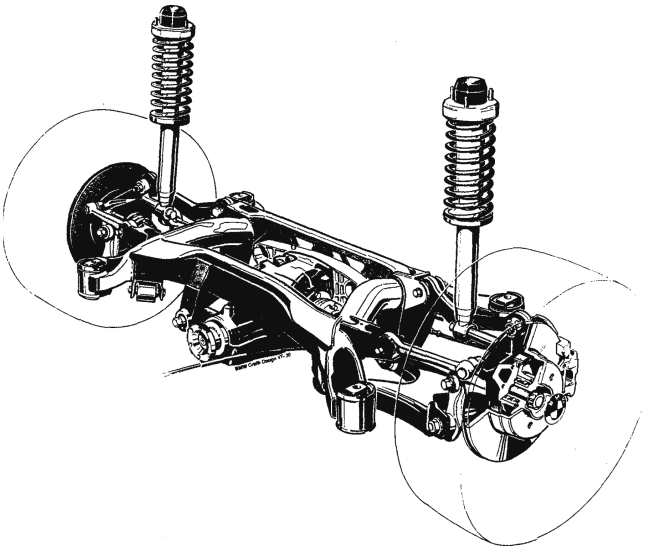

FIGURE 21.58 Multi-link rear suspension. (Courtesy of BMW AG, Munich, Germany, 1994.)

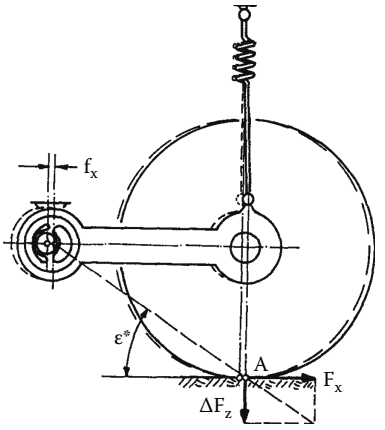

FIGURE 21.59 Compliant suspension under braking force.

twisting torque. Horizontal transverse displacements of the inner joints of the two upper rod links and, with that, undesired steering angles are avoidable by positioning the links at the height of the longitudinal beams of the subframe—which forms an almost planar rectangle in this region and therefore provides sufficient stiffness in any horizontal direction.

Finally, a question may be discussed briefly that often arises among suspension engineers: whether there is an influence of the suspension's compliance on the kinematic suspension characteristics or not.

The trailing-arm rear suspension in Figure 21.59 has a rubber joint for good longitudinal compliance and is here loaded by a braking force F_x combined with the respective "dynamic" wheel-load release ΔF_z. Since the resulting force of F_x and F_z acts in the direction of the joint, the state of "100% anti-lift" geometry is achieved. However, the braking force causes an elastic rearward deflection f_x. This deflection obviously does not lead to any change worth mentioning regarding the static diagram of forces. That, which is clearly to be seen with this simple mechanism, also applies to more complicated suspensions: the elastic deflection of a (statically determinate) mechanism is of negligible influence on the positions of the links and so on the static diagram of forces.

Any attempt to define "suspension characteristics" that consider the elastic deformations will be useless and misleading. For instance, an elastic longitudinal displacement of 5 mm per 100 mm wheel travel would simulate a support-angle contribution of 3°, meaning about 15%–20% anti-dive geometry at a passenger car front axle or about 25% anti-lift or anti-squat geometry on a vehicle with single-axle drive. For the same reason, attempts to determine suspension characteristics by measuring the path of the wheel on a realistic system will give dubious results concerning the internal reaction forces and torques of the system with wheel travel. The only reliable method for determining kinematical suspension characteristics is to consider the (theoretical) "stiff" mechanism—which, of course, means that they best follow from calculation of the kinematic model.

21.8 CONCLUSION

A wheel suspension is a kinematic mechanism that enables deliberate influencing of the vehicle's reactions to vehicle-dynamic events like traction, braking, and cornering.

An attempt has been made in this treatise to touch upon the most important aspects of and influences on suspension design, including the effects of such elements as driveshafts and hub reduction gears and of elastic mountings.

For more precise information about related topics, special books [12] and standard works or handbooks are available on vehicle dynamics, tire properties, and vibrations [13–19] as well as construction elements like brakes [20], driveshafts [2,21], metallic springs [22,23], or rubber springs [24,25].

22.1 INTRODUCTION

One approach to classifying automotive suspensions places them into three categories: passive, semiactive (SA), and active. Passive suspensions are defined here as those that do not require any external power or energy sources; their component tuning is fixed and not adjusted during operation. A typical passive suspension consists of mechanical springs and shock absorbers with no electronic control. SA suspensions contain elements whose behavior is adjusted through computers or similar means but that do not require a significant level of power input for their operation. One example is the adjustable damper whose valving requires some signal level power (typically electrical) but substantially less than a high-force hydraulic piston, for instance. A typical SA suspension is visually similar to a passive system but employs electronically controlled dampers with associated sensors (heave, pitch, roll), microprocessor, and wiring. These actuators absorb and dissipate mechanical energy but do not supply mechanical energy to the

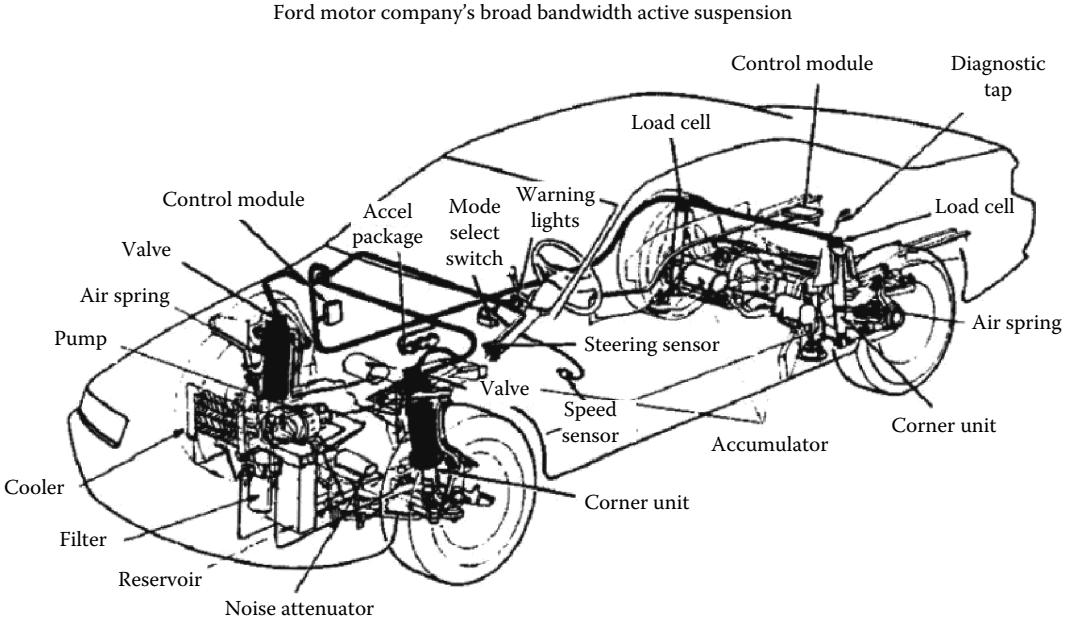

FIGURE 22.1 Typical hydraulic fully active suspension system and components.

rest of the vehicle system. Fully active suspensions contain actuators that are typically controlled through closed-loop means and require significant power for operation. Active systems both dissipate and supply mechanical power to the vehicle system as a whole. System complexity increases further with a typical fully active suspension, which includes the aforementioned electronics, some sort of electrohydraulic actuation with pumps, valves, and associated sensors. Figure 22.1 shows the components of a typical fully active system [1] including actuators, sensors, microcontroller, and hydraulic supply system.

Chapter 31 describes the overall system design concepts and goals for active suspension design. These require simultaneously managing the trade-offs between ride comfort, road holding, and allowed suspension stroke or rattlespace. These theoretical results provide indicators of potential active suspension benefits and corresponding requirements for actual hardware development and implementation including actuator force capability, power, and bandwidth. Other concerns include packaging, cost, reliability, serviceability, noise/vibration/harshness (NVH), and fault tolerance. The various control approaches described in Chapter 31—skyhook control, optimal control, etc.—produce desired actuator forces that can be considered as part of an outer loop. These in turn provide the command or reference values for the inner-loop force production and tracking as shown in Figure 22.2. The actual delivery of this desired force tracking is a very challenging task in practice (see Section 22.3). Some of the challenges include high-fidelity force control in the face of the always present disturbances due to road irregularities, limited actuator bandwidth, stroke and force authority, and inherent system friction.

The payoff for a well-designed system can be high given the potential system-wide benefits to vehicle dynamic performance—ride, handling, safety, etc. Driver reactions to such a system can be quite positive. Active suspensions attracted considerable attention in the mid-eighties with the widely publicized demonstrations of the Lotus Esprit experimental vehicle. This car evolved through many years of R&D work. A January 21, 1987, *The New York Times* article describes the vehicle capabilities as follows:

> Test drivers usually emerge from the car with their imagination in overdrive. 'The greatest single advance in car engineering since the war,' the British magazine *Car* declared on the cover of a recent issue. Car's editor, Steve Cropley, wrote that one could take the benefits of all other modern automobile developments, 'add them up and double the total—and you might come somewhere near the degree to which full active suspension improves a car.'

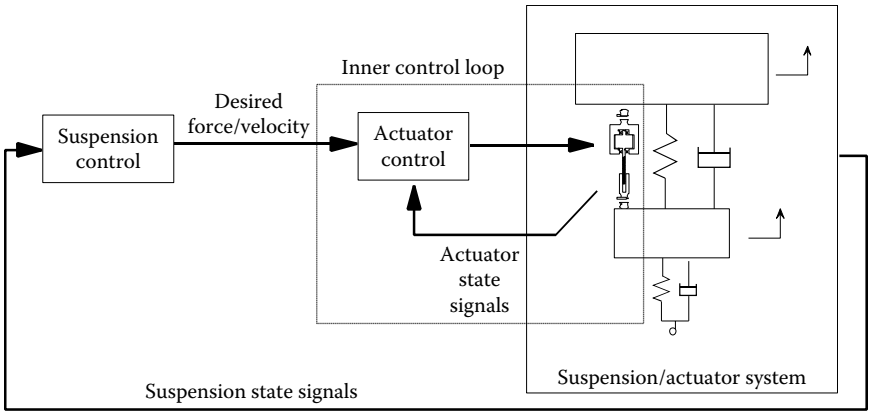

FIGURE 22.2 Inner-/outer-loop suspension control.

Doug Nye, a contributing editor of the American magazine *Road & Track*, said he was initially skeptical, but 'in fact it is amazing'. He said, 'I've been writing about cars for 24 years and honestly found it the most impressive thing I've ever tried'.

As always, these statements contained some hype and should have been taken with a grain of salt. In particular, the earlier comments refer mainly to substantial improvements in vehicle handling under somewhat specialized and severe maneuvers. The corresponding improvement in ride comfort, which is probably more relevant to an average consumer, was not clearly demonstrated then and was the subject of subsequent work. Nevertheless, the early demonstrations pointed to potentially "leap-frog" function improvements in vehicle ride and handling, with related impacts on overall vehicle controls and safety. This, in turn, spurred increased industry-wide activities, which eventually resulted in the introduction of the first narrow-bandwidth or "slow-acting" active production units from Nissan and Toyota in the 1990s and subsequent entries from Citroen (active roll control) and Mercedes (the so-called "Active Body Control" (ABC) suspension described in Section 22.4.1.1).

The following sections focus on the hardware side of active and SA suspension design including implications for control. Section 22.2 presents various types of active and SA actuator hardware. Section 22.3 describes hardware-related considerations related to control system design. Section 22.4 discusses various hardware implementations of advanced suspension concepts. Relevant vehicle models are presented in Section 22.5. Related considerations are summarized in Section 22.6.

22.2 ACTUATOR HARDWARE TYPES

Implementation of active and SA suspensions has been accomplished with a wide variety of hardware, each with its own design trade-offs. These trade-offs include typical engineering concerns such as performance, cost, complexity, and reliability. Performance generally reduces to the suspension actuator's bandwidth limit or its ability to reject roadway disturbances of increasingly higher frequency. As a result, fully active suspensions can be divided into two groups—high (or wide or broad) and low (or narrow) bandwidth. High-bandwidth actuators are defined here as those capable of controlling the higher-frequency wheel-hop suspension mode (roughly 10 Hz) as well as the lower-frequency body mode (roughly 1 Hz). These require force control capability well above 10 Hz. Narrow- or low-bandwidth actuators control only the body mode and can relax the bandwidth requirement to around 5 Hz; typically they are characterized by reduced power requirement. However, by definition they would also imply inferior performance as compared to the high-bandwidth systems. Figure 22.3 shows typical topologies for high- and low-bandwidth

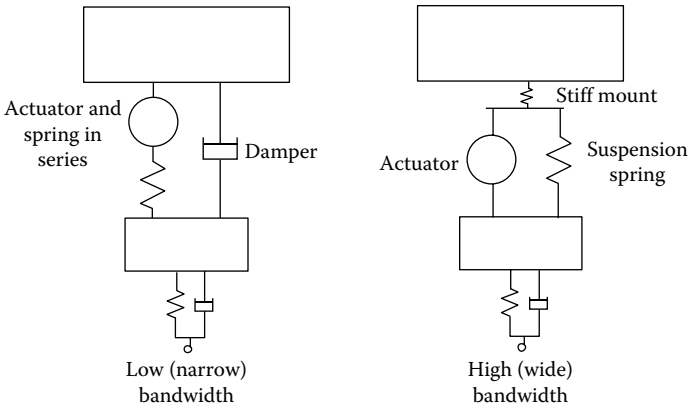

FIGURE 22.3 Typical high- and low-bandwidth suspension topologies.

systems. To fully exploit the high-bandwidth force capability of an actuator, a designer should avoid introducing too much force-filtering compliance between the actuator and the sprung and unsprung masses. Thus, traditionally, high-bandwidth systems contain only a relatively stiff mount and operate in parallel with the primary suspension compliance. The primary suspension compliance in a low-bandwidth system is typically a coil spring or some accumulator of the same type as the actuator (i.e., hydraulic/pneumatic) placed in series with the active actuator. SA suspension actuators are usually dampers with adjustable rate. They too are subject to bandwidth constraints, which limit their potential effectiveness. The following section presents electrohydraulic, electric, SA, and load-leveling actuators and some of their associated analysis and design considerations.

22.2.1 Electrohydraulic Actuators

Electrohydraulic actuation is by far the most common seen in experimental and production fully active suspensions. Hydraulic piston–cylinder units offer the necessary force capability and bandwidth for active suspension control while meeting typical suspension packaging requirements. Drawbacks include inherent energy losses due to perpetual fluid pumping and the service and maintenance requirements of a system of couplers and hoses filled with hydraulic oil. Figure 22.4 shows simplified schematic diagrams for both low- and high-bandwidth hydraulic actuation methods. For both systems, a servo valve is used to move high-pressure fluid into and out of a cylinder. The low-bandwidth actuator contains a large hydraulic compliance in series with the piston in the form of a large accumulator. This tuned element "filters" the hydraulic fluid pressure fluctuations acting on

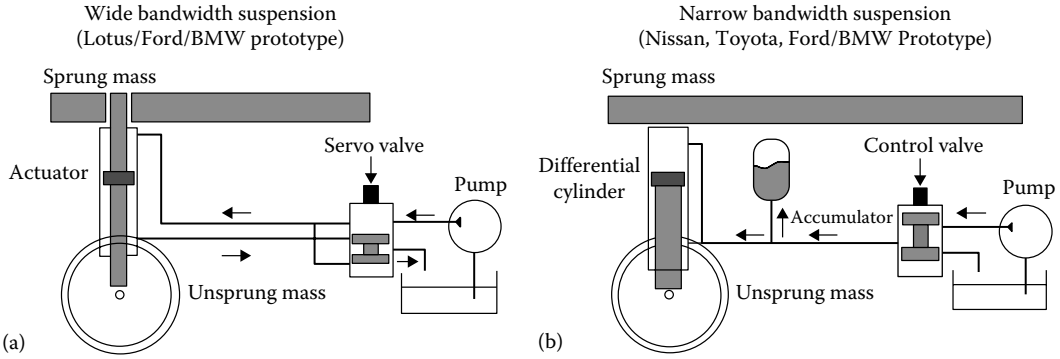

FIGURE 22.4 Typical high-/low-bandwidth (a)/(b) electrohydraulic suspension layouts.

the accumulator/piston pair, thereby reducing the effective actuation bandwidth of the system while at the same time diminishing the effects of (higher-frequency) road input disturbances.

Typical electrohydraulic actuator model is summarized in Appendix 22.A. In the same appendix, this actuator model is applied to a simple quarter-car model of vehicle ride dynamics.

22.2.2 Electrical Actuators

Electrical actuation may offer several possible advantages including high-force production bandwidth, low NVH, ease of serviceability, and the opportunity for energy regeneration. These advantages are potentially offset by issues relating to weight and limited maximum force capability. High-bandwidth systems may also require higher-voltage electrical infrastructure in the vehicle—a potentially costly requirement. A potentially attractive, electromechanical implementation of a practical broad-bandwidth actuator has been proposed in [2,3]. The proposed electrical active suspension (EAS) actuator, shown in Figure 22.5, consists of a ball–nut combination, which is used to transform the rotational power from a highly efficient permanent magnet motor into a corresponding suspension force and translational velocity. The stator, which carries the majority of the actuator's mass, is mounted to the sprung mass (body) of the vehicle leaving only the ball nut and lower bushing/mount to contribute to the unsprung (wheel) mass. In addition to facilitating higher bandwidth, the electronic controls for the unit allow energy regeneration when the actuator is removing mechanical energy from the suspension system. The primary challenge controlling the actuator unit arises from the inertial coupling of the sprung and unsprung masses by the rotating inertia of the actuator. Any motion across the sprung and unsprung masses results in rotation of the motor's armature. This inertial motion must be carefully controlled to guarantee that the actuator does not act as a rigid member connecting the vehicle body and wheel at high frequencies. The same phenomenon drives the design of the upper and lower actuator bushings to ensure a reasonable compliance for the whole device at high frequency. Additional details can be found in [4].

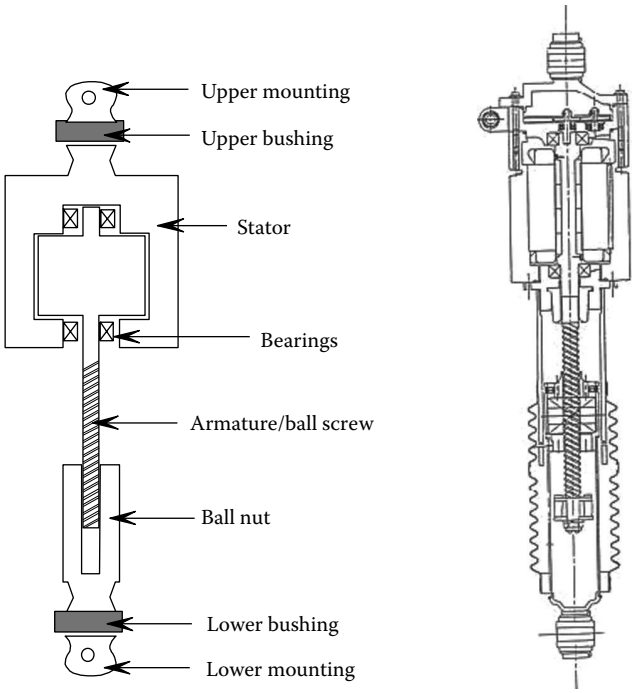

FIGURE 22.5 Ford electric active suspension actuator concept.

While the earlier concept is based on a rotational electromechanical motor or power source, a more recent approach based on the linear motor motion and permanent magnets has been mentioned in [5]. In this case, the very effective control of suspension forces is claimed based on the experience gained from many years of successful production of premier speaker systems from the Bose Corporation. According to [5], the suspension system also contains the so-called damper weight that helps to reduce the wheel hop, which is reminiscent of the dynamic absorber (DA) or tuned mass damper discussed in Section 22.6.4. According to [5], the linear motion suspension concept seems promising; however, no actual vehicle test data have been reported thus far and it will be interesting to see future progress with this intriguing concept.

22.2.3 Semiactive Actuators

SA control is usually accomplished using an adjustable damper in parallel with the main suspension spring. Damping rate for each actuator is determined by the chosen control law as described in Chapter 31. Adjustable dampers can be constructed from pneumatic or hydraulic piston–cylinder combinations with electromechanical control of an orifice usually placed in the piston face. Actuator bandwidth is then established by the reaction time of the controlling valve and associated force production dynamics. Alternatively, magneto-rheological (MR) fluids can be employed to change the viscosity of the working fluid, which, in turn, changes the force across the actuator. This method benefits from faster response time, although limited fluid life can contribute to service concerns. One MR damper application is found in the 2002 Cadillac Seville STS where its MR fluid, codeveloped by Delphi and Lord Corporation, is composed of suspended iron particles in a base fluid of synthetic hydrocarbon. Its continuous variable damping is adjusted at 1000 Hz. The fast response time of the MR damper enables closed-loop vehicle stability control through the control of lateral and longitudinal load transfer characteristics of the suspension during transient movements [6].

One method for reducing the bandwidth requirement of the orifice control valve is to employ the resistance control SA damping method demonstrated experimentally in [7]. Here, a dual-acting damper is used that contains two control valves, each setting the damping rate of the device in only one direction of operation (jounce or rebound). The orifices are switched in and out using passive check valves. These passive valves provide the high-bandwidth switching required by the high-frequency tire motion, while the low-bandwidth control valves are only required to move in response to the relatively low-bandwidth body motion. Figure 22.6 demonstrates the operation of this device. Depicted are sprung mass velocity, $\dot{z}_s$; relative velocity across the damper, $\dot{z}_s - \dot{z}_{us}$; the controlled damping rates used for jounce and rebound dampers (as a function of the body motion); and the resulting combined damping rate for the device, b_s. The combined damping rate provides the high-frequency changes desired while using only low-bandwidth control valves. A cost savings is potentially realized by replacing a single high-performance, high-bandwidth valve with two lesser performing valves of lower total cost.

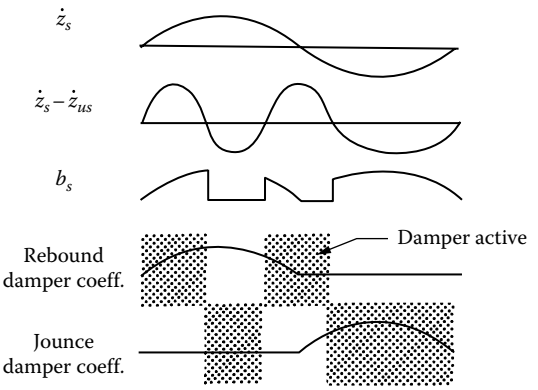

FIGURE 22.6 Operation of combined dampers.

22.2.4 Load Levelers

Load-leveling suspensions are constructed topologically similar to low-bandwidth suspensions in that the equilibrium point of the main suspension spring is the primary adjustment. However, they operate in a very low-bandwidth manner, being incapable of controlling even the low-frequency body mode. Instead, they perform similarly to passive suspensions but offer the capability of "rebalancing" the posture (or attitude) of the vehicle to maintain an appropriate vehicle stance under a wide range of loading conditions and properly center the suspension in the available rattlespace. As such, they act as a slow integrator. They also allow for a softer main spring and are commonly seen on luxury vehicles with a plush ride.

Load-leveling suspensions are often constructed using pneumatic springs whose equilibrium length is adjusted by changing the volume of air in the spring. This is accomplished by means of an air pump and simple on/off valve. Bang–bang control is typically used to set the spring length according to a set of ride height sensors. Typical examples of electronically controlled load leveling can be seen in 1984 Lincoln Continental. The electronically controlled air suspension system (see Figure 22.7a and b) allows its spring to be 32%–38% softer than a corresponding steel spring suspension while maintaining vehicle stance and suspension travel [8]. In this and most other load-leveling suspensions, height sensors are used to trigger the adjustment of the air amount in the spring. In Lincoln Continental, signals from the ignition, doors, and brake systems are also used to ensure leveling only when necessary. For example,

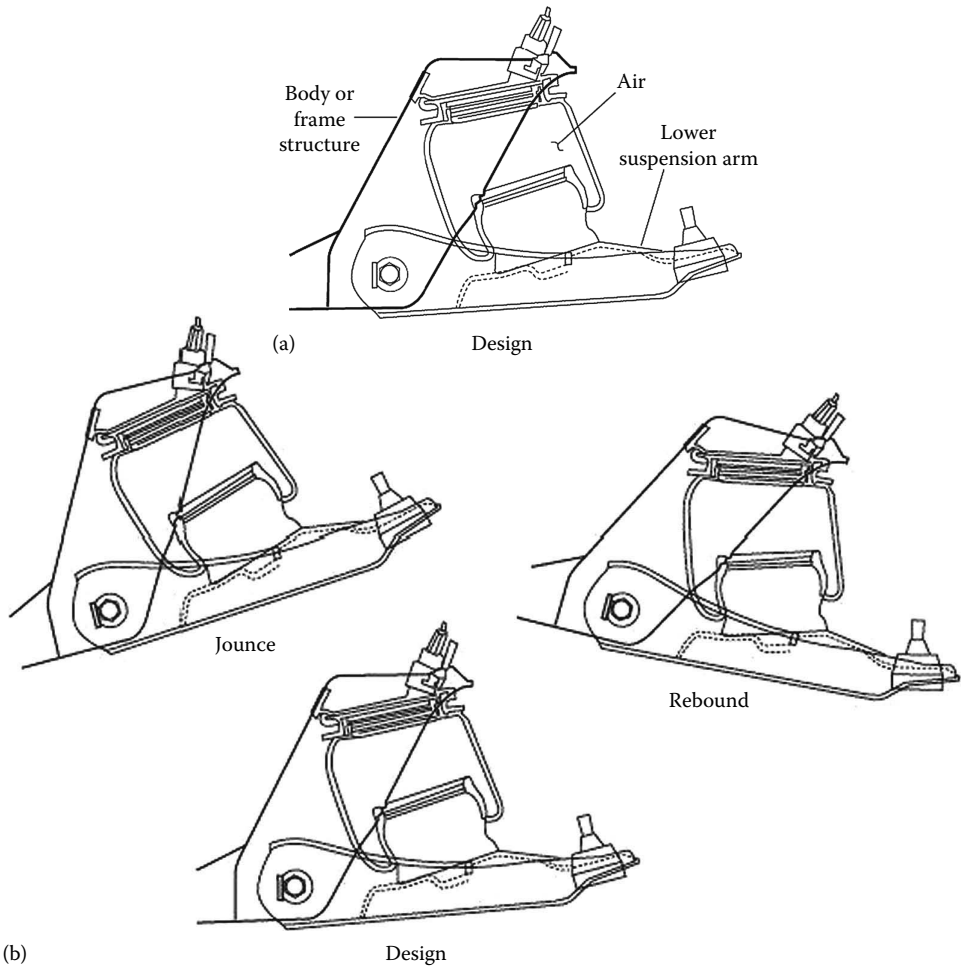

FIGURE 22.7 (a) Typical spring-on-arm air spring and (b) air spring operational modes.

if the ignition is on and the door is opened, the vehicle will level within 50 s to account for additional driver and passenger weight. If the ignition is off, only limited leveling events will occur.

22.3 HARDWARE-RELATED CONSIDERATIONS

Active suspension control system design is challenging in its requirement to balance several design trade-offs such as ride comfort, handling, and rattlespace use simultaneously. Often, the design analysis idealizes the actuators, assuming that they operate at limitless bandwidth or that their bandwidth characteristics are uniform over the entire range of operation conditions. These simplifications, while helpful for system-level analysis, need to be reconsidered when pursuing practical suspension realizations. Thus, the control problem is further complicated when more detailed hardware considerations are included. Typical hardware concerns are actuator bandwidth limits, friction effects in the actuators and associated hardware, and determining the appropriate control system topology for a given actuator. These are discussed in more detail in the following text.

22.3.1 Friction

Even a relatively small amount of dry friction can substantially degrade ride performance and lead to a significant discrepancy between the projected and actual ride benefits achieved with active and SA suspensions. For example, for a 3000 lb/1364 kg vehicle with a per-corner weight of 750 lb/341 kg, a corresponding actuator dry friction of only 25 lbf/111 N can contribute to a respectable 3.3% g root mean square (rms) sprung-mass acceleration. To see this, assume that the desired acceleration (or corresponding net sprung-mass force) is zero, that the actuator bandwidth is well below the wheel-hop frequency, and that the wheel-hop dynamic motion is sufficiently agile to "break" the friction (if it were not, then the suspension would lock and result in the undesirable situation of "ride-on tires" where both vehicle sprung and unsprung masses would ride on tire spring).

22.3.2 Leakage

There are a number of possible leakage paths for an electrohydraulic active suspension actuator. This includes the leakage across the piston seals, leakage across the supply and vent ports, as well as cross-port leakage. In particular, the cross-port leakage can be a significant factor influencing the overall system dynamic behavior [9]. In effect, this leakage acts in series with the hydraulic oil compliance; this can be seen by imagining the actuator servo valve operating at/around its centered position (see Figure 22.8). The net effect of this is that the corresponding vehicle/suspension modes have more damping, especially in the dominant, sprung-mass-related mode.

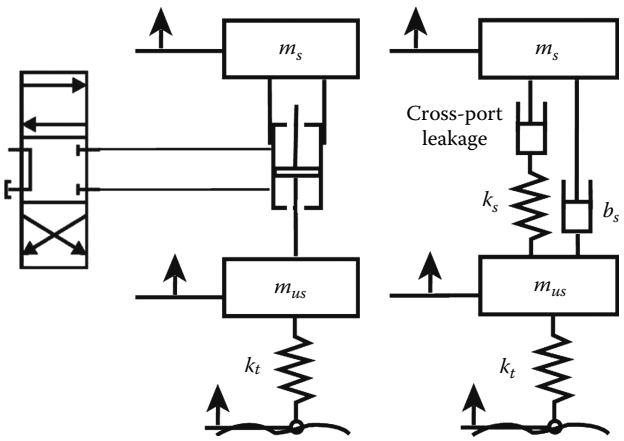

FIGURE 22.8 A wide-bandwidth active suspension schematic and corresponding model.

22.3.3 Actuator Controls: Force versus Displacement Tracking

An important aspect of practical significance for active suspensions is the issue of actuator dynamics and its interaction with vehicle system dynamics. In practice, the challenging task of high-fidelity actuation requires a good understanding of underlying system dynamics and a mastery of related mechatronic design skills. For example, consider the earlier hypothetical case of the constant, for example, zero net desired sprung-mass acceleration for the best possible ride comfort. Even this seemingly inconspicuous and easy task of producing the constant actuator force equal to the sprung-mass weight can be quite challenging. Chiefly, as outlined in [10], the main issue here is the suspension force variations created by relative velocity motion across the suspension mounting points, which in effect acts as a force disturbance generator. Elimination of these effects is one of the main tasks of the inner-loop force delivery subsystem.

Note that the elimination or containment of these disturbances also precludes or diminishes the introduction of any additional vehicle dynamics into the inner-loop force-tracking subsystem. It has been shown in [11] that through this additional dynamic effect, the poles of the base (vehicle) plant become zeros of the resulting closed-loop system. More precisely, the inner-loop force-tracking system can be represented via a block diagram shown in Figure 22.9, where C_{in} represents the inner-loop controller and G_a and G_p are the actuator and plant transfer function, respectively. The corresponding transfer function between the desired and actual force delivered at the suspension actuator is

$$G_{ff} = C_{in}\frac{G_{fi}}{1 + C_{in}G_{fi}} \tag{22.1}$$

where

$$G_{fi} = \frac{G_a}{1 + G_pG_h} \tag{22.2}$$

Here, G_h summarizes the feedback path created through actuator hardware, which represents suspension force changes due to relative motion across the suspension mounting points. This coupling or feedback effect is present with most hardware implementations, although the degree of the coupling may vary and depends on the kind of suspension implementation concept one is dealing with (electrohydraulic vs. electrical). In general, it is more difficult to exactly counteract this term in the case of electrohydraulic actuators due to many highly nonlinear effects—such as viscosity temperature dependence and air entrainment—and some form of adaptation will most likely be needed, as elaborated in [12]. For completeness, Figure 22.9 also shows an outer or main loop controller C_{out}, which may include an appropriate observer or (Kalman) filter.

From the earlier transfer functions (Equations 22.1 and 22.2), one can see that the open-loop poles of the vehicle plant (G_p) become the zeros of the resulting force-tracking inner-loop configuration (G_{ff}). In the case of a typical quarter-car vehicle model, this means that there are two pairs of relatively lightly damped zeros in this inner loop. The first pair corresponds to the dominant, sprung-mass-related heave mode of vibrations, which is typically of relatively low frequency

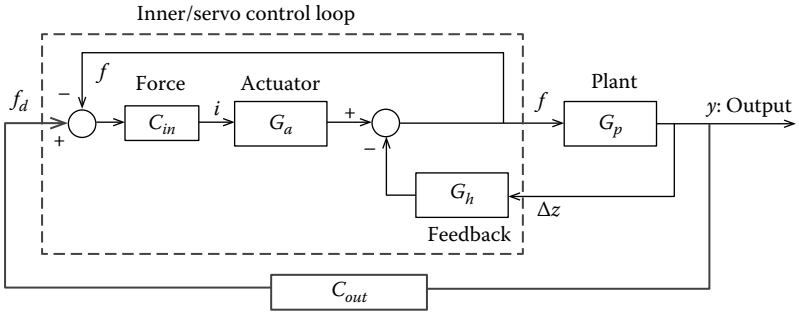

FIGURE 22.9 Force-tracking actuator controller design.

around 1 Hz. The amount of damping in this mode may vary, but it can be close to the corresponding passive case where the damping ratio is around 0.2–0.3. For example, incorporating a passive or SA damping component as an integral part (or in addition) to an active suspension actuator, one can relatively easily increase the damping ratio of the earlier dominant mode to 0.1–0.2.

The second pair of zeros corresponds to the wheel-hop mode, which typically resides around 10 Hz with relatively small amount of inherent damping. As such this mode is much more challenging to contain. This pair of zeros will be the limiting factor for high-performance system capabilities, due to the fact that the resulting closed-loop poles will tend toward system zeros. One way to improve this situation and increase the effective wheel-hop damping is through structural hardware changes by introducing the dynamic vibration absorbers tuned at the wheel-hop frequency. This can also improve the overall system ride and handling performance, as discussed in Chapter 31. It is interesting that one of the best-ride small vehicles ever produced, the legendary Citroen 2CV, embodied the dynamic vibration absorbers for the wheel-hop mode. While this was done in the context of an essentially passive suspension, based on Chapter 31 it is anticipated that a well-developed future active suspension system will incorporate some form of passive or (semi)active vibration absorbers.

A different approach to eventually achieving the same or similar ride and handling performance as with the earlier force tracking was proposed in [12,13]. This time instead of following the desired force command, the inner loop is to be designed to follow the (equivalent) desired suspension displacement traces. This configuration can be represented in a block diagram form as shown in Figure 22.10. The corresponding transfer function between the desired and actual displacement delivered at the suspension actuator is

$$G_{zz} = C_{in} \frac{G_{zi}}{1 + C_{in} G_{zi}} \tag{22.3}$$

where

$$G_{zi} = \frac{G_a G_p}{1 + G_p G_h} \tag{22.4}$$

While with this approach the vehicle plant poles are no more the overall system zeros, the resulting set of zeros now contains the plant zeros, which physically corresponds to the case where the sprung and unsprung masses ride together on tire spring. Neglecting the tire damping, the resulting zeros now form a pure complex conjugate pair and as such they are more challenging than the previously

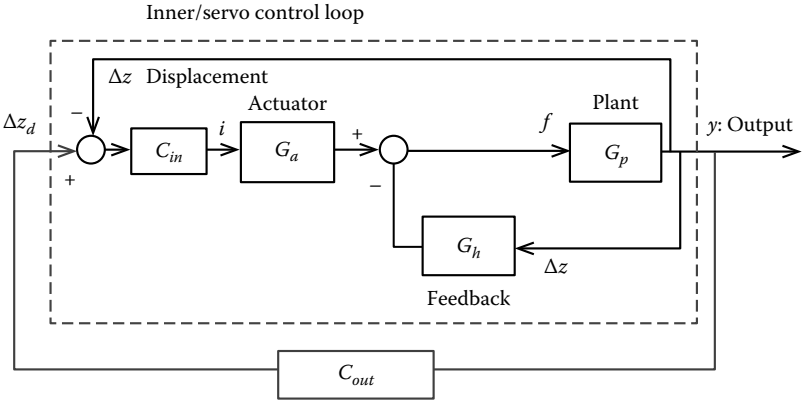

FIGURE 22.10 Displacement-tracking actuator controller design.

discussed sets found with the force-tracking approach. In addition, the limiting frequencies are now smaller, since the frequency of bandwidth limiting zeros from Figure 22.10 is lower than the wheel-hop mode frequency of the bandwidth limiting (lightly damped) zeros from Figure 22.9.

Whether one uses force- or displacement-tracking approach will, among other things, also depend on the prevailing flow or velocities and displacements across the actuator. Large velocities or flows, such as seen with off-road vehicles, may be more effectively dealt with through the displacement-tracking approach. In this case, the flow-control valves can be used too. More about this can be found in Section 22.3.4.

22.3.4 Actuator Bandwidth

When dealing with active suspensions, an important practical consideration refers to actuator bandwidth requirements and limitations. This typically refers to actuator force generation bandwidth for all possible motions across the actuator mounting points. One distinguishes between low- or narrow-bandwidth (or slow-acting) and high- or broad-bandwidth (or fast-acting) suspensions. The former attempts to control only the relatively slow body mode and as such their bandwidth is typically between 3 and 7 Hz. On the other hand, the broad-bandwidth suspensions attempt to control both the body and wheel-hop modes, and thus, their bandwidth should be typically above 12–15 Hz.

One way to control the bandwidth is by introduction of additional compliances in the form of gas–spring accumulators possibly augmented with SA damping. This has a positive side effect of providing a high-frequency, NVH isolation. Additional insight into related structure and dynamics is given in [14], where typical narrow-bandwidth suspension configurations were analyzed with the help of bond graph modeling methodology applied to simple, quarter-car vehicle models shown in Figure 22.11. A generic suspension configuration from Figure 22.11a includes a (possibly variable) hydraulic damping valve, hydropneumatic accumulator, and two oil flow sources, Q_A and Q_B, controlled by appropriate electrohydraulic valves. The equivalent, all mechanical, structure can then be derived with the help of a bond graph from Figure 22.11b with a transformer ratio set to one. The resulting structure is shown in Figure 22.11c. Note that the hydraulic damping and pneumatic compliance are in effect acting geometrically in parallel with each other.

In practice, only one of the two flow sources will typically be present. One example when only V_A is present is shown in Figure 22.11d. This configuration is typical of air suspensions actuators. On the other hand, a possible hardware structure for the case when only V_B is present is shown in Figure 22.11e, which is similar to a typical hydraulic suspension unit. Further potentially important extensions of the earlier generic configurations may include a consideration of hydraulic inertias, valve/solenoid dynamics, spool resistances, and other related effects, which can be elegantly incorporated with the help of bond graph modeling technique.

22.4 HARDWARE IMPLEMENTATIONS

Despite considerable research into active suspension control designs, only a few systems have emerged. Most of these are prototypes for research and development, while even fewer can be seen in the commercial marketplace. Several of these systems are presented in the following, divided into broad- and narrow-bandwidth categories.

22.4.1 Narrow-Bandwidth Active Suspension

Some narrow-bandwidth systems have been brought to market with limited success. An example of narrow-bandwidth suspension hardware is shown in Figure 22.12a based on [15]. It includes (1) an accumulator (for bandwidth limitation and NVH containment); (2) a mechanical, supporting spring (although this may be absent in some implementations); and (3) a relatively inexpensive pressure-control valve. Structurally, this hardware is similar to the configuration from Figure 22.11e, with the single flow source V_B. Note the single-acting actuator configuration, which is simple and inexpensive.

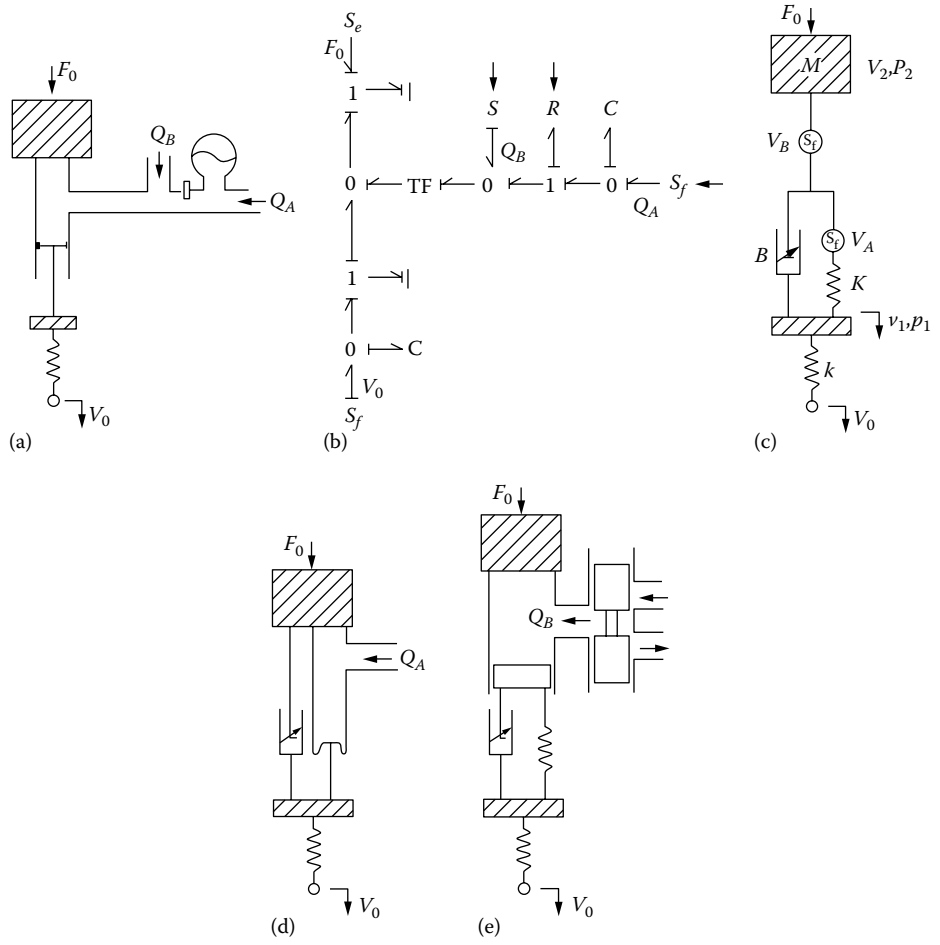

FIGURE 22.11 Narrow-bandwidth suspension configurations and related bond graph. (a) A generic suspension configuration, (b) the equivalent bond graph illustration, (c) the resulting equivalent mechanical structure, (d) example when only V_A is present, and (e) example when only V_B is present.

It does, however, limit the system controllability on the rebound stroke, which is in good part determined by the spring/accumulator settings. While typical, the configuration of Figure 22.12a is not the only one possible and future narrow-bandwidth suspensions may profit from the added flexibility of double-acting actuators and judicious choice of accumulators and parallel springs.

Another hardware alternative would result by replacing the earlier pressure-control valve in Figure 22.12a, with an appropriate flow-control valve. A schematic of a typical proportional, pressure-compensated flow-control valve [16] is shown in Figure 22.12b. It consists of a pressure-control valve augmented by a solenoid-controlled flow metering orifice. Due to a particular interconnection between the two, the valve spool will maintain a constant pressure drop ΔP across the metering orifice, which is preset to a desired value through appropriate solenoid control voltage. This, in turn, will result in a desired output flow, independent of input and output pressure variations.

In the context of narrow-bandwidth suspension actuators, a possible application of the earlier flow-control valve can be rationalized as follows. Any force production with such an actuator will be accompanied with corresponding displacements and velocities of the in-series compliance (cf. Figures 22.11e and 22.12). Thus, in this case, instead of a force control, one can consider the related flow-control problem. However, due to the hardware simplicity, the more direct approach via the pressure-control valves seems to be preferred in practice and is the only one seen in actual production implementations thus far.

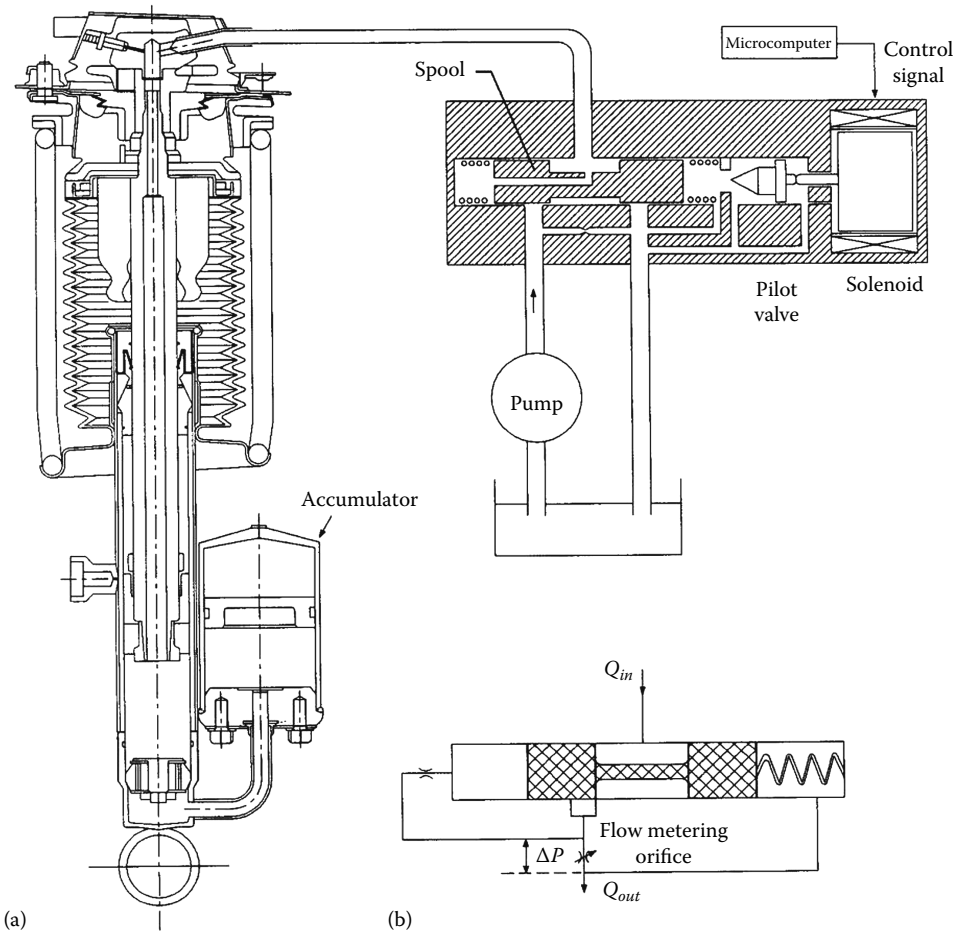

FIGURE 22.12 (a) Schematic diagram of Nissan Infinity Q45, (b) Schematic of a typical proportional, pressure-compensated flow-control valve.

22.4.1.1 Mercedes "Active Body Control"

DaimlerChrysler introduced the "ABC" system on the 2000 CL sedan. The system consists of four low-bandwidth (5 Hz) hydraulic actuators providing fully active load leveling, heave, pitch, and roll control.

Figure 22.13 provides a schematic representation of an ABC suspension system [17,18]. The primary hydraulic cylinder is in series with the steel coil spring. This cylinder sets the spring preload and the series arrangement leads to the low-bandwidth system behavior. In parallel with the spring/cylinder is a twin-pipe gas shock absorber (damper). Hydraulic fluid is supplied to each corner via a pump regulated to 200 bar, and an accumulator at each axle provides pressure leveling during peak loads. High-pressure fluid is carried by two valve blocks—one at each axle. Each block contains two 3-way proportional valves—one for each corner—which are used to maintain plunger pressure and a 2-way shutoff valve for each corner to lock the cylinder when the vehicle is stopped and to provide fail-safe operation. Return fluid is damped through a return accumulator.

The ABC system utilizes multiple sensors for mechanical state measurements. Sensors include longitudinal and lateral accelerometers, three vertical accelerometers (for bumping, pitching, and rolling detections), as well as a level sensor and a plunger position sensor at each wheel. Additionally, several hydraulic pressure sensors are used for pressure control and monitoring.

The ABC system employs various algorithm modules for vehicle dynamic control depending on the vehicle states. Functions provided include speed-based load leveling and ride height adjustment,

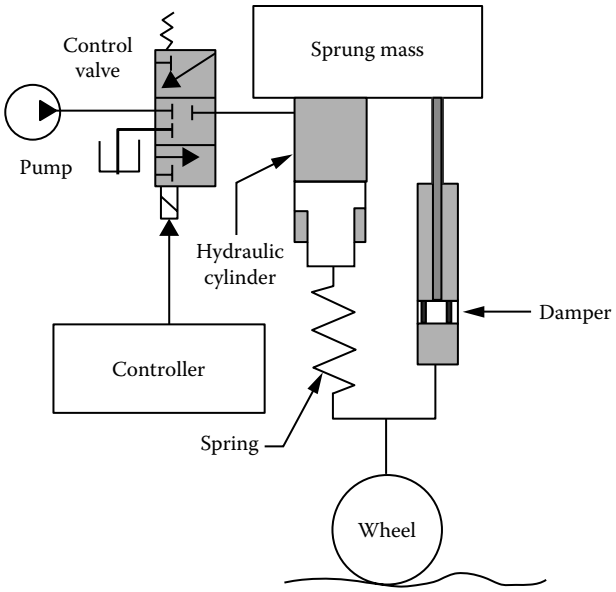

FIGURE 22.13 (a) Schematic diagram of Nissan Infinity Q45, (b) Schematic of a typical proportional pressure-compensated flow-control valve.

skyhook control of the vehicle body heave mode, roll control for roll angle response to vehicle lateral acceleration, and pitch control for pitch angle response to longitudinal acceleration [18]. The algorithms are further controlled by driver input via instrument panel height and performance mode switches.

22.4.2 Broad-Bandwidth Active Suspensions

Since the broad-bandwidth active suspensions (BBASs) attempt to control both the slower body modes and the fast wheel-hop modes, it is in general to be expected that the broad-bandwidth systems will be more difficult to implement. It is expected that such suspensions will incur higher costs and fuel consumption [19]. On the other hand, one could also argue that there is a potential for increased fuel consumption of narrow-bandwidth suspensions due to increased pump flow requirement caused by more compliant hydraulics.

The influence of actuator bandwidth on basic system performance was summarized in [20]. A simplified analysis was done under the assumption that the actuator force production dynamics can be approximated via a simple, first-order, low-pass filter of specified bandwidth. It was shown that the 5 Hz bandwidth actuator can already deliver a performance that is relatively close to the limiting case corresponding to the ideal, infinitely fast actuator. This is in accordance with the analysis in Chapter 31 based on two degree-of-freedom (DOF) quarter-car models, which establishes that most of the ride benefits can be expected around the slow, body mode.

The earlier bandwidth-related study is only an approximate analysis, since it is based on a simple linear model that excludes any coupling influence of vehicle dynamics on actuator force production capabilities. Also, in practice, beyond certain frequencies any suspension performance is dominated by relevant passive components. The actual active suspension force production within the desired bandwidth and road disturbance constraints is a challenging topic in its own right, which is still an open field that may require innovative design solutions as well as full use of mechatronics and associated control system techniques. One possible approach may include the usage of sturdy, polymer-based tug-and-twist actuators proposed by Paynter [21,22].

To establish wide-bandwidth capability of a given actuator–vehicle system in the case of force tracking, one would typically first need to verify that the corresponding force frequency response

is flat up to the cutoff frequency (within 3 dB or 45° phase shift). This should be true for different command force levels and different motions across the actuator mounting points. Once confirmed, the potential benefits of such a full-fledged wide-bandwidth suspension would imply full usage of fast preview that can further improve the overall system performance especially by controlling the wheel-hop mode, as discussed in Chapter 31.

Even if not yet used for production vehicles, this type of suspension can be very useful for R&D work exploring and establishing maximum possible ride, handling, and even active safety benefits of different suspension concepts. It is in this context that most wide-bandwidth suspensions have been (and probably will continue to be) used by different automotive manufacturers and suppliers in their prototype vehicles. An example of a broad-bandwidth suspension that was developed in the late 1980s at Ford [1,23] is shown in Figure 22.1.

The Ford Thunderbird BBAS research vehicle used four high-fidelity electrohydraulic servo actuators, one at each corner of the vehicle. While a typical narrow-bandwidth suspension is controlled through three-way proportional pressure-control valves, the BBAS was controlled through four-way servo valves, which have much higher precision and speed of response. In addition, the BBAS actuators were based on double-acting cylinders being capable of equally fast rebound as well as jounce strokes. The vehicle also had one central and four corner-unit microprocessors for fast signal/control processing, four actuator displacement sensors and four load cells for inner-loop (force) calculations, and four air springs—one at each corner placed in parallel with the BBAS actuators. The air springs support and self-center the vehicle sprung mass as a typical load-leveling set would do and at the same time they provide lower sprung-mass natural frequency for more comfortable basic ride, which is then appropriately dynamically modified through the BBAS actuators. The system incorporated 26 various sensors, including accelerometers, pressure sensors, and vehicle speed sensors.

The BBAS control strategy was based on coordinated individual wheel control and consisted of two hierarchical levels [1,23]. The outer-loop level operated at the 20 ms rate. It calculated the desired corner forces for the four BBAS actuators and desired operating modes (handling or ride dominated) and checked the overall system integrity. The ride-related calculations were based on quarter-car vehicle models aimed at emulating skyhook damping at each corner, which is often very close to optimal possible ride benefit (see Chapter 31). In addition, different spring and damping rates were used depending on prevailing operating modes, that is, ride or handling; Table 22.1 summarizes typical parameters used [23].

The calculations also included roll and pitch attitude control during turning, braking, accelerating, and similar others; this was based on lateral and longitudinal acceleration signals and steering sensors.

TABLE 22.1
Typical Parameters Used in Ford BBAS

		Ride Mode		Maneuvering Mode	
Parameter	**Units**	**Front**	**Rear**	**Front**	**Rear**
Skyhook damping	lb-s/in.	23.5	10.0	23.5	10.0
	N-s/m	4115.3	1751.2	4115.3	1751.2
Conventional damping	lb-s/in.	3.0	3.0	8.0	4.0
	N-s/m	525.4	525.4	1400.9	700.5
Suspension spring	lb/in.	15.0	15.0	120.0	120.0
	N/m	2626.8	2626.8	21,014	21,014

The commanded or desired levels of corner forces were communicated to corner computers, which operated at higher sampling rates of 1 ms to implement the inner-loop force control based on feedback provided by load cell sensors. The corner units distributed the force requests between different servo valves. For example, the conventional (relative) suspension damping as well as the passive segments of skyhook force were provided by bypass or cross-port two-way servo valves that provided damping only when called for in a manner similar to SA damping control.

The BBAS R&D vehicle accomplished many of its key objectives, especially with respect to primary ride (up to circa 5 Hz) and handling. The typical results in terms of NASA ride metrics are summarized in [23], where a smaller number on the scale of 10 implies better ride. From this reference it can be seen that, on average, the active Thunderbird provided the best ride among a dozen different vehicles under consideration. The only areas where the BBAS had somewhat worse performance were on smooth roads, where Jaguar XJ6 and Lexus LS 400 (both well known for their smooth ride) had an advantage. This may be attributable to still less refined NVH (higher-frequency) levels that are a remaining challenge for BBAS concepts. Based on results summarized in [23], it should also be noted that the BBAS Thunderbird significantly outperformed both the baseline passive suspension Thunderbird and its narrow-bandwidth (NBAS) counterparts as exemplified by production Infinity Q45a and Toyota Soarer.

The handling characteristics of the active Thunderbird are compared with its passive (production) counterpart in [23]. The results of back-to-back tests show that the active vehicle results in more agile handling, with faster yaw response, less roll and pitch, and significantly larger maximum lateral acceleration (0.895 vs. 0.81 g). Thus, in a direct comparison between the two vehicles, the active car displayed significant improvements in both vehicle ride and handling.

While achieving the BBAS and all their potential benefits in the strict sense of broad-bandwidth suspensions still remains an illusive goal, a significant progress has been achieved with the previous early efforts. This holds particularly for the case of primary ride and handling. The challenging areas in need of further development include secondary ride, NVH, and system power consumption, complexity, and cost. Possible approaches here include introduction of tuned vibration absorbers for wheel-hop mode and addition of controlled in-series compliance, which if properly designed would provide appropriate NVH isolation. This also further reduces the distinction between the BBAS and their NBAS counterparts.

22.4.3 Semiactive Suspensions

One of the first production SA suspensions was introduced in the 1987 Thunderbird Turbo Coupe employing electronically controlled damping [24]. The damping is adjusted according to driving conditions such as during hard cornering, braking, acceleration, and at high speeds. The damping adjustment is accomplished by opening a rotary shutter valve to allow oil to bypass the piston valve (see Figure 22.14). Check valves in the shutter assembly further allow the damping at the same setting/rotating position to be different for compression and extension.

22.5 VEHICLE MODELS

In this section, we briefly review different vehicle models that are used for the design of optimal suspension ride control algorithms. We start with simple, quarter-car models, which allow for only 1D, vertical, or heave motion. Within this setting, the simplest possible one DOF model consists of just the vehicle or sprung mass, which, as shown in Figure 22.15, is supported by a suspension actuator positioned between the vehicle and ground. Moreover, it is a common practice to assume that the vehicle is moving forward with constant velocity V, so that the road roughness disturbance appears as a vertical input proportional to V and the spatial slope of the road unevenness. It is in this context that we refer to the so-called "moving" ground.

Adding a wheel/tire subassembly (unsprung mass) to the earlier one DOF structure leads to two DOF, quarter-car models as shown, for example, in Figure 22.16. The unsprung-mass mode is often referred to as "wheel hop" and is characterized by relatively light damping and a natural frequency

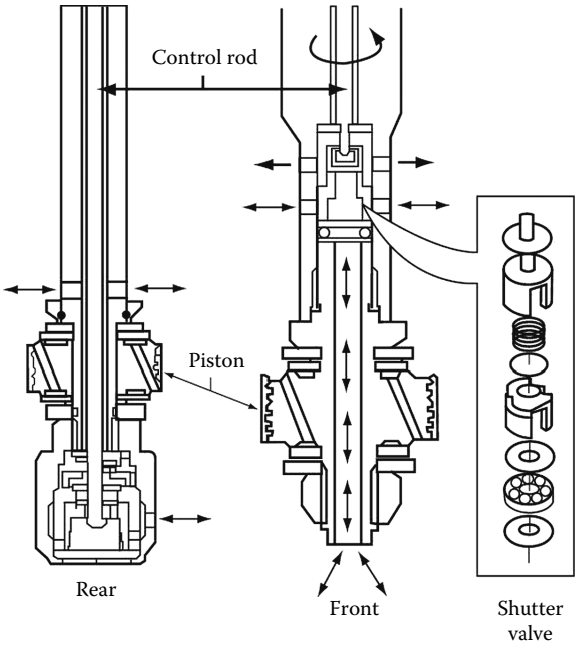

FIGURE 22.14 Adjustable shock absorber used in 1987 Thunderbird Turbo Coupe. (From Soltis, M.W., Thunderbird turbo coupe programmed ride control (PRC) suspension, SAE Paper 870540, 1987.)

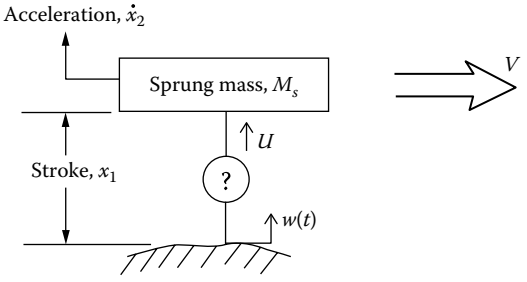

FIGURE 22.15 A one DOF model.

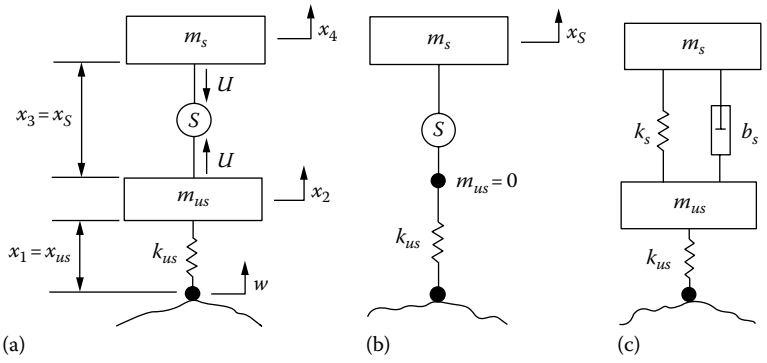

FIGURE 22.16 A two DOF model: (a) with active suspension, (b) corresponding limiting case, (c) with conventional passive suspensions.

between 8 and 12 Hz. The principal body mode, or sprung-mass mode, is typically around 1 Hz, with active suspensions leaning toward lower, 0.5 Hz range values. The related state–space equations are summarized in Appendix 22.A. A justification for the simple two DOF model can be found in [25]. The authors use detailed ADAMS™-based vehicle models and step responses to identify the two DOF model parameters. For the typical McPherson strut suspension shown in Figure 22.17, it was found that using the simple component-based data (e.g., the unsprung mass would typically consist of corresponding wheel, knuckle, and attached linkages) would suffice. However, for some other suspension configurations—such as double-wishbone suspensions—there could be significant differences between the ADAMS™ identified data and the component-based data due to differences in corresponding kinematic paths during typical ground input events.

Typical half-car, 2D models include sprung-mass pitch and heave or vertical modes (Figure 22.18), often augmented by front and rear unsprung-mass vertical dynamics and possibly engine/transmission block dynamics. The full-car, 3D models, on the other hand, include vehicle roll as well as the pitch and heave modes (Figure 22.19). These models consider only rigid body motions and are based on lumped-parameter, linearized dynamics, which are well suited for applications of the LQG optimal control technique.

A typical automotive ride dynamic model is most often confined to close-to-linear operation characterized by relatively small sprung-mass velocities and displacement angles and suspension and tire deflections. To what extent this assumption remains satisfied is best evaluated through actual vehicle tests. Some useful related results can be found in [26]. The authors compare

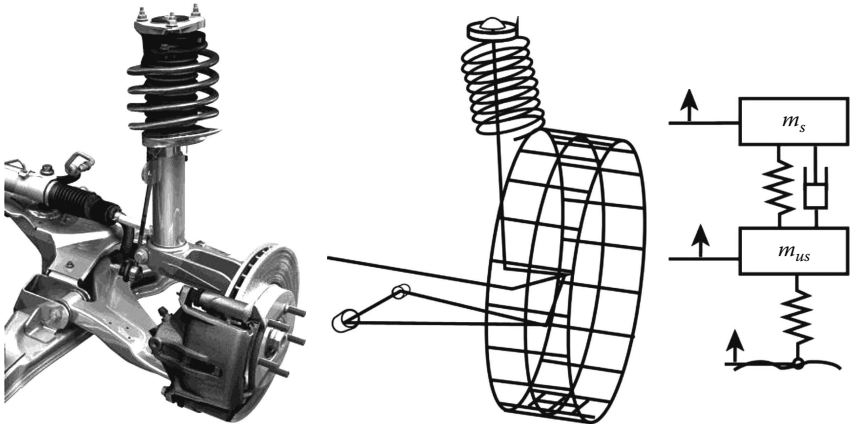

FIGURE 22.17 McPherson strut suspension and its equivalent two DOF model.

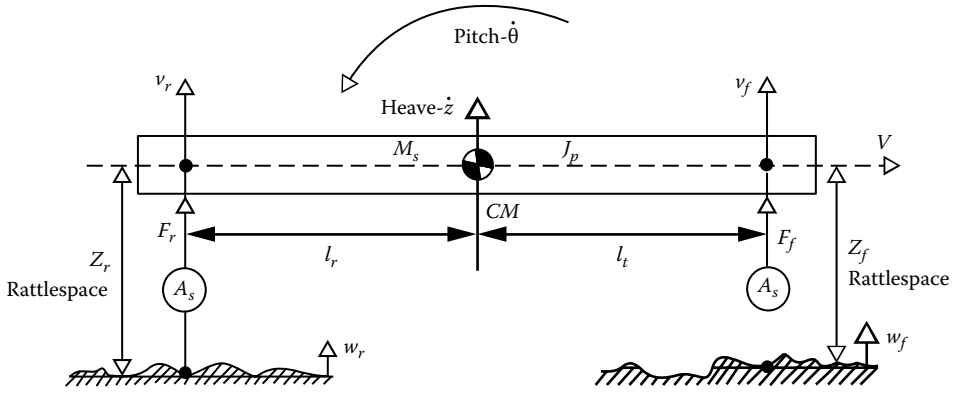

FIGURE 22.18 Half-car two DOF model.

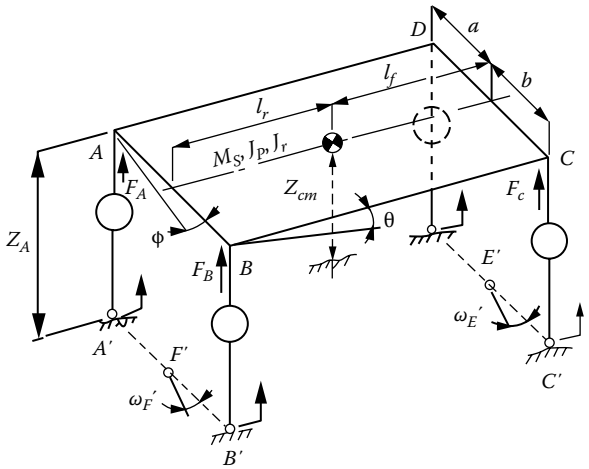

FIGURE 22.19 3D vehicle model schematic.

measured and predicted vertical accelerations at the driver's seat location for the same measured road input sequence. The prediction is based on a linear, seven DOF vehicle model of a 1974 Buick Luxus with conventional, passive suspension. The seven DOFs were made to correspond to rigid body heave, pitch, and roll, and four DOFs for unsprung-mass dynamics (the vertical displacements of each of the four wheels). The results of this study [26] showed a close match up to frequencies of about 10 Hz, with discrepancies above 10 Hz being primarily due to unmodeled high-frequency elastic modes and other neglected phenomena, such as tire unbalance and engine-block dynamics.

The same reference also compared linear vehicle models of different complexity. This was done through a comparison of predicted acceleration responses for the quarter-car, two DOF; half-car, four DOF; and the earlier full-car, seven DOF models. It was concluded that the difference between the various models is relatively small, especially when the difference between predicted and measured traces is considered. This gives credence to the usage of simpler, linear models, particularly when used in preliminary studies that, as in the present case, serve to establish the prevailing trends and benefits.

Another set of comparisons with measured data was pursued in [27], where a linear 2D, single-track, six DOF vehicle model was used, consisting of sprung-mass heave and pitch, front and rear unsprung-mass bounce, and engine and passenger dynamics. The results in terms of measured and predicted center of gravity C.G. acceleration power spectrum densities (p.s.d.'s) and left front spindle (unsprung-mass) acceleration p.s.d.'s are reproduced in Figures 22.20 and 22.21, respectively. The data were obtained with a 1979 Ford Fairmont traversing Ford's Dearborn Proving Ground straightaway at 55 mph. For the analysis, the measured road spectrum was approximated via appropriate exponential/log functions. Comparing the measured and predicted acceleration, it can be concluded that the agreement is in general very good for frequencies up to about 12 Hz, with the discrepancy at higher frequencies being again attributed to unmodeled, higher-frequency flexible modes, tire unbalance, and various nonlinearities.

The linear, low-order models are in general adequate for system-level studies such as optimal suspension control synthesis and analysis that will be discussed in Chapter 31. Such system-level studies serve as a precursor necessary to establish the potential benefits and overall trends and R&D directions. Once a candidate suspension has been established in this way, further evaluations would typically proceed via more refined and complex models that would include flexible modes, actuator dynamics, and various nonlinear effects. Since ride and handling are the attributes with many inherent subjective components, final evaluation and verdict still implies the need for actual vehicle test drives and verification.

22.6 OTHER CONCEPTS

22.6.1 Anti-Dive, Anti-Squat, and Anti-Pitch Suspension Designs

In passive suspensions, geometry may be used to modify the load transmission paths so that the weight transfer associated with longitudinal acceleration and braking is only partially supported through suspension travels. Under proper design measures, the complementary amount of load then results in reduced suspension travel or "anti-suspension travel"; this amount is supported through suspension linkages instead of suspension spring deflection and travel. The amount of anti-suspension travel consequently effects the vehicle attitude and is referred to as anti-squat (usually associated with acceleration), anti-dive (usually associated with braking), or anti-pitch, which is often used as a general term for vehicle attitude correction.

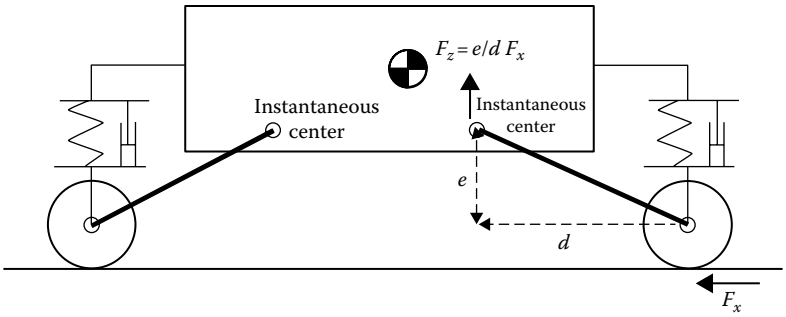

FIGURE 22.22 Illustration of equivalent trailing arm and anti-squat geometry for a rear-wheel-drive, independent rear suspension vehicle.

The mechanics of the anti-x features can be explained through an "equivalent trailing arm analysis" (see Figure 22.22) that recognizes that all suspensions are functionally equivalent to a trailing arm [28]. The mechanics can also be explained through an "equivalent compliance analysis" [29,30] that translates the suspension geometry, kinematics, and bushing compliance into an equivalent compliance regarding the reaction forces and moments onto the vehicle.

Active suspensions, on the other hand, can insulate the vehicle from both road irregularities and load disturbances (e.g., inertial load induced by braking, accelerating, or cornering), independently of each other, something that is not possible with their passive counterparts. An active suspension design that improves the load responses while maintaining the ride comfort characteristic of a soft passive suspension is discussed in [31]. An active suspension control designed with certain amount of anti-x features in mind can further be combined with the more common approach of anticipation or feedforward control to counteract gas/brake pedal applications. In any case, the amount of existing passive and/or active anti-x and their effects should be taken into account when calculating feedforward control.

22.6.2 Delft Suspension

The so-called Delft suspension represents an original design approach toward practical active or actively modulated suspension [32–34]. Conceptually, the overall suspension force is controlled via the mechanism shown in Figure 22.23. The suspension mechanism force F_C is controlled by changing the adjustable lever distance "*b*" in Figure 22.23. This concept was realized through a 3D contraption comprising of a cone mechanism with one end of the spring *S* from Figure 22.23 attached to the vehicle sprung mass at point A and the other to an adjustable crank mechanism regulated by an electrical servomechanism. The crank rotation causes the spring to rotate along the surface of an imaginary cone, with the length of the spring remaining theoretically constant. The net effect is that the force F_C from Figure 22.23 is now continuously controlled through the servo–crank mechanism rotations, with ideally negligible power consumption.

To date, good success was reported with the attitude control during cornering and braking. However, in practical implementation, the power consumption was still significant [20], and limited ride tests reported thus far show about 10% improvements in the rms accelerations, which are primarily concentrated around the dominant, sprung-mass oscillation mode. Since the earlier concept embeds the characteristics of a variable (SA) spring suspension, it is expected to have significant practical ride improvement potentials, which may be materialized through further developments in the future.

22.6.3 Roll-Control Suspensions

While fully active suspensions imply certain cost and complexity issues, as a compromise solution to improved ride and handling with moderate cost and complexity increases, a number of automotive manufacturers have been introducing active and SA suspensions that are focused on vehicle roll control only. Here a significant decrease in the power required can be achieved—along with performance

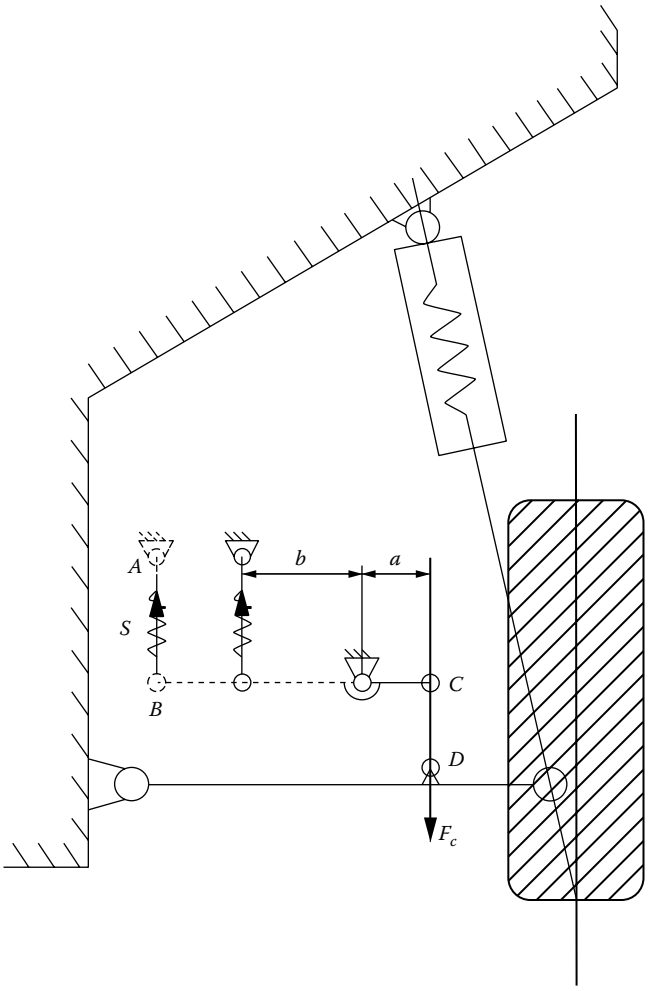

FIGURE 22.23 Delft suspension mechanism with variable lever "*b*." (Based on Venhovens, P.S.Th. et al., Semiactive vibration and attitude control, *Proceeding of International Symposium on Advanced Vehicle Control*, Yokohama, Japan, pp. 170–175, 1992.)

improvement—by feeding forward driver's action as reflected through steering wheel, brake, and accelerator pedal inputs. It is well known that a good ride comfort can be achieved with softly tuned passive or SA suspension, with corresponding soft roll bar settings. However, this will result in large pitch and roll motions during more aggressive braking and cornering, respectively. The active (or SA) roll control is then used to satisfy these conflicting constraints. In practice, the concept is typically realized by inserting a small hydraulic jack and a gas spring accumulator with a control solenoid, all placed in series with the anti-roll bar. The anti-roll bar can be as stiff as in street race cars, without negatively impacting the straight-line ride since the solenoid connecting the hydraulic jack and the accumulator is then kept open, thus lowering the effective stiffness of the roll bar—accumulator combination. This situation is shown in the upper portion of Figure 22.24.

During turns, however, the solenoid is closed, so that the full stiffness of the beefed-up anti-roll bar acts to prevent excessive vehicle roll—see the middle portion of Figure 22.24. In the case of extreme turns, the anti-roll action can be further amplified by directing high-pressure oil into the appropriate hydraulic jack cylinder as shown in the lower portion of Figure 22.24. A production implementation of this concept can be found in 1995 Citroen Xantia Activa [35], where it effectively augments the already established ride capabilities of their Hydractive or hydropneumatic load-leveling suspension [36].

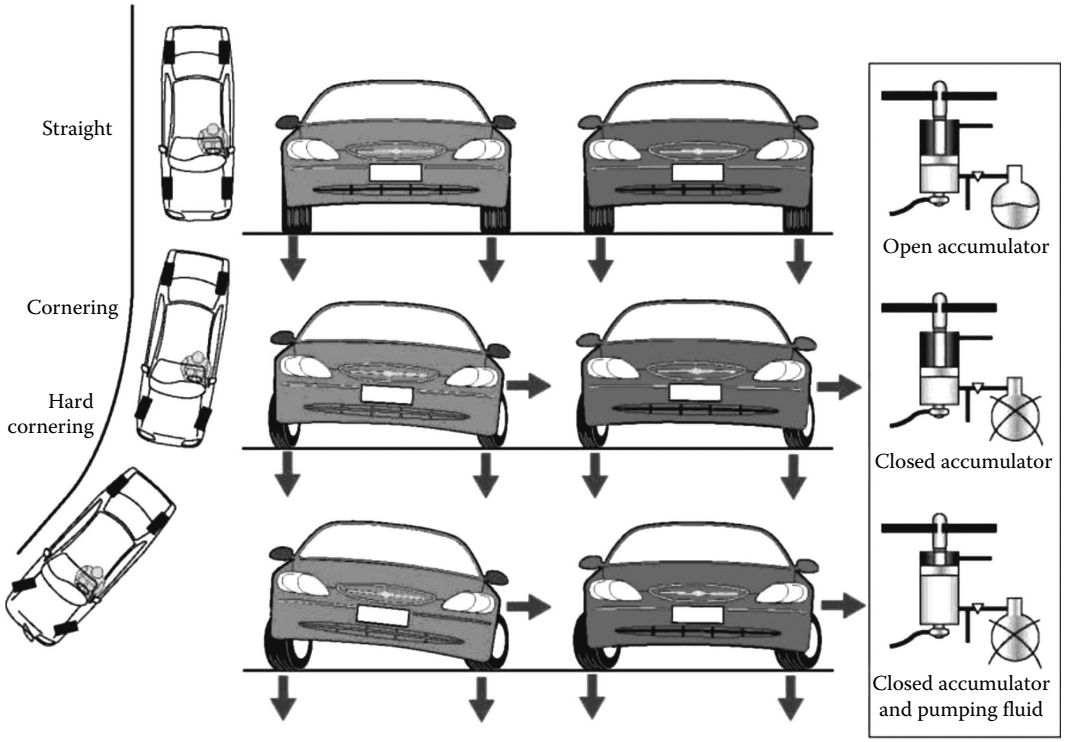

FIGURE 22.24 Roll control during straight-line driving and cornering.

The benefits of roll control were also discussed in [37], where increased anti-roll moments have been achieved with the help of a hydraulic rotary actuator inserted around the middle of the stabilizer bar. A similar type of rotary actuators was fitted at the front and rear axles of some recent higher-end BMW vehicles, which led to the "Dynamic Drive" concept described in [38]. The front and rear roll-control actuators are controlled by means of two electronically regulated pressure-control valves, which minimize the roll motion in corners and road input roll disturbances, while at the same time they contribute to overall vehicle steering accuracy and agility. Future benefits of active roll control will be focused around increased functionality and improvements in overall vehicle stability and active safety through coordinated action with other vehicle control systems, such as brakes, active steering, and electronically controlled all-wheel drive. This can be particularly useful in emergency maneuvers such as sudden need for vehicle stabilization and control during evasive actions on slippery road surfaces.

22.6.4 Dynamic Vibration Absorbers or Tuned Mass Dampers

In its most elementary form, DAs or tuned mass dampers consist of a mass–spring–damper oscillator system tuned to "absorb" the excessive oscillations at a target natural frequency. Typically, this target resonance is characterized by lack of adequate damping, so that in effect the DA here serves to augment the critical resonance mode damping. To date the only known production application of DA in the context of suspensions could be found on the Citroen 2CV—a small car that has acquired a "cult" status in view of its many original characteristics including the superior ride.

While the DA mass constitutes only a small fraction of the target resonance mass, it still adds weight, so in order to justify this additional device, it is important to clearly establish the related benefits. This was done in [39]. From there it can be seen that the DA can nicely complement the active suspension and facilitate full realization of its potentials. This is further enhanced with active DA means for further substantial increase in potential benefits [20,39].

22.6.5 Additional Considerations

While the main emphasis in this chapter was on secondary or sprung-mass suspension, it is also possible to introduce advanced active or SA suspension elements at other vehicle locations. Examples include isolation of vehicle seats and heavy-duty truck cabins [20]. These can further enhance the protection of vehicle occupants and cargo from road-/drive-induced vibrations, especially if combined with the previously mentioned sprung- and unsprung-mass suspensions.

Finally, it should be mentioned that most if not all of production active suspension units introduced to date are of narrow-bandwidth variety (Section 22.4.1). However, future progress in hardware and microelectronics may facilitate full exploitation of broad-bandwidth suspension capabilities. These include exploiting the potentials of preview controls discussed in Chapter 31, as well as implementing rapid and proactive interventions in case of sudden, safety-related maneuvers. It is conceivable that future advanced suspensions could include fast unsprung actuators in tandem with adaptive sprung-mass actuators with gradually varying bandwidth; this could be achieved through interchangeable sets of SA springs and dampers. This is an example of a judicious suspension structure based on sound control/systems insight and principles. More about the latter can be found in Chapter 31.

22.A APPENDIX

A two DOF quarter-car model equipped with a hydraulic active suspension actuator is presented here. With the assumptions that the springs and damping are linear and the tire damping is negligible and with the help of bond graph analysis (see Figure 22A.1), the active suspension system can be represented mathematically as

$$\dot{x} = Ax + Bf + B_w\dot{w}$$

where the four states x_1–x_4 are defined as in Figure 22.16a,

$$A = \begin{bmatrix} 0 & 1 & 0 & 0 \\ -\omega_{us}^2 & -2\zeta\rho\omega_s & \rho\omega_s^2 & 2\zeta\rho\omega_s \\ 0 & -1 & 0 & 1 \\ 0 & 2\zeta\omega_s & -\omega_s^2 & -2\zeta\omega_s \end{bmatrix}$$

$$B = \begin{bmatrix} 0 \\ \rho \\ 0 \\ -1 \end{bmatrix}, \quad B_w = \begin{bmatrix} -1 \\ 0 \\ 0 \\ 0 \end{bmatrix}$$

and

$$\omega_s = \sqrt{\frac{k_s}{m_s}}$$

$$\omega_{us} = \sqrt{\frac{k_{us}}{m_{us}}}$$

$$\zeta = \frac{b_s}{2m_s\omega_s}$$

$$\rho = \frac{m_s}{m_{us}}$$

where
m_s is the sprung mass
m_{us} is the unsprung mass
k_s is the suspension spring constant
k_{us} is the tire spring constant
b_s is the suspension damping coefficient
z_s is the sprung-mass displacement
z_{us} is the unsprung-mass displacement
f is the active actuator force
w is the road disturbance displacement, as shown in Figure 22A.1

The hydraulic actuation system (see Figure 22A.2) can be described, based on servo-valve dynamics [16,40], as

$$\dot{f} = \frac{\sqrt{2A_p}\beta k_{xd}}{V} x_{sp} \cdot \text{signsqrt}\left(\frac{P_s - \text{sign}(x_{sp})f}{A_p}\right) + \frac{2A_p^2\beta}{V}(\dot{z}_{us} - \dot{z}_s)$$

$$\dot{x}_{sp} = \frac{1}{\tau}(-x_{sp} + k_{sv} i_{sv})$$

where
A_p is the piston area
β is the fluid bulk modulus
k_{xd} is the orifice flow coefficient
x_{sp} is the servo-valve displacement
$\text{signsqrt}(y) \equiv \text{sign}(y)\sqrt{|y|}$
P_s is the supply pressure
V is the cylinder chamber volume
τ is the time constant for servo-valve displacement
k_{sv} is the valve gain

If we linearize the hydraulic equation around the servo-valve operating point, we have

$$2C_x x_{sv} + 2A_p\left(\dot{z}_{us} - \dot{z}_s\right) = \frac{V}{\beta A_p}\dot{f}$$

$$\tau\dot{x}_{sv} + x_{sv} = K_v i_{sv}$$

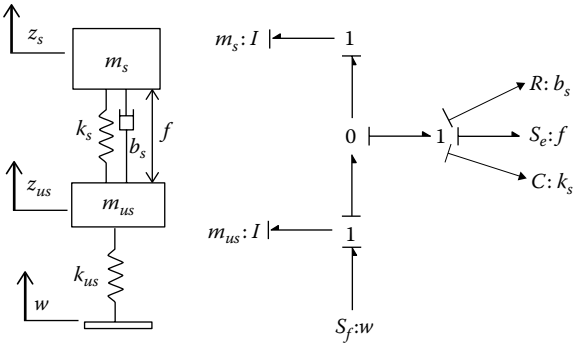

FIGURE 22A.1 Two DOF quarter-car model and its bond graph.

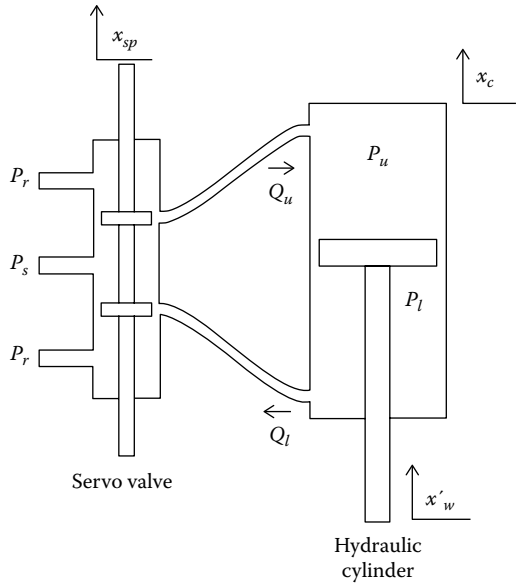

FIGURE 22A.2 Hydraulic servo valve.

And the linear quarter-car active suspension model can be extended [40] as

$$\frac{d}{dt}\begin{bmatrix} z_{us}-w \\ \dot{z}_{us} \\ z_s-z_{us} \\ \dot{z}_s \\ f \\ x_{sv} \end{bmatrix} = \begin{bmatrix} 0 & 1 & 0 & 0 & 0 & 0 \\ -\omega_{us}^2 & -2\zeta\rho\omega_s & \rho\omega_s^2 & 2\zeta\rho\omega_s & \dfrac{-\rho}{m_s} & 0 \\ 0 & -1 & 0 & 1 & 0 & 0 \\ 0 & 2\zeta\omega_s & -\omega_s^2 & -2\zeta\omega_s & \dfrac{1}{m_s} & 0 \\ 0 & \dfrac{2\beta A_p{}^2}{V} & 0 & -\dfrac{2\beta A_p^2}{V} & 0 & \dfrac{2\beta A_p^2}{V}C_x \\ 0 & 0 & 0 & 0 & 0 & \dfrac{-1}{\tau} \end{bmatrix} \begin{bmatrix} z_{us}-w \\ \dot{z}_{us} \\ z_s-z_{us} \\ \dot{z}_s \\ f \\ x_{sv} \end{bmatrix}$$

$$+ \begin{bmatrix} 0 \\ 0 \\ 0 \\ 0 \\ 0 \\ \dfrac{k_v}{\tau} \end{bmatrix} i_{sv} + \begin{bmatrix} -1 \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \end{bmatrix} \dot{w}$$

23.1 INTRODUCTION

Since Aristotle (Greek philosopher 384–322 BC), the statement has been valid that the "whole is greater than the sum of its parts." This is also true when looking at complex technical correlations. Thus, the overall system analysis results in an added value, because it is more realistic to get the actual behavior of a technical system by using system analysis methods rather than analyzing single components or parts only.

Due to the growing demands on optimum transmission solutions—particularly with regard to drivelines or complex powertrains in automotive applications—the overall system analysis of entire drive systems becomes more and more important [1]. The "engineerlike" design of powertrains cannot be realized successfully just by studying the single parts like engines, clutches, flywheels, manual or automatic transmissions (ATs), and gear stages. According to the "spirit of the whole" (i.e., in terms of the overall system analysis), the interactions and interdependences of all drive elements due to dynamic effects have to be considered throughout the process of development and design. For this reason, powerful simulation software packages and results derived from measurements and test rig investigations are necessary to get all details and information for the best model generation and well-suited practically relevant computation methods. The interdisciplinary application of different technical areas is crucial to comply with the general technical demands. The most important technical areas concerning the analysis of drivelines are mechanics, electronics, control engineering, hydraulics, pneumatics, thermodynamics, and fluid dynamics.

Nowadays, one of the principal targets is the optimization of the dynamic and acoustic characteristics of the overall system integrated into the computer-aided classic analysis of torsional and lateral vibrations of vehicle powertrains and engines. In the future, the desired dynamic effects (mechanical vibrations, acoustic effects) are part of a design guideline to create an optimum powertrain and driveline configuration. Therefore, the *n*oise, *v*ibration, and *h*arshness (NVH) studies become a central research and development (R&D) domain. The subject "NVH analysis" is synonymous with the optimization of dynamic effects occurring in a driveline.

In the following chapters, we will focus on the analysis of the dynamic behavior of automotive drivelines in more detail. See also the standard literature to learn more on the basics of dynamics and vibrations in mechanical systems [2–5] and also the layout and computation of drive elements including the analysis of stresses and life [6]. A summary of the basic and state-of-the-art technologies of the elements in automotive drivetrains is given in Refs. [7,8].

23.2 PROCEDURE OF THE ANALYSIS OF DYNAMIC EFFECTS IN A DRIVELINE

The analysis of dynamic effects in drivelines requires a specific procedure. Due to the typical dynamic behavior of a driveline, most problems can be solved by analyzing torsional vibrations or in some cases also lateral vibrations or even the combination of both. In this chapter, we will stick to the torsional vibration analysis (TVA). There are several methods on how to handle the calculation of torsional vibrations. As most of the drive systems have a complex structure with nonlinear characteristics, a purely analytical approach is nearly impossible or difficult for the daily use in the R&D process in the automotive industry. Therefore, finite-element methods (FEMs) or multibody system (MBS) methods are commonly used for TVAs. A special and industry-proven method is the simulation in the time domain using discrete models [9,10].

The typical and recommended procedure during such a TVA is presented in Figure 23.1 [11]. This procedure will be explained in the following chapters in more detail.

23.3 TORSIONAL VIBRATION MODELS OF A DRIVELINE

In order to understand the overall system behavior of drivelines using computer-aided methods, it is necessary to create a high-quality computer model that meets practical relevance and is also easy to use. The importance of this step is often disregarded in everyday R&D life so that a more detailed model generation process is essential [1,5,9,10,12].

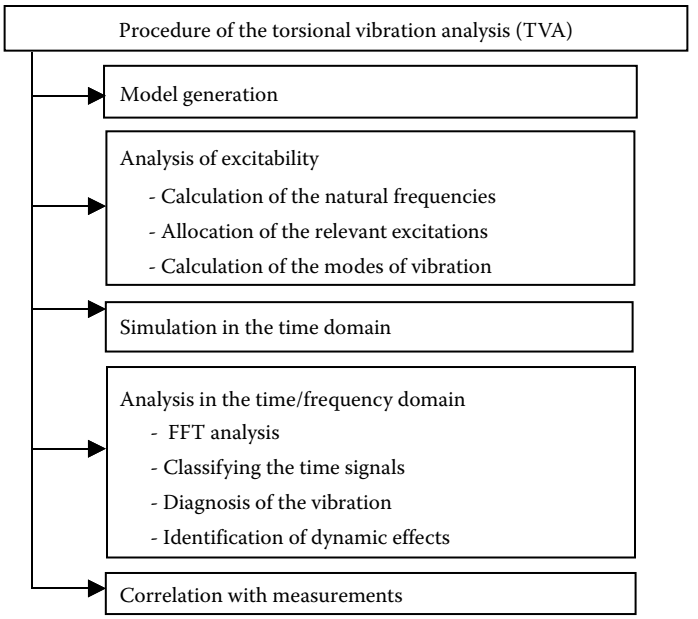

FIGURE 23.1 Procedure of the TVA.

It is recommended to generate different models according to the specific problems (e.g., for a more basic study, to solve specific problems occurring at various transmission elements like in gear stages or universal shafts or to optimize single components like dual-mass flywheel (DMF) and clutches). A uniform model for all conceivable applications is nearly impossible and uneconomical, although engineers often prefer to find such an ideal model.

The analysis of torsional vibrations in a driveline can be carried out using MBS models that are based on discrete models. Such a model consists of lumped inertias connected by stiffness elements (flexible, elastic connections). The inertias (i.e., moments of inertia) are modeled as rigid masses, and the stiffnesses (standing for shafts, gear stages, connections between two coupling halves, etc.) have no masses. Dimensions of the dampings are not necessary for the calculation of the natural frequencies and modes of the vibration; that is why an undamped system is considered first. In most of the cases, the influence of damping on the natural behavior of a torsional system is not significant (however, later we need the damping properties for the simulation!). The system structure may be straight, branched, or even intermeshed (Figure 23.2). Between two neighbor inertias, we always consider a speed ratio and a stiffness with a parallel relative damper (Figure 23.3). The dynamic behavior of a two-mass system is mathematically described in the standard literature [2–4]. The formulation is based on the following differential equation (equation of motion):

$$J\ddot{\varphi} + c\dot{\varphi} + k\varphi = T(t) \tag{23.1}$$

where

J stands for the moment of inertia
c is the relative damping coefficient
k is the torsional stiffness

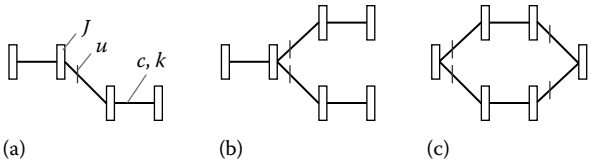

FIGURE 23.2 Structure of a discrete torsional vibration system. Examples of (a) straight, (b) branched, (c) meshed systems. *J*, rotating mass (inertia); *c*, damping; *k*, stiffness; *u*, speed ratio.

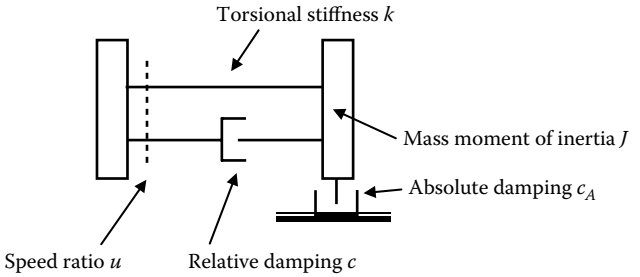

FIGURE 23.3 Basic vibration system consisting of two flexibly connected masses (inertias).

The external excitation is defined by the time-dependent torque T that may also depend on the angle φ and/or velocity $\dot{\varphi}$.

Considering the rotating "shaft element" (base element, cylinder element), where d_2 = outer diameter (O.D.), d_1 = inner diameter (I.D.), L = cylinder length, ρ = density, and G = shear modulus, the *polar mass moment of inertia* is calculated by the following general equation:

$$J_p = J = \rho I_p L \ [\text{kg m}^2] \tag{23.2}$$

The axial moment of inertia—as mentioned in Equation 23.2—can be calculated as follows:

1. *Solid shaft*

$$I_p = \frac{\pi}{32} d^4 \ [\text{m}^4] \tag{23.3}$$

2. *Hollow shaft*

$$I_p = \frac{\pi}{32} (d_2^4 - d_1^4) \ [\text{m}^4] \tag{23.4}$$

The *torsional stiffness* is

$$k = \frac{GI_p}{L} \ [\text{N-m/rad}] \tag{23.5}$$

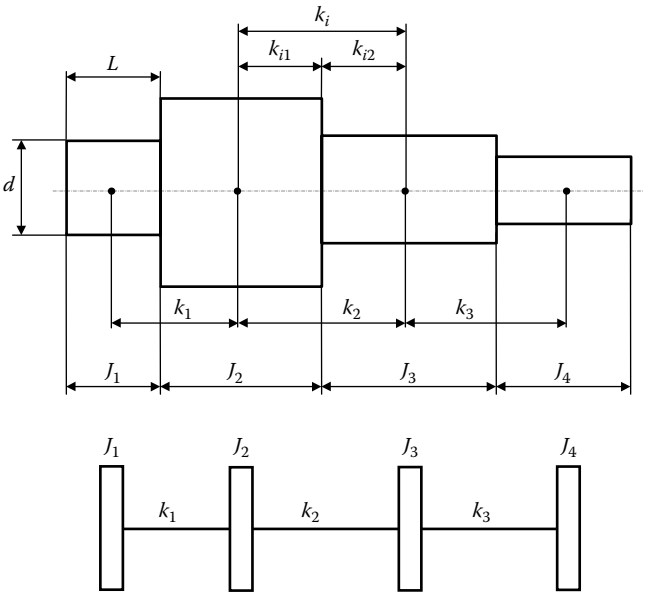

FIGURE 23.4 Multiple stepped shaft with indicated sections as lumped inertias and stiffnesses (d = diameter, L = length, J = mass moment of inertia, k = torsional stiffness).

The formulas show that either the moment of inertia or the stiffness is proportional to the fourth power of the diameter. Considering the length of the cylinder, the moment of inertia increases linearly, while the torsional stiffness is inversely proportional to the length of the considered element. Therefore, it is important for the model validation to check the accuracy of the diameters.

For the calculation of the moments of inertia and the stiffnesses, the shear modulus ($G = 8 \cdot 10^{10}$ N/m^2 for steel) and the material density ($\rho = 7650$ kg/m^3 for steel) must be considered.

If a torsional vibration model should reflect a multiple stepped shaft (Figure 23.4), we have to model every "significant part" of the shaft either as rigid inertia or as stiffness element. The splitting of the shaft into "significant parts" means that the real geometries are split into mass concentrations (i.e., mass moments of inertia) or in elasticities (i.e., torsional stiffnesses). Often the cylindrical elements of such a stepped shaft are modeled as mass moments of inertia, whereas the connections in between become representative torsional stiffnesses. It is important to note that the lining of "partial stiffnesses" leads to an "*elastic series connection*." The total stiffness is always less than the smallest partial stiffness due to the reciprocal accumulation of the stiffnesses (Equation 23.6).

Moments of inertia always refer to the center of gravity of the shaft sections. If necessary, a shaft section combines several smaller sections to a larger single inertia element. In this case, the moments of inertia are calculated in the form of series connections between adjacent inertia elements. The multiple stepped shaft in our example shows several shaft sections that correlate with the discrete structure of the torsional vibration model.

The series connection of multiple stiffnesses (general formulation) is

$$k_{total} = \frac{1}{\sum_{\nu} 1/k_\nu} \tag{23.6}$$

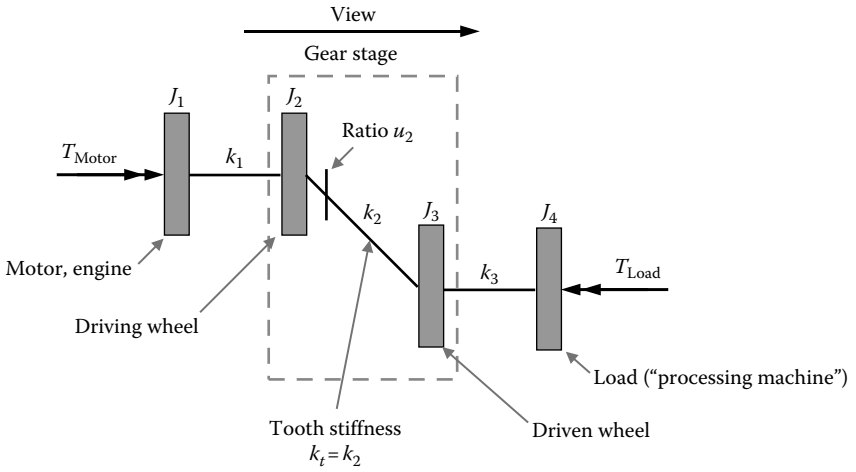

FIGURE 23.5 Vibration model showing details of the properties used to define gear stages.

For the calculation of the *tooth stiffness* k_t (this implies the stiffness between two gear wheels or pinions), the following basic approach for the determination of the substitute stiffness can be used [9]:

$$k_t = k_{spec} \frac{b}{\cos\beta} r_0^2 \,[\text{Nm/rad}] \tag{23.7}$$

where

k_{spec} is the specific tooth stiffness, for example, 10–20 [N/mm/μm]
b is the tooth width [mm]
β is the helix angle [degree]
r_0 is the pitch circle radius (related to the subsequent pinion) [mm]

The recommended values for k_{spec} are based on the literature [13,14]. A generally accepted figure for the mesh stiffness k_{spec} of normal teeth typically for spur gears is 1.4×10^{10} N/m/m [14,15]. However, in order to get the best values for the relevant tooth stiffnesses, we have to take into account the significant effects of the tooth design that can be numerically evaluated by modern FEM models. Different manufacturing methods produce different root shapes and affect stiffness, but the main variations arise from variation of pressure angle or undercutting.

A typical vibration model assuming a tooth stiffness k_t as "torsional stiffness" is presented in Figure 23.5. For the calculation of the tooth stiffness, the pitch circle radius must be applied to the driven wheel with the inertia J_3.

The model size depends on the complexity of the engineering targets. The maximum natural frequency in the computer model should always be greater than the maximum most significant excitation and acoustic frequencies [11].

In order to reduce a model in terms of a reduction of inertia and stiffness stations and therefore a minimization of the maximum natural frequency, a special method based on Rivin's approach [5,9,12] should be used. Reduction guidelines should be noticed in general [11].

23.4 ANALYSIS OF EXCITABILITY

23.4.1 Basics

For the interpretation of the dynamic behavior of a driveline, the "analysis of excitability" is necessary [11]. The first step of the analysis of the dynamic behavior of a drive system comprises the analysis of the natural behavior (in terms of natural frequencies or eigenvalues and

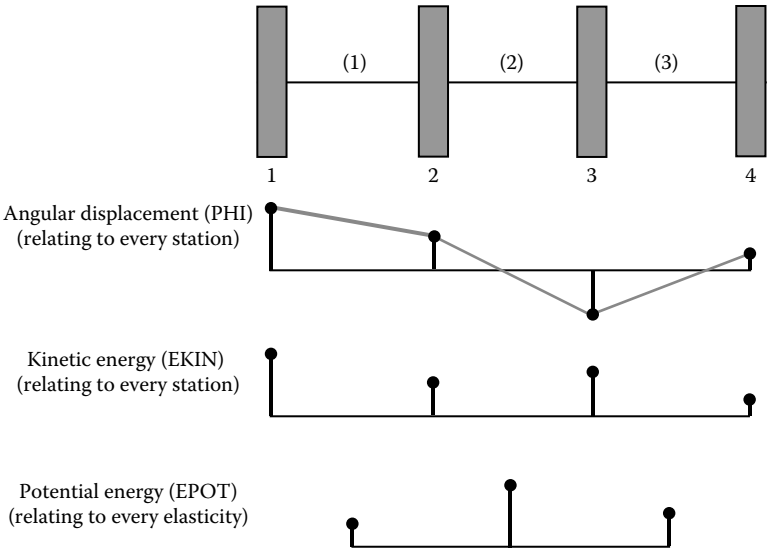

FIGURE 23.6 Presentation of a vibration mode referring to a specific natural frequency.

the corresponding modes or vibration modes or eigenmodes). The system natural behavior is the "portrait" of a dynamic system and therefore of significant interest for the basic understanding of a dynamic analysis. The natural frequencies and modes are usually calculated for the undamped and linearized system.

As an example, Figure 23.6 shows the modes of vibration for one specific natural frequency of a straight four-mass system (four moments of inertia, three stiffnesses) visualized as the normalized values of the angular displacement (PHI), the kinetic energy (EKIN) of every rotating inertia, and the potential energy (EPOT) for every torsional elasticity.

In order to interpret the modes, the following aspects should be noticed:

1. The EKIN amplitudes represent the most important stations (inertias) that might be sensitive in case of external excitations (e.g., engine, flywheel, or any other large inertias) at this station.
2. The EPOT amplitudes represent the most important elasticities (torsional stiffnesses) that might indicate a critical element in resonance, if an excitation does exist with the corresponding excitation frequency and a considerable dynamic amplitude.
3. The combined interpretation of the EPOT and EKIN modes shows how far the drive system experiences a resonance-type amplification in a specific driveline element. This is expressed by "excitability." It must be noticed that a quantitative statement can only be made by simulation methods.

23.4.2 Sensitivity of the Natural Behavior

For the global, superior system understanding as well as for the system identification, the knowledge of the sensitivity of the system in case of the analysis of excitability is crucial. With the help of the statement about the sensitivity of a system, the question concerning the sensitivity of the variation of particular parameters and also the sensitivity due to tolerances and uncertainties of data can be answered, too. That offers not only the opportunity but also the danger to influence the dynamic characteristics by the specific variation of particular system parameters (e.g., stiffnesses and inertias). Further information can be taken from the literature [9,16]. Figure 23.7 shows a two-parametric evaluation of the

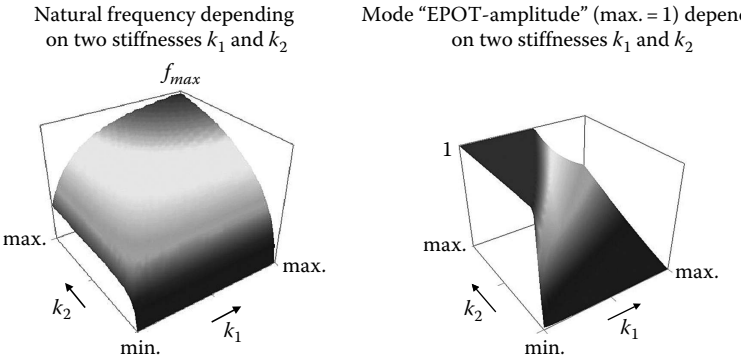

FIGURE 23.7 Analysis of the sensitivity of the natural driveline behavior by the variation of characteristic elasticities (k_1 = stiffness for clutch/damping plate, k_2 = stiffness for side shafts of a rear-wheel-driven car); the amplitudes of the normalized modes are visualized by the gray shades.

system behavior of a vehicle driveline with reference to a specific mode at a selected natural frequency. Additionally, measurements can be rated and become understandable with the help of the sensitivity analysis of the natural behavior.

23.4.3 Resonance Diagram

Usually resonances are graphically presented in a so-called Campbell diagram (*resonance diagram*). This diagram presents the frequencies (=speed-dependent excitation frequencies for every order and also the speed-independent natural frequencies) versus speed (e.g., engine speed) and may visualize possible resonance speeds. The order lines correspond to the significant harmonic excitations.

The following table assigns possible excitation sources to their typical excitation frequencies (Table 23.1). The speed n [rpm] is always the speed of the corresponding drive element that produces the excitation.

There are several types of excitations. One excitation line might correspond to the second order of a combustion engine (e.g., four-stroke four-cylinder engine); another excitation line refers to the excitation of an aggregate [e.g., compressor and pump]. Furthermore, excitation lines are also caused by so-called parametric excitations as found in gear stages due to the fluctuating tooth stiffnesses (mesh frequencies).

TABLE 23.1
Excitation Source and Corresponding Excitation Frequencies

	Excitation Source	Excitation Frequency Depending on the Frequency $f = n/60$ [Hz] Where n = Speed [rpm]
1	Clutch (+backlash), compressor, turbine; excitation due to unbalances or eccentricities	**$1 \times f$ or $2 \times f$**
2	Universal shaft, slider crank	**$2 \times f$**
3	Gear drive	Gear mesh frequency
	z_G = number of teeth	**$1, 2, 3 \times z_G \times f$**
4	Pump, fan, ventilator	Blade-passing frequency
	z_P = number of blades	$z_P \times f$
5	Compressor, pump, two-stroke combustion engine	**$1, 2, 3, \ldots, k \times f$**
6	Four-stroke combustion engine	**$0.5, 1.0, 1.5, 2.0, \ldots, k \times f$**

Speed-proportional excitations of electrical drives, which depend on the motor characteristics, can also be visualized as typical excitation lines within a resonance diagram. As unbalances and eccentricities often occur in drivelines, the first and second excitation orders referring to every speed of the shafts can always be noticed.

Since the natural behavior is usually calculated according to a linear torsional vibration system, the time- and speed-independent natural frequencies can be displayed as horizontal lines. Intersections between the natural frequency lines and the order lines can lead to resonances. A resonance, which relates to a specific station of the driveline (e.g., a stiffness station in case of a torque-response signal), only exists as important magnitude (e.g., amplified torque response), if the following items are effective all together:

1. Excitation and natural frequency coincides.
2. Excitation amplitudes are significant.
3. Corresponding vibration mode shows significant amplitudes at the station, which is analyzed.

Large resonance peaks can lead to damages inside the driveline. A stress and life analysis must show that the current excitations are within the allowable limits [6]. Smaller resonance peaks do not affect the durability, but they can lead to serious noise problems inside the driveline or to disturbing vibrations (quality issues). Therefore, even small mode energies (i.e., small amplitudes in the vibration mode) may cause acoustic problems. This fact plays a major role in the NVH analysis. Typical resonance diagrams are presented in Figure 23.8.

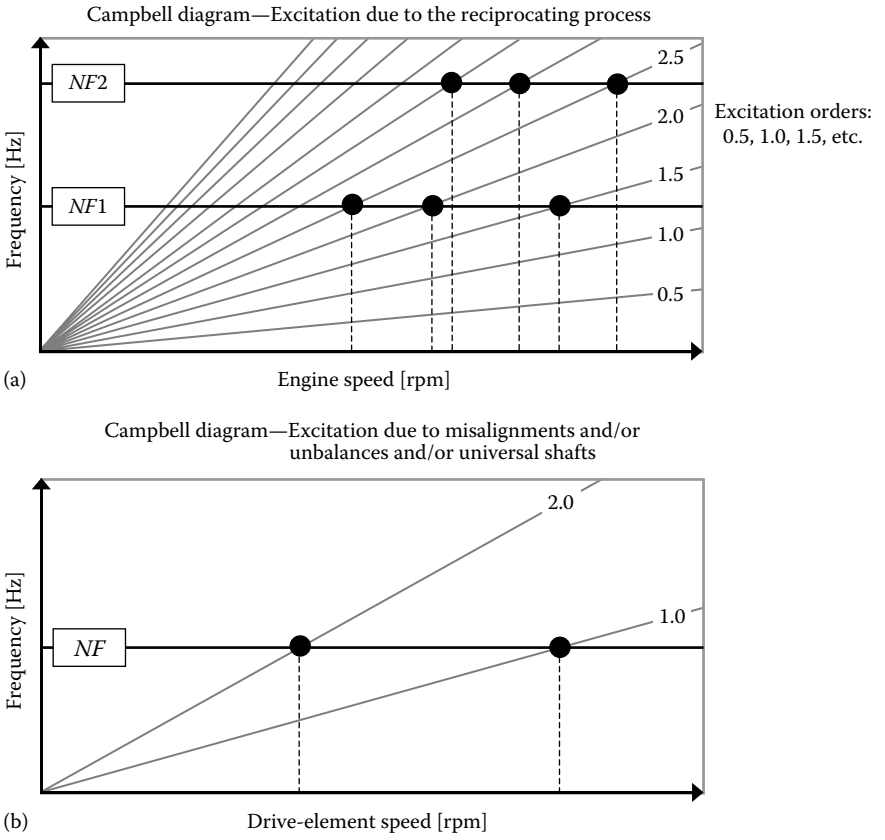

FIGURE 23.8 Typical resonance diagrams with highlighted resonance points (=dark circles): (a) engine excitation, (b) misalignments and/or unbalances and/or universal shafts.

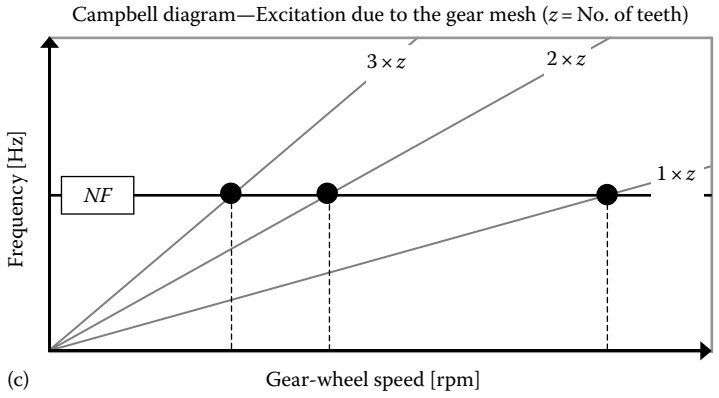
(*continued*)



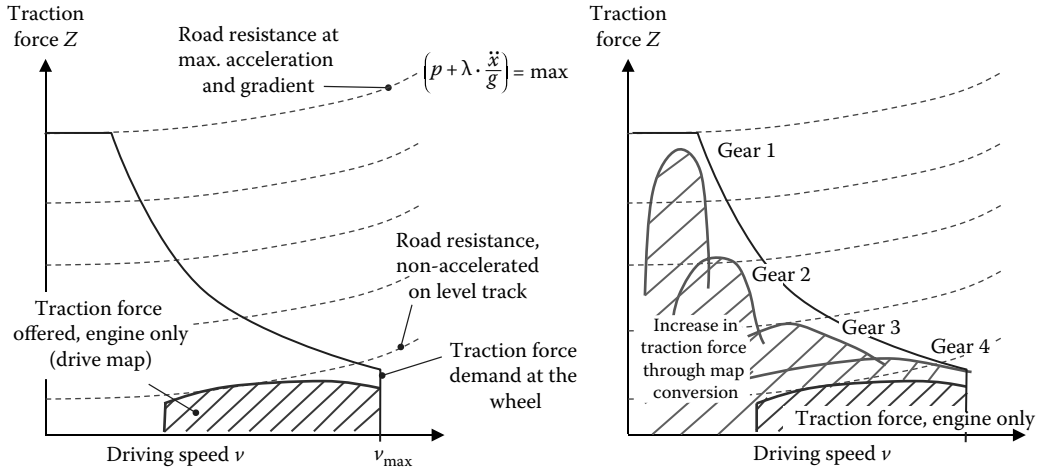


FIGURE 23.8 (continued) Typical resonance diagrams with highlighted resonance points (=dark circles): (c) gear mesh (dynamic tooth stiffness). *NF* = natural frequency, z = number of teeth.

23.5 COMPONENTS OF A DRIVELINE

The basic functions of the drivetrain include the support of the vehicle optimized in terms of fuel consumption, emissions, noise, comfort, and performance. It focuses on the conversion of the primary engine maps into secondary wheel maps (Figure 23.9). Starting devices and transmissions, which have to meet specific demands, are used in conventional drivetrains to fulfill these functions. General descriptions of the components in an automotive drivetrain are given in Ref. [8].

Figure 23.10 exemplifies a standard drivetrain used in many vehicles. A longitudinally mounted combustion engine with flange-connected starting device and transmission is typical of this drivetrain design. The power is transferred by a propshaft from the transmission output to the rear axle gear with integrated differential. The differential outputs are connected to the wheels by the drive shafts. The differential is required for wheel speed compensation of the driven axle in case of cornering.

Primary function of the transmission: conversion and adjustment of the engine map to the demand map.

FIGURE 23.9 Adjustment of the power map of a combustion engine to the traction force demand at the wheel by conversion of the map due to a multispeed transmission. Acceleration and uphill or downhill driving would be limited without conversion.

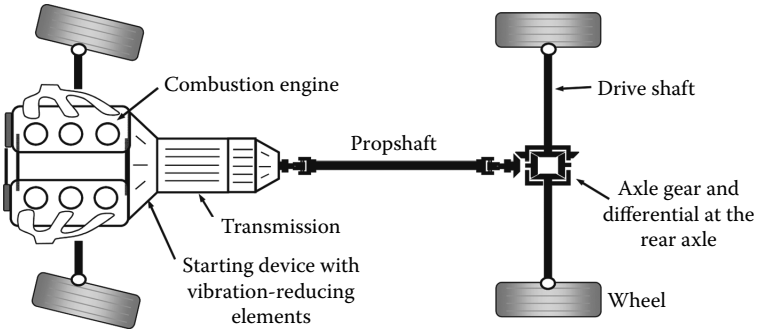

FIGURE 23.10 Components of a standard drivetrain: The power in the conventional drivetrain is transferred from combustion engine to the transmission by the starting device and to the wheels by shafts and axle gear.

Besides this design, front longitudinal or front transverse installations are common. For the first one, the propshaft is not required since the power is transferred to the drive shafts of the front axle by an axle gear and differential integrated in the transmission. The latter one includes a combustion engine mounted transversely to the longitudinal vehicle axle and usually also a transmission with integrated axle gear and differential. All drivetrains have specific requirements on the transmission design (see Section 23.5.3).

The mechanical power required to drive the vehicle is generated by the combustion engine and is available as speed and torque at the transmission input shaft. It is typical of modern internal combustion piston engines that they can only produce torque when the idle speed is reached and that they have a maximum speed. Other important characteristics are the fluctuation of torque due to single ignition of each piston and the resulting irregular crankshaft speed. To reduce the irregularity, flywheels and torsional vibration dampers are installed in modern drivetrains (see Section 23.5.2).

In conventional drivetrains, starting devices are used to bridge the speed gap resulting from the necessary minimum engine speed. The most common types of these devices include mechanical friction clutches and Trilok converters (cf. Section 23.5.2.2). They are mounted in front of the transmission. The transmission is the most important part involved in the conversion of the maps. The ratio of the transmission as a speed torque converter can generally be adjusted in different gears. The most important transmission designs in serial production will be introduced in Section 23.5.3. The ratio of the axle gear is usually constant. The overall ratio of the drivetrain is determined by the product of both the transmission ratio and the axle gear ratio. The overall ratio normally ranges from 2 (highest gear) to 16 (starting gear):

$$i_{Overall} = i_{Transmission} \cdot i_{FinalDrive} \tag{23.8}$$

Propshafts within the drivetrain transmit rotary power and are able to compensate spatial displacement of components, for example, caused by wheel angle while cornering. The wheel is finally responsible for the conversion of the rotary drivetrain movements and torques into translational movements and forces.

As a matter of fact, the combination of all mentioned rotating drive elements in a vehicle driveline is critical for the overall dynamic sensitivity and also NVH characteristics of the total rotating system [17]. Therefore, it is a must to analyze the dynamic behavior of this system as a whole and to understand the detailed characteristics and importance of every single drive component.

23.5.1 Engine

Combustion engines are reciprocating machines—as typically used in vehicle drives—and are usually working according to the four-stroke process. As the name implies, the operation of a four-stroke internal combustion engine comprises four basic steps that repeat with every two revolutions (720°) of the engine (Figure 23.11). The typical dynamic engine excitation is

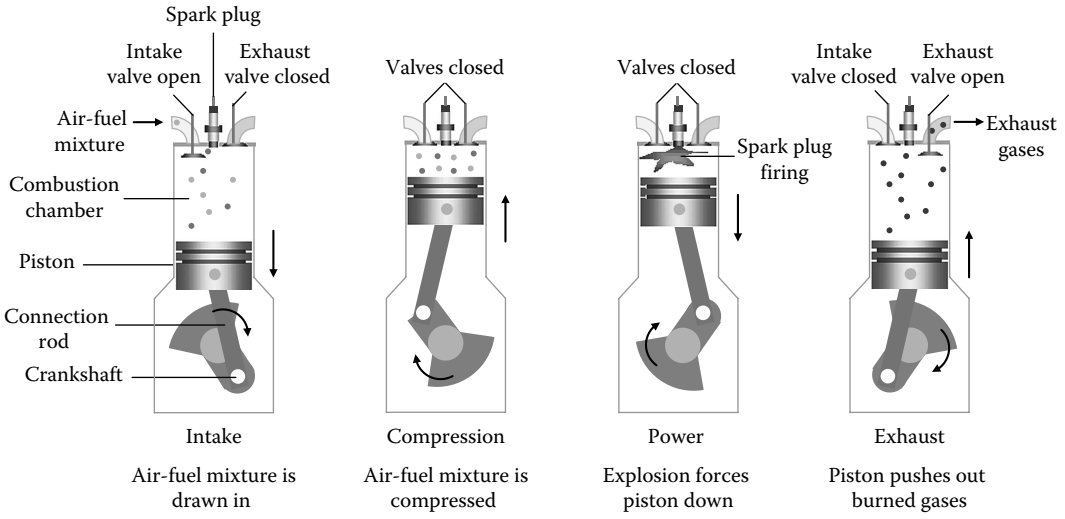

FIGURE 23.11 Four-stroke cycle of a reciprocating combustion engine in a vehicle.

described by tangential force curves or recalculated as torque-angle functions, mostly represented by Fourier coefficients depending on the process characteristics (gasoline, Diesel) as presented in Figure 23.12 [18,19].

The rotational irregularity at the crankshaft is caused by the combustion characteristics of combustion engines. Only when the fuel is burnt, a drive force is generated that produces torque at the crankshaft. For a four-cylinder four-stroke engine, there are thus two force peaks per crankshaft rotation due to two-plug ignition. Irregularities of the second engine order can thus be observed at the crankshaft. This reduces the service life of the drivetrain components due to continuously changing torque load on the one hand, and on the other, vibrations in the drivetrain are induced that are perceived as influencing the comfort negatively.

23.5.2 Flywheel and Clutch

23.5.2.1 Torsional Vibration Damping at the Transmission Input

A combination of increase in inertia and vibration damping is usually applied in the drivetrain to reduce the effects of the engine-related (primary side) vibrations on the residual drivetrain. In the simplest case, a flywheel is used to increase the rotary inertia of the crankshaft, so the torque fluctuation does not influence the speed very much. This additional mass, however, affects performance and fuel consumption negatively, since inertia to be accelerated in driving maneuvers increases significantly particularly in lower gears. A clutch–spring–damper system is therefore integrated in the clutch disk (Figure 23.13). Suitable spring stiffness leads to uncritical vibration response of the drivetrain on the transmission input side, with its natural angular frequency ν being reduced in a way that it results in an isolation frequency Ω below the double idle frequency of the combustion engine (Figure 23.15a). The vibration irregularity in normal vehicle operation on the primary side is damped considerably due to the resulting damping characteristics, so the load on the transmission input is reduced. Vibration amplification only occurs when starting the engine.

Conventional clutch–spring–damper systems, however, can only damp rotational fluctuations up to a certain amplitude. Furthermore, good damping characteristics at low excitation frequencies, that is, low engine speeds, are achieved by low stiffness of the spring elements, which leads to perceptible load-alteration effects that are thus evaluated as negative. But modern car engines are characterized by higher torques even at low speeds as well as reduced idle speed and fewer pistons (downsizing), resulting from the wish for reduced fuel consumption and emissions. This in turn leads to increasing

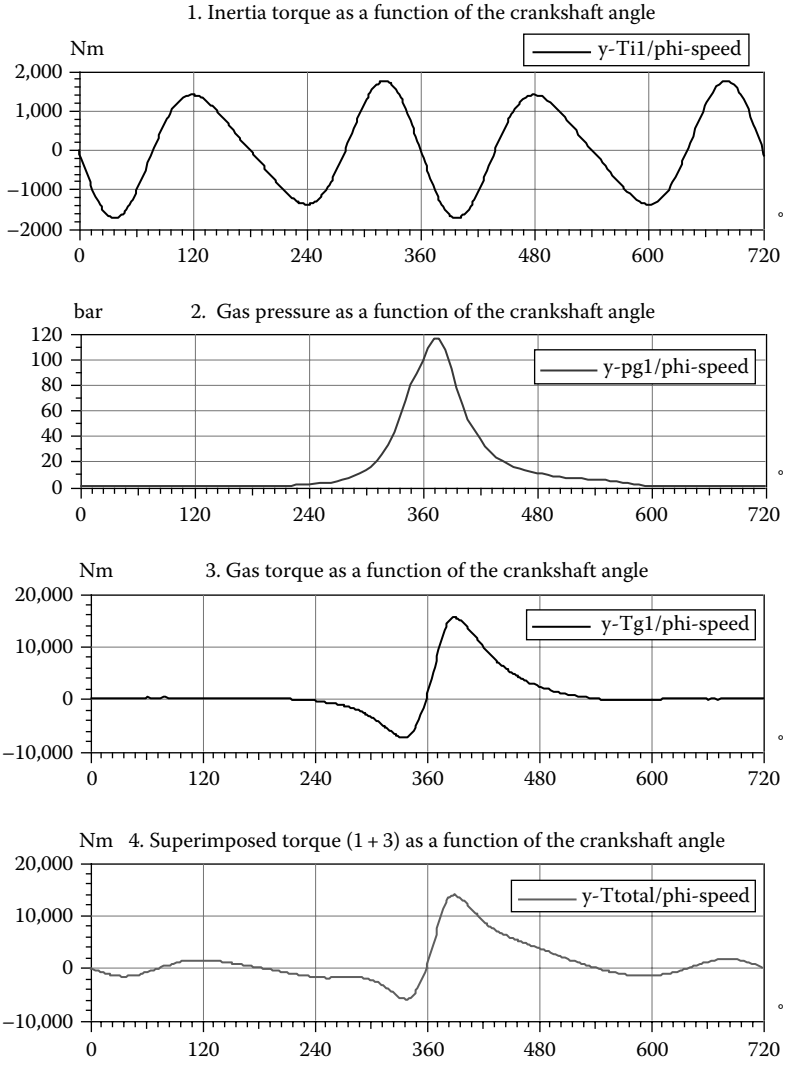

FIGURE 23.12 Typical presentation of engine excitation torques.

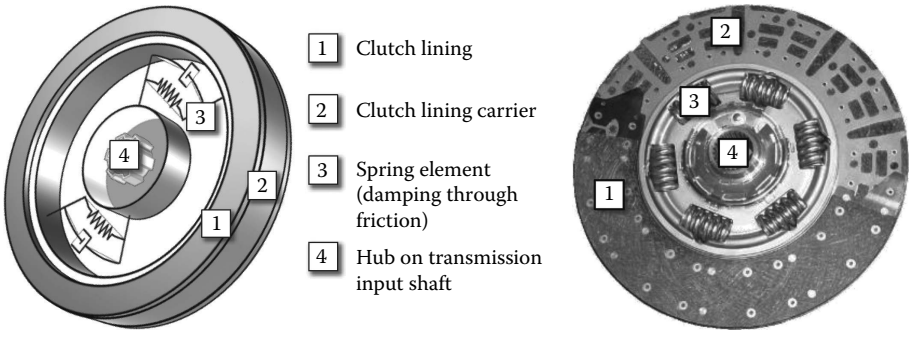

FIGURE 23.13 Conventional clutch–spring–damper system. There are tangential spring packs between the inner part with connecting hub to transmission input shaft and the friction lining carrier. The damping effect is caused by friction.

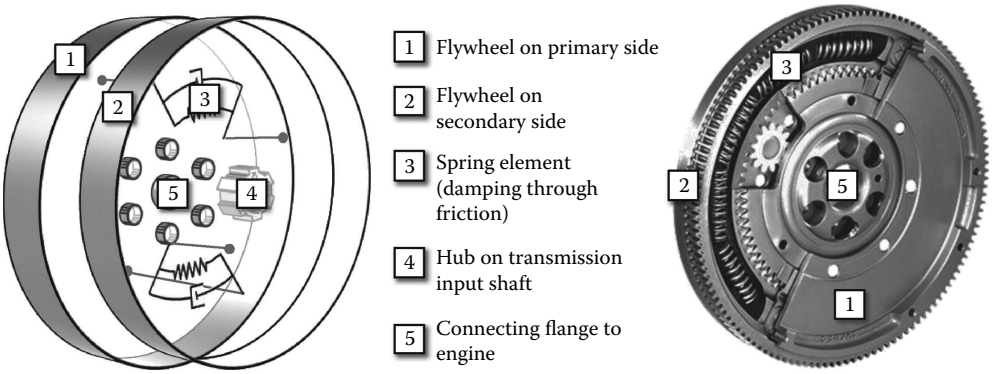

FIGURE 23.14 DMF: Flywheels on the primary and secondary sides are connected by a spring pack. Flange and hub connect them to engine and transmission.

rotational irregularity especially in the critical range of low frequencies. For this reason, alternative technologies are required to protect the transmission input efficiently from torsional vibrations. Established technologies include the so-called DMF (Figure 23.14). Here, the conventional flywheel (single-mass flywheel) of the crankshaft is divided into a primary and secondary flywheel, and a (multistep) tangential spring system is placed between them. The vibration system at the transmission input is thus changed in a way that additional vibration modes are generated and the characteristic amplification function of rotational irregularities of the engine is changed in a positive way: the isolation frequency shifts toward lower speeds below the engine idle speed due to the less dominant natural frequency (Figure 23.15b). The main disadvantage of this technology is the high cost for a DMF.

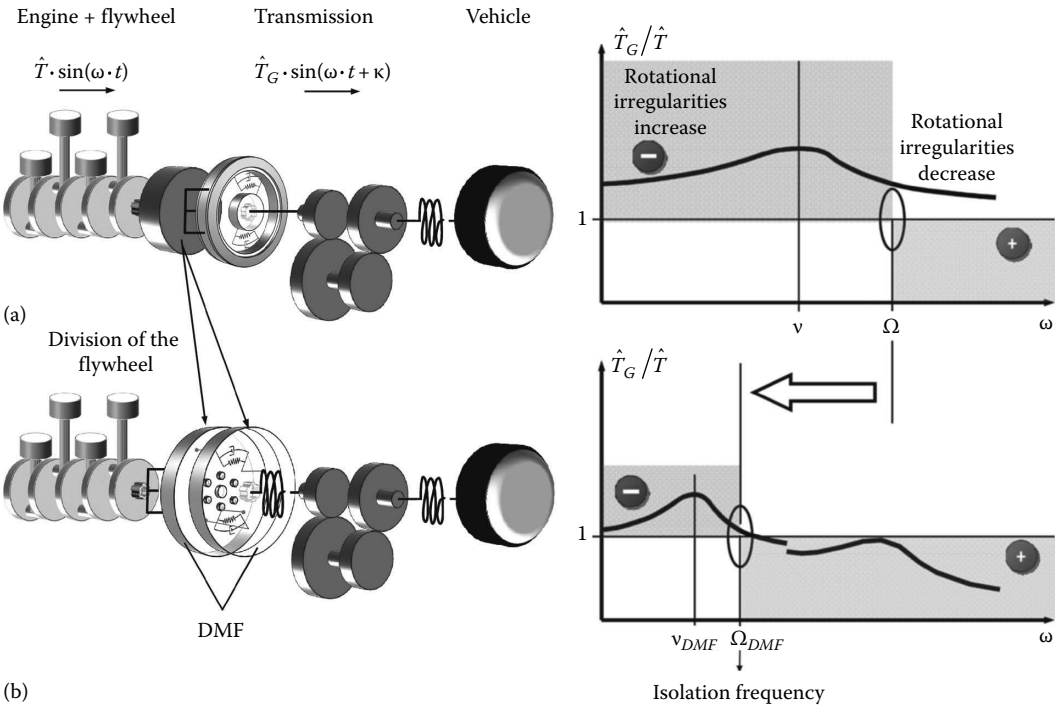

FIGURE 23.15 Vibration absorption at transmission input by conventional vibration dampers (a) and DMF (b).

This is the reason why researchers look for alternative technologies that guarantee good vibration damping with only minor additional consumption (e.g., centrifugal pendulum).

Extended details are found in Refs. [20–22].

23.5.2.2 Starting Devices

As described earlier, even the most modern combustion engines are able to provide power at the crankshaft when reaching a certain speed. Below this limit, the torque generated by the pistons is inadequate to overcome friction loss. Therefore, it is necessary to include a starting device in the drivetrain that helps to bridge the speed gap. What the nowadays often used starting device clutch and torque converter have in common is the power loss that occurs in the form of heat that has to be stored or emitted when starting. In general, the requirements on starting devices can be summarized as follows:

- Separating drivetrain from running engine if the vehicle is at standstill or during gear change
- Bridging speed when starting
- Vibration isolation
- "Overload protection" in case of blocked engine

23.5.2.3 Mechanical Clutches

Mechanical friction clutches, either as dry clutches for manual or Dual-clutch transmissions (DCTs) or as wet multidisk clutches with oil cooling in DCTs, are not torque converters. This means that the speeds for both halves of the clutch can differ, but the torque for both parts is identical.

Figure 23.16 represents the layout of a dry mechanical friction clutch. It usually consists of a clutch disk with friction lining between a pressure plate and the flywheel or the secondary flywheel of a DMF. The clutch disk is connected to the transmission input shaft so as to prevent rotation, and spring packs can be integrated in case of a conventional clutch–spring–damper system. Flywheel and pressure plate rotate together with the engine speed. If the clutch is not actuated, the pressure plate is pressed to the clutch disk by a disk spring that induces normal force. This force dictates the

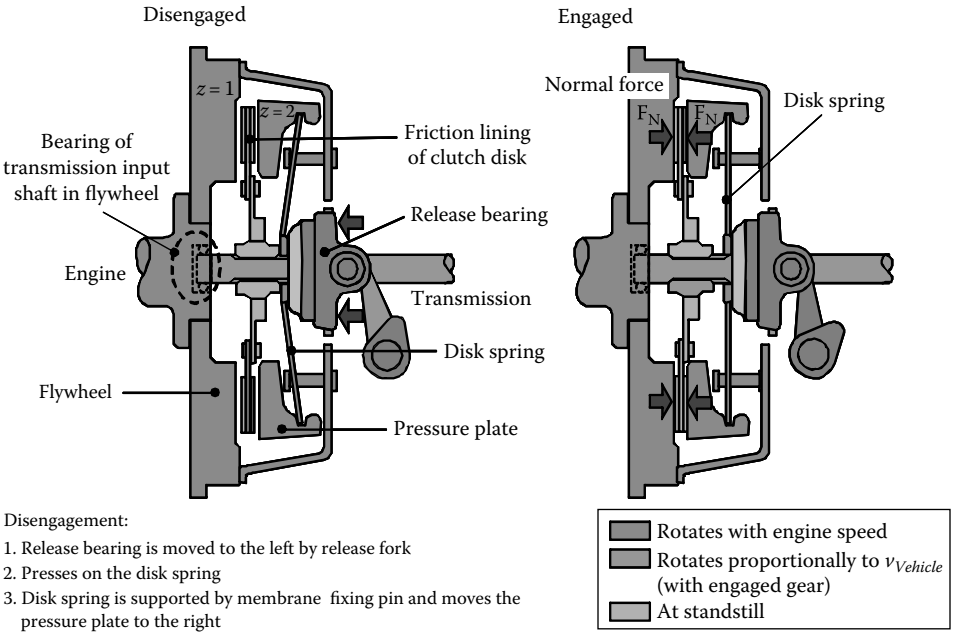

FIGURE 23.16 Structure and function of a mechanical friction clutch with disk spring.

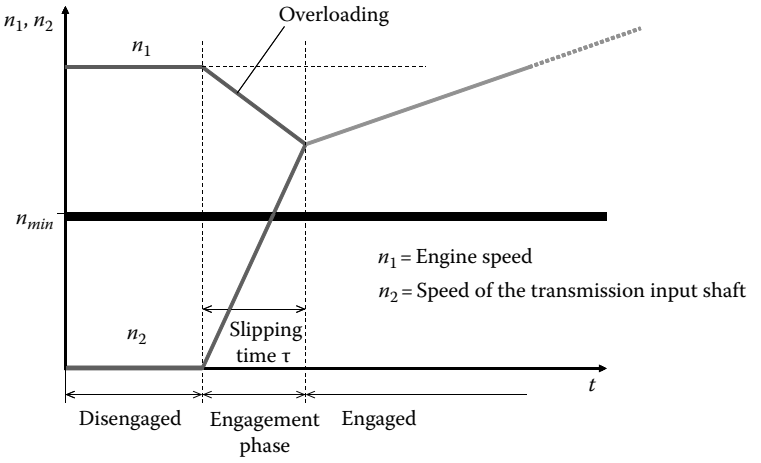

FIGURE 23.17 Speed curves of engine and transmission input during starting. During the engagement phase, the clutch slips and thus transmits torque. If the accelerator is not increased, the engine speed decreases slightly until the transmission input speed reaches the level of the engine speed.

transmittable clutch torque. During disengaging, the load on the disk spring is released by a release bearing and the pressure plate is separated from the clutch disk. The spring characteristics affect the force in the clutch pedal significantly. In case of an automated manual transmission (AMT), the actuators move the release bearing.

During engaging the clutch slips, that is, both parts of the clutch rotate at different speeds with normal force and transmitted torque. During the start-up process as illustrated in Figure 23.17, the clutch slips in the "engagement phase." The clutch transmits torque from the engine to the transmission and thus to the wheels. The vehicle is accelerated and the transmission input speed increases, while the engine speed is reduced—assuming the driver does not increase the accelerator. As soon as transmission input speed and engine speed are identical, the state of the clutch changes from friction to adhesion and the engaging process is completed.

During the engagement phase, friction power loss occurs in the clutch in the form of heat input to the clutch lining. Thus, the clutch heats up considerably. The heating depends on transmitted torque, vehicle mass, and starting gear ratio. For this reason, not all heavy and powerful vehicles can be equipped with dry friction clutches. Wet shift elements or the so-called hydrodynamic torque converter is therefore used.

23.5.2.4 Hydrodynamic Torque Converter

Hydrodynamic torque converters are based on the principle of hydrodynamic clutches. They consist of a pump that is connected to the engine and a turbine connected to the transmission input. Oil circulates between both of them (Figure 23.18). In case of the torque converter, a so-called stator is added to this type of clutch. Up to a certain speed ratio of turbine and pump, the stator diverts the flow of the oil, so the torque at the turbine is increased. The range where the speed ratio $\nu = n_{Turbine}/n_{Pump}$ is smaller than in the so-called coupling point is called converter range. The smaller the speed ratio, the higher the so-called torque increase $\mu = T_{Turbine}/T_{Pump}$ (Figure 23.19). The reason for this is flow diversion at the stator, which causes torque at the stator that is supported by the sprag clutch. This stator torque is also available at the turbine in addition to the torque from the pump. The hydrodynamic two-phase converter, also named Trilok converter after the inventor, is therefore not only a speed converter but a simple hydraulic transmission in the form of a speed torque converter. At the coupling point and beyond, the flow at the stator is changed in a way that it rotates over the sprag clutch and the torque is not increased.

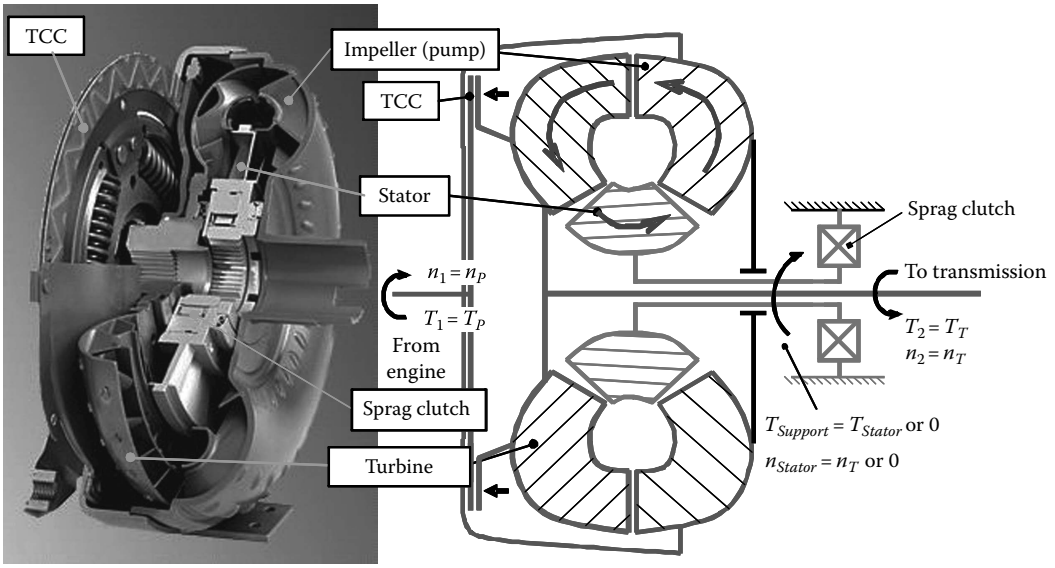

FIGURE 23.18 Construction of a hydrodynamic two-phase converter (Trilok converter).

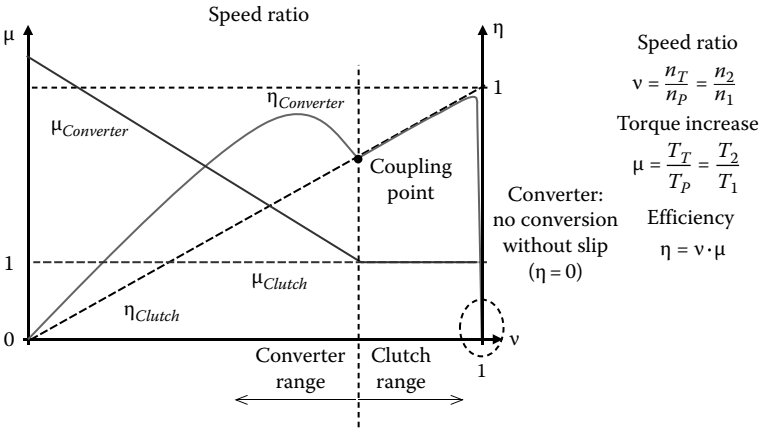

FIGURE 23.19 Torque ratios and efficiency of mechanical friction clutches and hydrodynamic two-phase converter.

While the clutch slip determines the efficiency of mechanical clutches, higher efficiency during starting can be achieved with a hydrodynamic converter due to the increase in torque (Figure 23.19). An important disadvantage of the converter is that power can only be transmitted if there is a speed difference between pump and turbine. This results in reduced efficiency during constant driving. For this reason, nowadays a so-called torque converter lockup clutch (TCC) is used, which connects pump and turbine mechanically. Furthermore, this mechanical connection reduces the so-called rubber band effect, which describes the roaring of the engine in case of load reversal and the sluggish response of the vehicle. But to use the good damping characteristics of the converter especially during gear change, the TCCs are used with controlled slip in some operating states that are critical in terms of vibration.

Due to their design, the hydrodynamic converters allow the transmission of high torques. The good damping characteristics as well as converter increase lead to high driving comfort, which is the reason why this type of starting devices is mainly used in high-quality vehicles.

Extended details are found in Refs. [23,24].

23.5.3 Manual and Automatic Transmission

The transmission does not only convert speed but also torque. This means that speed and torque at the transmission input differ from those at the output. The power, however, remains the same, except for losses (efficiency).

There is at least one ratio resulting from the relation of the speeds at transmission input and output:

$$i_{Transmission} = \frac{n_{Transmission\ Input}}{n_{Transmission\ Output}} \tag{23.9}$$

According to the type of transmission, one gear (axle gear), several gears (manual transmission = MT), or an infinite number of gears (continuously variable transmission = CVT) are possible, with speed-reducing ratio ($i > 1$) as well as speed-increasing ratio ($i < 1$, so-called overdrive gears).

Taking the transmission efficiency

$$\eta_{Transmission} = \frac{p_{Transmission\ Output}}{p_{Transmission\ Input}} = 1 - \frac{p_{Transmission\ Loss}}{p_{Transmission\ Input}} \tag{23.10}$$

into account, the following relation between the transmission input torque and the output torque $T_{Transmission\ Output}$ applies:

$$T_{Transmission\ Output} = T_{Transmission\ Input}\, i_{Transmission}\, \eta_{Transmission} \tag{23.11}$$

The following criteria can be used to classify vehicle transmissions:

- *Degree of automation*: There are "MTs" (cf. Section 23.5.3.1) as well as "semiautomatic and fully ATs" (AMT, CVT, DCT, AT; cf. Sections 23.5.3.2 through 23.5.3.5), with automatic starting and shifting as well as automatic selection of shift points [25]. Principally, the efficiency of MTs is higher than of ATs, which always require additional energy to operate the actuators. This energy cannot be used to drive the vehicle.
- *Type of power transmission*: The drive power can be transmitted in different ways. It is transmitted mechanically in conventional transmissions, and fluid-mechanically transmitted only in the hydrodynamic converter. In modern hybrid drivetrains, there are so-called electric power split transmissions with mechanical as well as electric power transmission.
- *Strategy of ratio adjustment*: In this context, stepped ATs with discrete steps and "CVTs" are differentiated (CVT; cf. Section 23.5.3.3). The ratio of the CVT can be selected freely within the limits given by the design.
- *Design*: According to the drivetrain layout, different transmission concepts are required. Transmission input and output of so-called *inline transmissions* are arranged coaxially. Spur gear transmissions (MT, AMT, DCT) therefore have to have at least two ratio steps (Figure 23.20a): in general, there is a constant transfer from the input to the so-called countershaft and gear ratio to the output shaft. Planetary transmissions (AT, cf. Section 23.5.3.5) comply with this. Inline transmissions are especially used for standard design drivetrains (Figure 23.10). This design allows for a direct gear with a ratio of and high efficiency with the torque being directly transmitted from input to output shaft. If the engine is mounted longitudinally and the axle of the vehicle is driven, where the engine is mounted, so-called *transaxle transmissions* are used primarily (Figure 23.20b). This type of transmission combines transmission ratio and axle drive and allows for the required rotation of the pivot axle by 90°. For transversally mounted engines, *transverse transmissions* are used (Figure 23.20c). They have two or more parallel shafts, but the output is not coaxial to the input. Axle gear and axle differential are generally integrated in the transmission.

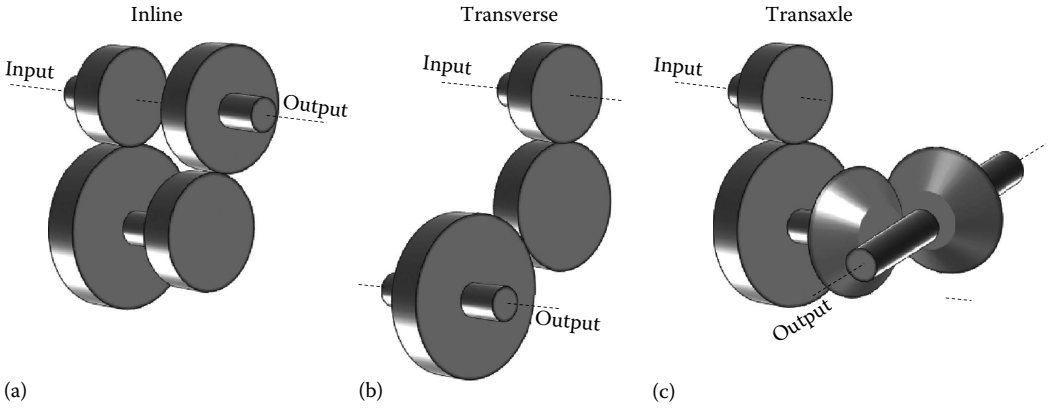

FIGURE 23.20 Transmission designs for different drivetrains. (a) Input and output shafts of standard drivetrains are arranged coaxially. (b) The axle positions of transmissions for transversally mounted engines are parallel but different, usually with an integrated axle gear. (c) Transaxle transmissions are used for longitudinally mounted engines and combine primary transmission and axle gear but with a 90° rotation around the pivot axis.

- *Interruption of traction*: In transmissions that only have one clutch as a starting device (MT, AMT), the clutch usually has to be opened during shifting since the gear change requires an unloaded transmission. When the clutch is opened, power cannot be transferred to the wheel, so the traction is interrupted. During acceleration, this results in a considerable longitudinal acceleration interruption (cf. Figure 23.21). Transmissions with more than one clutch (DCTs and ATs), however, can change gears without interruption of traction since the torque of a (disengaging) clutch is transmitted to another (engaging) one. The torque is transmitted to both clutches during gear changes, so the driver ideally does not recognize the change.

In the following, the most important transmission designs will be described.

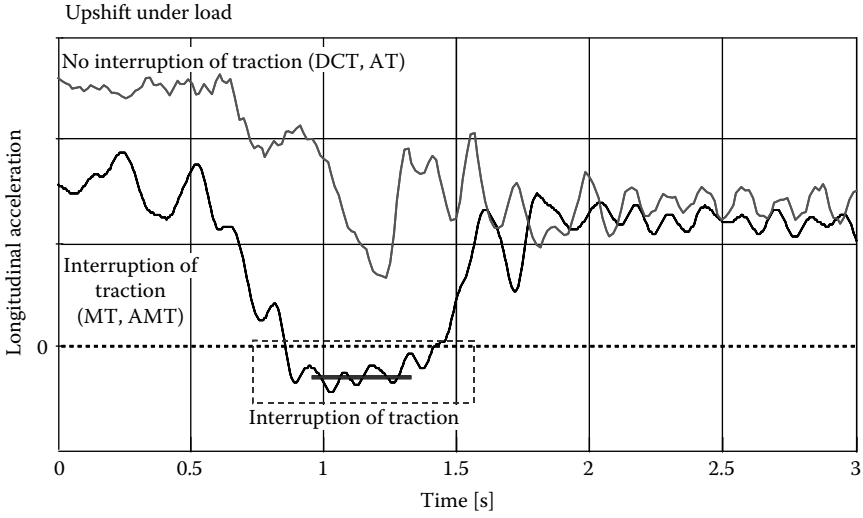

FIGURE 23.21 Curves of longitudinal acceleration during shifting under load with and without interruption of traction. In case of transmissions with traction interruption (MT, AMT), the longitudinal acceleration decreases significantly and is partially negative, while the changes in longitudinal acceleration are hardly recognizable when the traction is not interrupted.

23.5.3.1 Manual Transmission

MTs are the best accepted type of transmissions in Europe as well as in many important markets worldwide due to their low manufacturing costs and high efficiency. MTs are spur gear transmissions. The gear pairs for each gear are arranged on at least two parallel shafts, each pair consisting of a fixed gear and an idler gear. The fixed gear is fixed to a shaft, while the idler gear can rotate freely on the other shaft. Only if a gear is engaged, idler gear and shaft are connected by a shift unit (often synchronization units).

Figure 23.22a illustrates the structure of an MT for inline installations: the torque is transmitted constantly from the input (left) to the countershaft. According to the engaged gear, the torque is transmitted to the output shaft coaxially to the input shaft and from the output shaft to the axle gear. The fifth gear as a so-called direct gear is special since the power is directly transmitted from the input to the output shaft. An additional intermediate gear is required for the reverse gear, which causes the reversal of direction of rotation. Figure 23.22b shows the structure of a transverse transmission. As opposed to the inline transmission, the gear-dependent torque is directly transmitted from input shaft to countershaft, which is also the output shaft. The torque is then transferred to the integrated axle gear. Since the axial space—particularly in case of transversally mounted engines—is limited, small transmissions are required. Therefore, so-called multi shaft concepts are often used, consisting of several countershafts (partial shafts). The torque is transmitted from the input shaft to the countershafts and then to the differential (Figure 23.23).

There are many modern approaches to optimize the gear design and gear shift concepts [26–29].

23.5.3.2 Automated Manual Transmission

AMTs are basically of the same design as MTs, but the driver actions "operating the clutch" and "changing gears" are replaced by automatic operations through electric or hydraulic actuators. This is controlled by an electronic transmission control unit with complex control and communication structure. The driver is therefore relieved of these tasks, and fuel consumption can be reduced through an optimized selection of shift points [30,31].

The AMT is especially used for sports cars due to very short shifting times and high efficiency—the trend, however, is toward DCT instead of AMTs. The primary advantage of the AMT

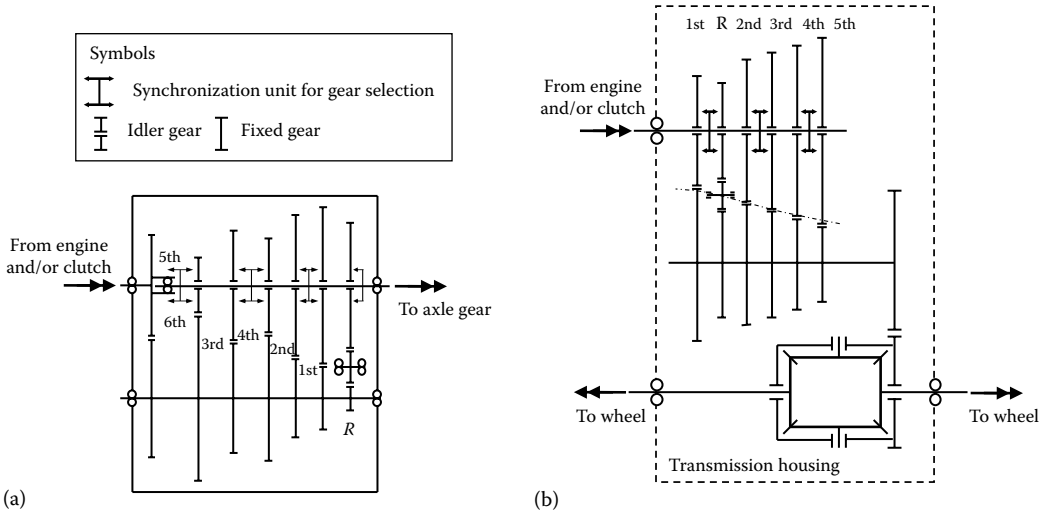

FIGURE 23.22 Layout of an MT for (a) inline use (e.g., standard drive) and transverse use (e.g., front-transverse). In case of (b), axle gear and differential are already integrated.

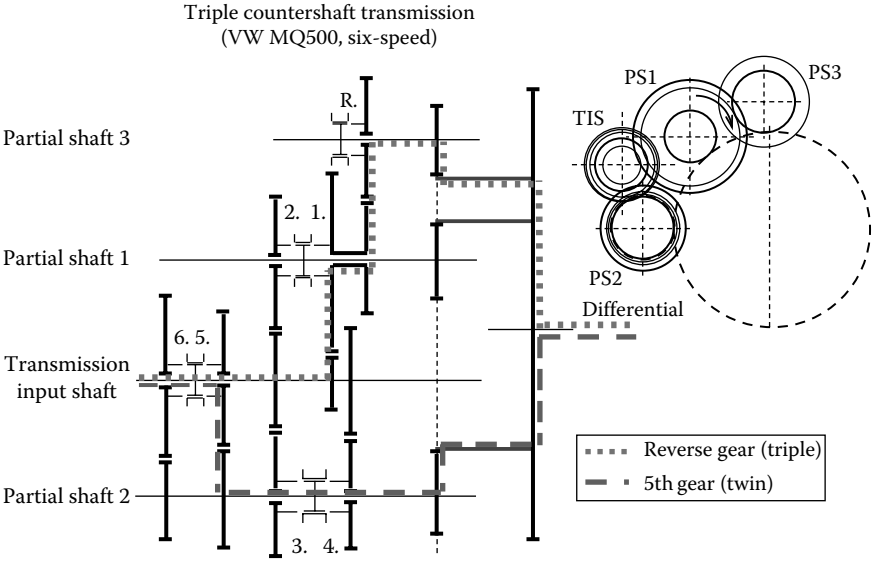

FIGURE 23.23 Six-speed triple-countershaft transmission MQ500 by Volkswagen with several partial shafts that are connected through the big differential gear.

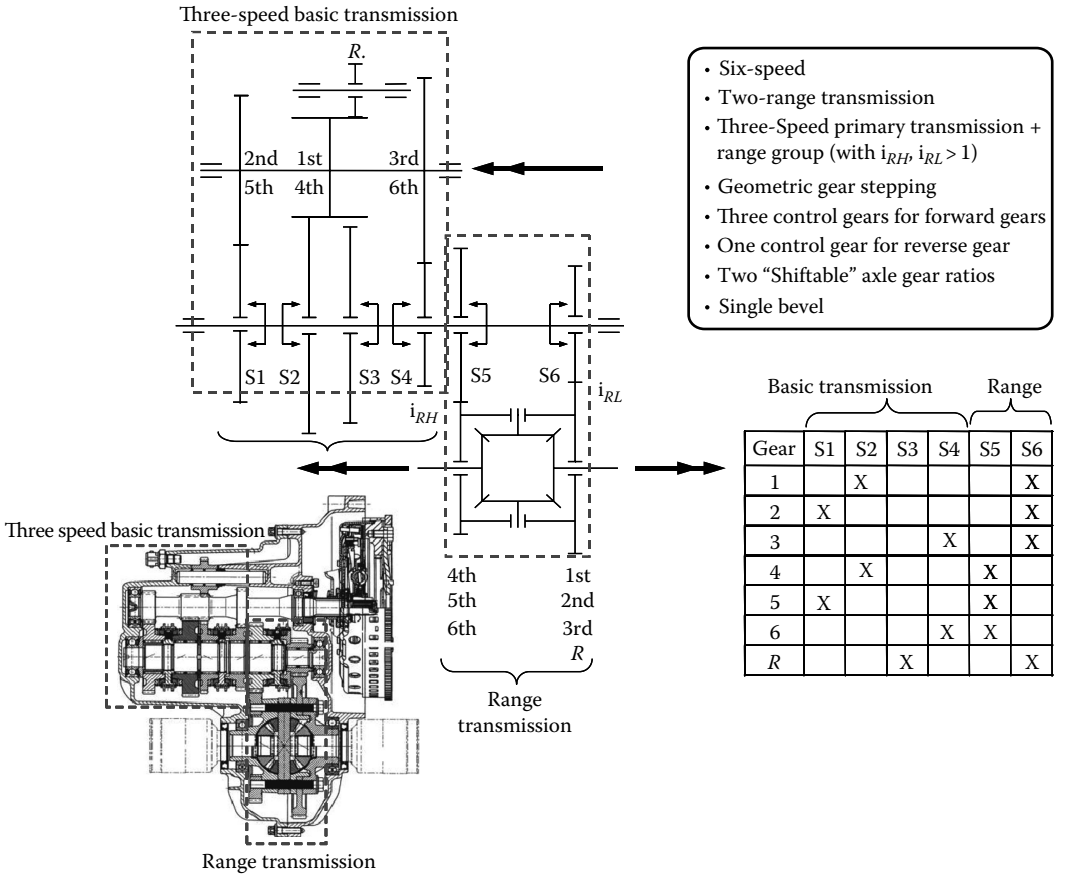
in connection with small vehicles (lower price class) is the cost. It is quite uncomplicated to automate MTs due to the so-called "add-on" design, resulting in a low-cost AMT. Furthermore, the high efficiency of AMTs has to be mentioned, which is higher than that of conventional ATs.

In addition to the add-on approach, there are AMTs that were designed as such. One example is the multigroup transmission of the Smart (Figure 23.24), which could not be shifted manually. The automation allows for a very small transmission design.

23.5.3.3 Continuously Variable Transmission

The transmission ratios of CVTs can be adjusted freely within design limits. The CVTs have an infinite number of gears. This is advantageous in combination with the characteristics of a combustion engine, since operation in an optimal point depending on the driving situation is possible. A constant engine speed can also be achieved through continuous change in transmission ratio if the speed is changed.

The so-called variator is the core of the CVT. It is used to change the transmission ratio between initial and final ratio continuously. The most common mechanical variators include a rotating element at input as well as output that are fixed through a linking element. The contact radii between linking element and input or output element can be varied to adjust the ratio.



Most of the standard CVTs are so-called belt drive transmissions (Figure 23.25). A chain or belt is used as a linking element between two conical disks at the input and two at the output. Adjusting the axial distance of the pairs of disks changes the rotation radii of the belt or chain, which define the ratio.

The advantages of free ratio selection, however, are often compensated by a comparatively high energy input to generate the clamping force of the variator despite having made progress. Furthermore, these designs have not been very successful at least in European markets due to the unusual engine behavior of vehicles with CVTs.

Extended details are found in Refs. [32,33].

23.5.3.4 Double-Clutch Transmission

DCTs are designed as spur gear transmissions, similar to MTs. The difference is that there are two clutches at the transmission input. The transmission is divided into two partial transmissions: one for the odd (1, 3, 5,…) and one for the even gears (2, 4, 6,…). The partial transmissions are

	Basic transmission				Range	
Gear	S1	S2	S3	S4	S5	S6
1		X				X
2	X					X
3				X		X
4		X			X	
5	X				X	
6				X	X	
R			X			X

FIGURE 23.24 Layout of the AMT by Getrag, used in the Smart. It is a multigroup transmission, that is, two transmissions engage one after the other. Both transmissions are engaged at the same time when shifting from 3 to 4 or from 4 to 3, which would not be possible manually.

connected to the output. One clutch each is responsible for one partial transmission; the clutch for the odd gears as starting clutch is usually larger in diameter. During operation, one clutch is closed, while the other does not transmit torque. To reduce the influence of the rotational irregularities of the combustion engine and the load-alteration effect, the clutch is usually operated at a very low slip.

The advantage of this transmission design compared to MT or AMT designs is the fact that gears can be changed without interruption of traction because the torque is transferred from one clutch to the other during shifting (power shifting or clutch-to-clutch shifting). The following gear is preselected in the unloaded partial transmission, so the shifting times are short. The clutches are usually controlled hydraulically by a complex mechatronic control unit. DCTs for higher torques are equipped with wet multidisk clutches with oil cooling, whereas smaller DCT designs aiming for efficiency have dry clutches. Figure 23.26 shows the schematic diagram of a seven-speed DCT for front transverse installations with dry clutches.

A more detailed example is shown in Section 23.6.3.4. Extended details are found in Refs. [34–37].

23.5.3.5 Automatic Transmission

ATs are usually based on planetary transmissions with various combinations of gearsets and a hydrodynamic torque converter as starting device. A simple planetary transmission consists of a

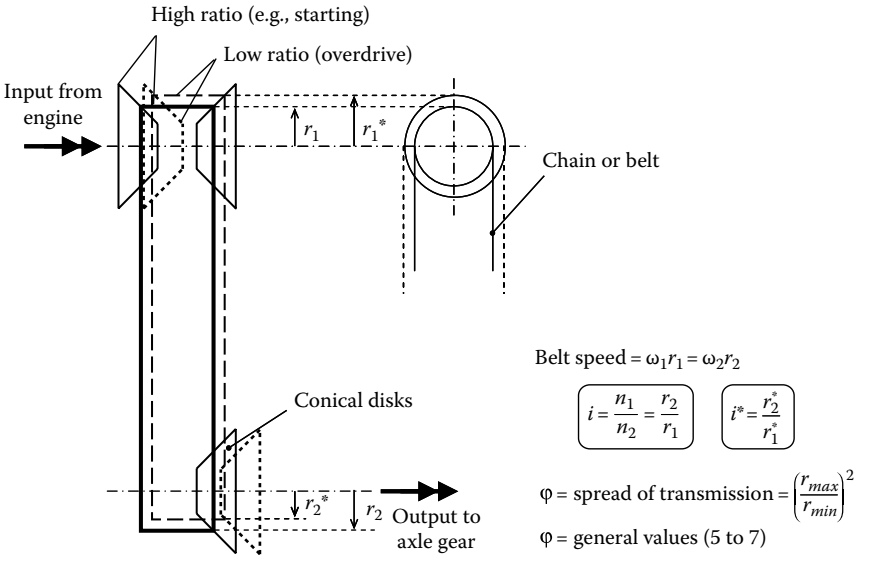


FIGURE 23.25 Function and ratio adjustment by means of a belt drive transmission. Through specific axial displacement of the conical disks, the rotation radii of the belt or chain at input and output are varied, resulting in a change in the ratio of the variator.

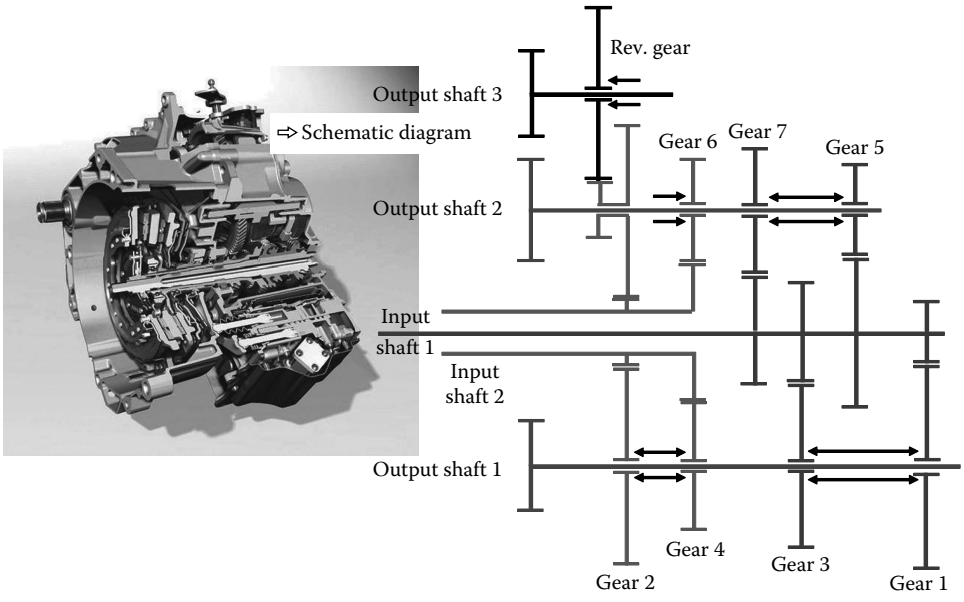

FIGURE 23.26 Layout of the seven-speed DCT DQ200 for front transverse installations by Volkswagen with dry double clutches. Both input shafts have one clutch and are responsible for either odd or even gears. The power flows from the respective input shaft to one of the output shafts and on to the axle gear with integrated differential. The synchronization units (double-headed arrows) are arranged in such a way that more than one gear step lies between the pairs of gears that are controlled by one synchronization unit. Therefore, gears can always be preselected for a gear change of one gear step (up- and downshifts).

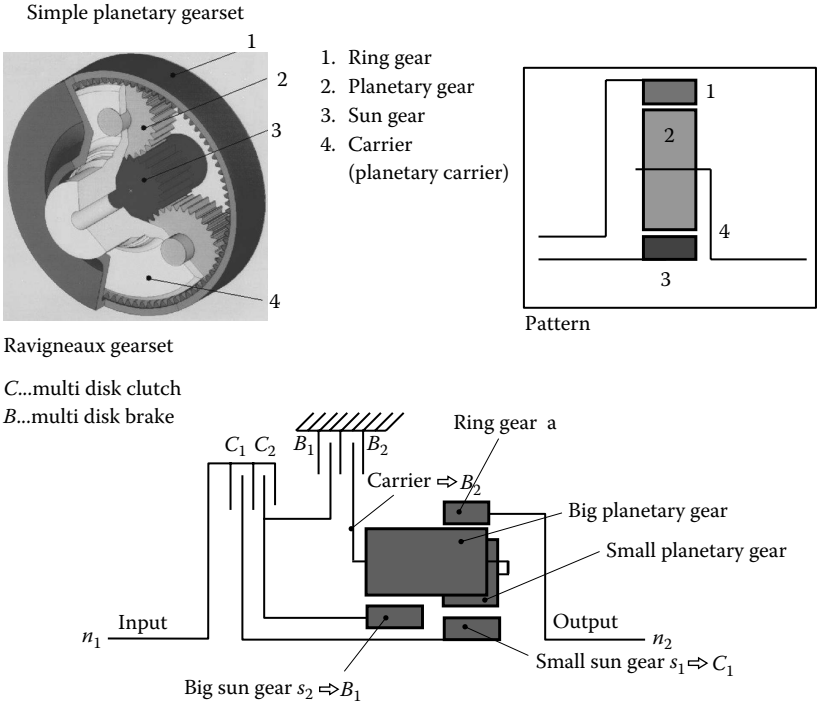

FIGURE 23.27 Structure of a simple planetary gearset and a Ravigneaux gearset. The Ravigneaux gearset consists of a simple planetary gearset and a second gearset with the planets meshing the planetary gears instead of the ring gear of the first gearset. The carriers of both gearsets are connected to each other.

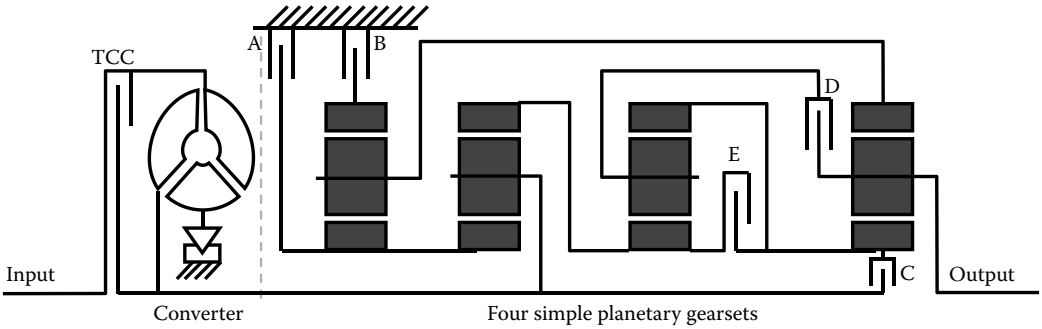
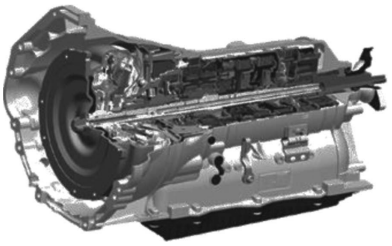
central sun gear, an exterior ring gear, and several planetary gears between the sun and ring gears. The axes of the planetary gears are connected by a carrier (Figure 23.27). Sun gear, ring gear, and carrier are each connected to a shaft through which power can be transmitted or with which the respective component can be held to the transmission casing. All shafts are arranged coaxially. Different ratios can be achieved depending on the respective input and output shaft or which shaft is fixed. Most of the ratios, however, are not suitable for use in vehicles. For this reason, different gearsets were developed that allow for better transmission ratios. This, for instance, includes the Ravigneaux gearset represented in Figure 23.27.



There are usually several gearsets in modern ATs. Their shafts can be connected by clutches or held by brakes. Depending on which of these so-called shift elements is activated (i.e., transmits torque), different ratios are possible. In this way, up to eight forward gears are available in modern transmissions. The power flow is partially split in a complicated way, whereby the gear system can be used optimally and high power density can be obtained. Figure 23.28 exemplifies the layout of an eight-speed AT.



Wet multidisk clutches and brakes with oil cooling are installed as shift elements to change gears, like in DCTs as overlapping shifting. Thus, ATs also allow shifting without interruption of traction force. Shifting is controlled mechatronically, again like in DCTs.

Extended details are found in Refs. [38–40].

23.5.4 Drive Shafts

Most automobile applications comprise a longitudinal shaft to deliver power from the engine or transmission to the other end of the vehicle before it is transmitted to the wheels. A pair of short drive shafts commonly is used to transfer the power from a differential, the transmission, or the transaxle to the wheels. All drive shafts are important elasticities in the driveline and are therefore

responsible for the natural dynamic behavior concerning torsional vibrations. They are also sensitive to NVH effects and influence the "dynamic and acoustical quality" of the total system [41].

23.5.4.1 Rear-Wheel Drive and Front-Wheel Drive

Inside a front-engined, rear-wheel drive (RWD) vehicle, a long drive shaft is required to transmit the power to the wheels. Two applications dominate

- The torque tube with a single universal joint
- The Hotchkiss drive with two or more joints

Most of these vehicles have a clutch and gearbox (or transmission) mounted directly onto the engine's output shaft with a drive shaft leading into a final drive inside the rear axle.

The drive shaft connecting the gearbox to a rear differential is called a propeller shaft, or propshaft. A propshaft assembly contains of the propeller shaft, a slip joint, and one or more universal joints. Where the engine and axles are separated from each other, as on a four-wheel drive (4WD) and inside RWD vehicles, it is the propeller shaft that transmits the drive force from the engine to the axles.

A drive shaft connecting a rear differential to a rear wheel may be called a half shaft. The name derives from the fact that two such shafts are required to form one rear axle.

Several different types of drive shafts are used in the automotive industry:

- One-piece drive shaft
- Two-piece drive shaft
- Slip-in-tube drive shaft

Further details are found in Ref. [42].

23.5.4.2 Four-Wheel Drive and All-Wheel Drive

These two applications evolved from the front-engine RWD layout. A new type of transmission called the "transfer box" is placed between the transmission and the final drives inside both axles. This action does split the drive into the two axles and may also include reduction gears, a dog clutch, or differential. At least two drive shafts are used, one from the transfer box to each axle. In some larger vehicles, the transfer box is centrally mounted and driven directly by a short drive shaft.

Modern light cars with all-wheel drive (AWD) may use a system that more closely matches a front-wheel drive (FWD) layout. The transmission and final drive for the front axle are combined inside one housing mounted at the side of the engine, and a single drive shaft connects the rear axle.

A more detailed example is shown in Section 23.6.1 (Figure 23.31) and in Ref. [43].

23.5.4.3 Cardan (Universal) Shaft

In case of drivelines with power transmission that is parallel shifted or has an angular offset, Cardan (universal) joints are usually used. Especially inside the automotive industry, Cardan joints are common, since the spatial location of the driven and non driven end is variable due to length compensation of the Cardan shaft. Nevertheless, it must be regarded that Cardan joints can also be the source of excitations, which can lead to resonance-like amplifications (load peaks) inside the driveline. This excitation is due to the nonuniform behavior that can be described by a π-periodic (mostly sinusoidal shape) change of the ratio.

The equations for the calculation of the momentums of universal shafts can be taken from the technical literature [44].

Usually, two "ratios" (meaning the transformation of the degree of imbalance between two joints and the interposed shaft), two spring–damper elements, and one mass moment of inertia are considered, and some principal parameters are required for the calculation of the excitation mechanism (apart from the usual inertias, stiffnesses, and dampings) as shown in Figure 23.29.

23.5.5 Differential Gear

A differential is a device, usually but not necessarily consisting of gears, capable of transmitting torque and rotation through three shafts, almost always used in one of the two possible directions (ways). In one way it receives one input and provides two outputs (this is found in most automotive applications). In the other way it combines two inputs to create one output, which is the sum, difference, or mean of the two inputs.

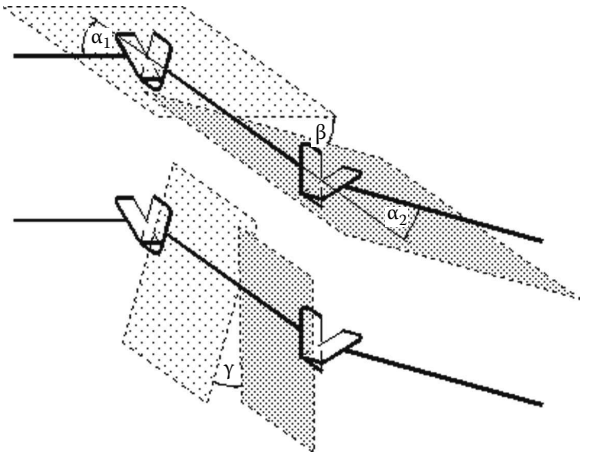

FIGURE 23.29 Angle definition inside the Cardan shaft, where α_1, α_2 = tilt angles at both connectors; β and γ = level angles (angular difference between two fork levels).

Inside automobiles and other wheeled vehicles, the differential allows each of the driving road wheels to rotate at different speeds, while for most vehicles supplying equal torque to each of them.

The purpose of the differential can briefly be described as follows. The wheels of a vehicle rotate at different speeds, especially when turning corners. The differential is designed to drive a pair of wheels with equal force while allowing them to rotate at different speeds. Inside vehicles without a differential, such as karts, both driving wheels are forced to rotate at the same speed, usually on a common axle driven by a simple chain-drive mechanism. When cornering, the inner wheel needs to travel a shorter distance than the outer wheel, so with no differential, the result is the inner wheel spinning and/or the outer wheel dragging, and this leads to a difficult and unpredictable handling, damage of tires, and possible failures of the complete drivetrain.

The superimposition of lateral and torsional vibrations sometimes occurs in differential gears in connection with the dynamic behaviors of the adjacent input and output shaft sections. Thus, such subsystems come up with typical dynamic effects that can only be solved in superimposed vibration models [45].

Extended details of modern differential gear concepts are found in Refs. [46,47].

23.6 SIMULATION OF THE DYNAMIC DRIVELINE BEHAVIOR: EXAMPLES

A quantitative statement concerning the current driveline excitation and system response (also considering nonlinear and transient effects) can only be made by the help of a "simulation in the time domain." A "steady-state simulation" (simulation in the frequency domain) is helpful in case of linear systems excited by harmonic excitation torques only; in this case the maximum amplitudes of the response functions (like torques) are computed for every speed step. As most of the effects in a vehicle driveline are nonlinear and also time transient (e.g., gear engagements), the applied simulation method is based on time-domain methods [9,10].

23.6.1 Drivelines: Studying Major Dynamic Effects in a Vehicle

Before starting the analysis of dynamics and NVH effects in drivelines in more details, let us study the sources of noise and vibrations that occur in a driveline.

Usually a driveline, excited by the typical fluctuations due to the reciprocating engine, consists of the flywheel (single- or twin-mass flywheel), the clutch, the manual or AT including all shafts, the differential gear with the side shafts, wheels, and tires. There are different drive concepts like

- FWD
- RWD
- AWD or 4WD

Figure 23.30 shows the typical drive elements of a RWD passenger car powertrain with the corresponding NVH phenomena that might occur [17,48].

If we consider truck powertrains (4WD or AWD), we observe similar NVH effects as presented in Figure 23.31 [48].

The numbers in Figure 23.31 refer to typical NVH effects (NVH phenomena) as presented in Table 23.2 (including the characteristic frequencies that are usually observed due to the mentioned effects). In the table, further references are mentioned referring to a more detailed description of NVH effects.

It is a must for the R&D engineers to design the vehicle driveline in such a way that the dynamic effects are analyzed a priori before prototypes are built or the first vehicles are tested in detail. Thus, it is crucial to be aware of the characteristics of the powertrain and driveline concepts concerning the state-of-the-art vehicles but also with reference to future vehicle design. The transmission concept is one of the key concepts of a vehicle powertrain. Usually, the transmission

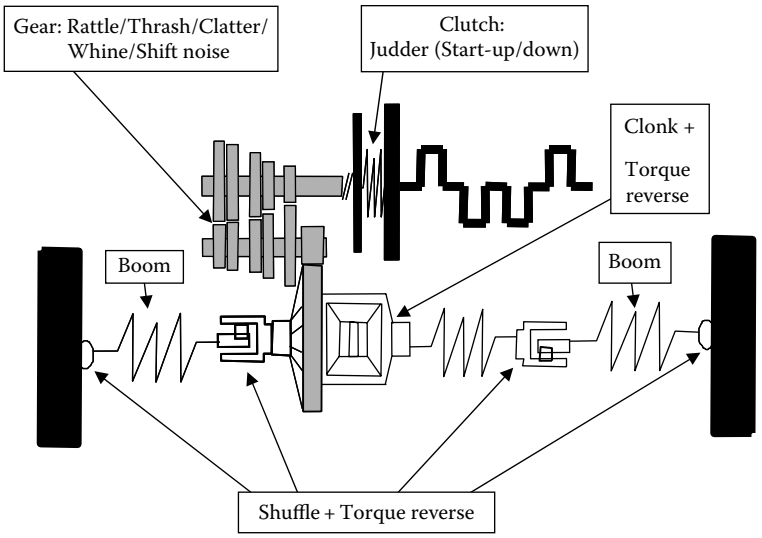

FIGURE 23.30 Typical NVH phenomena in a passenger car powertrain (FWD).

design has to be combined with the development of clutch systems or multi-mass flywheel systems including the damper design.

Furthermore, MTs lose importance in the global market. Typically, there are NVH problems in driveline configurations with manual MTs. Therefore, the development and NVH optimization of ATs become more and more significant. The customer attributes related to existing design concepts of various ATs are visualized in Figure 23.32 [57]. Obviously, no concept really fulfills all attributes in an optimum way. The customer attributes tend to a positive rating when considering a more modern design concept like higher numbers of gears in AT, or new concepts like DCT and CVT (cf. Section 23.5.3). However, concerning the dynamics, we have to reckon with new effects like self-excitations in the twin clutch due to negative friction gradients depending on the slip in case of a DCT or rubber band effects in case of a CVT. That is why modern transmission concepts require a very intense a priori dynamic analysis to find the best NVH rating. Apart from the dynamic effects, the driveline concept always has to meet all modern fuel economy requirements depending on the different classes of vehicles including best performance and efficiency. In most of the cases, the R&D engineer has to cope with typical target conflicts—and it is up to him to solve these system problems using modern computer simulation technologies, high-quality models, and testing results [58].

23.6.2 Nonlinear Behavior of Drivelines

Drivelines imply the interconnection of system elements with nonlinear effects as found in the clutch or two-mass flywheel (DMF = dual/two-mass flywheel), or during the synchronizing process, or as backlash in the total drive system (gear stages, transmission, and shafts), or as slip-dependent wheel–tire–road contact. Some typical characteristics are summarized in Figure 23.33. That is why dynamic effects dedicated to specific drive elements are often only understandable when the overall system behavior of all connected drive elements is considered.

23.6.2.1 Introducing a Simplified Calculation to Evaluate Gear Rattling

Gear rattling is a nonlinear effect that can considerably impair the inner room noise comfort of vehicles. For the optimization of this "NVH" phenomenon (cf. Section 23.6.1), the whole driveline must be regarded, because gear rattling is excited by external forces due to the engine torque fluctuations, while the rattle noise occurs inside of the gearbox due to the backlash in unloaded gear stages that are

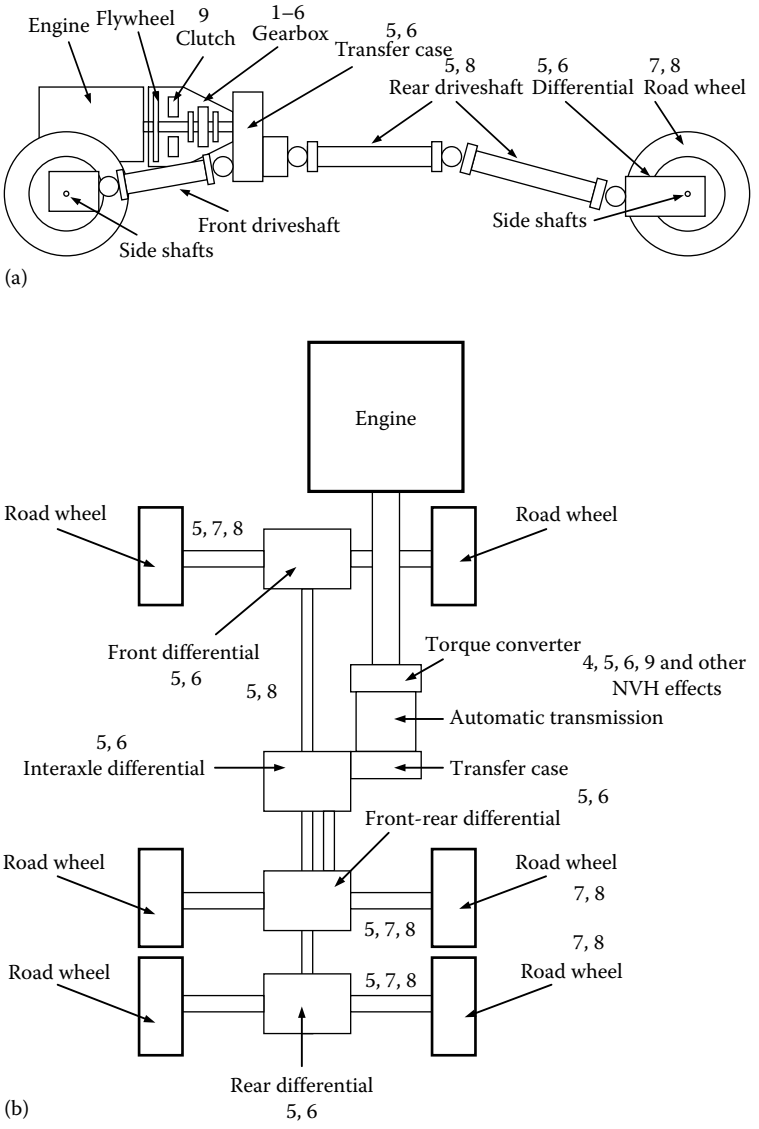

FIGURE 23.31 Typical NVH phenomena in a truck powertrain (4WD/AWD). (a) With an MT (4 × 4 drive) and (b) with an AT (6 × 6 drive).

not in the torque path of the transmission train. This means that a "gear problem" is not a localized problem of the gear but becomes a problem of the total drive system configuration. As a degree for the audible rattle noises, it is recommended to use minimized models first before starting with comprehensive simulation studies. Such models may be evaluated by the introduction of a so-called rattling factor [59], which allows the comparison of various gear design concepts in a very early R&D step.

Rattle vibrations originate inside toothing areas and are transported via gear shafts and bearings to the bearing housing and further over the vehicle body to the chassis. In order to compare the theoretical model with the acoustic measurements, a simplified noise model is used assuming that the sound power due to rattling is proportional to the power loss, which occurs due to shocks inside the toothing area [59]. If the loss energy is added over a time period and applies it to this time period, you receive the lost energy. The most significant influence on rattling noises is presented in Figure 23.34. It is obvious that the external excitation has the major influence compared to the backlash within the gear stages.

TABLE 23.2
NVH Effects and the Corresponding Frequency Range

Effect No.	NVH Phenomena	Typical Frequency Bandwidth
1	***"Rattling"/"Thrashing"*** [49–51]	Excitation **~20–120 Hz**
	During acceleration or coasting	Noise **~500–3000 Hz**
2	***"Clattering"/"Chattering"*** [52]	**~8–20 Hz**
	e.g., in idle position	Also higher frequencies due to noise
3	***"Clashing"***	**~25–80 Hz, 300–600 Hz, 1000–2000 Hz**
4	***"Gear Shift Noise"***	**~25–80 Hz, 300–600 Hz, 1000–2000 Hz**
5	***"Clonk"/"Clunk"*** [53,54]	**~300–600 Hz, 1000–2000 Hz**
	"Torque Reverse"/"Load Change"	**~1–10 Hz, 50–150 Hz, 1000–2000 Hz**
6	***"Gear Whining"*** [55]	**~500–4000 Hz**
7	***"Shuffle"/"Tip-in Back-out"***	**~1–10 Hz**
	Also known as "Bonanza" effect	
8	***"Boom"***	**~20–50 Hz, 100–250 Hz**
9	***"Judder"/"Shudder"*** [56]	**~10–90 Hz**
	Slip + friction effects depending on the coupling design	

The effect numbers refer to Figure 23.31.

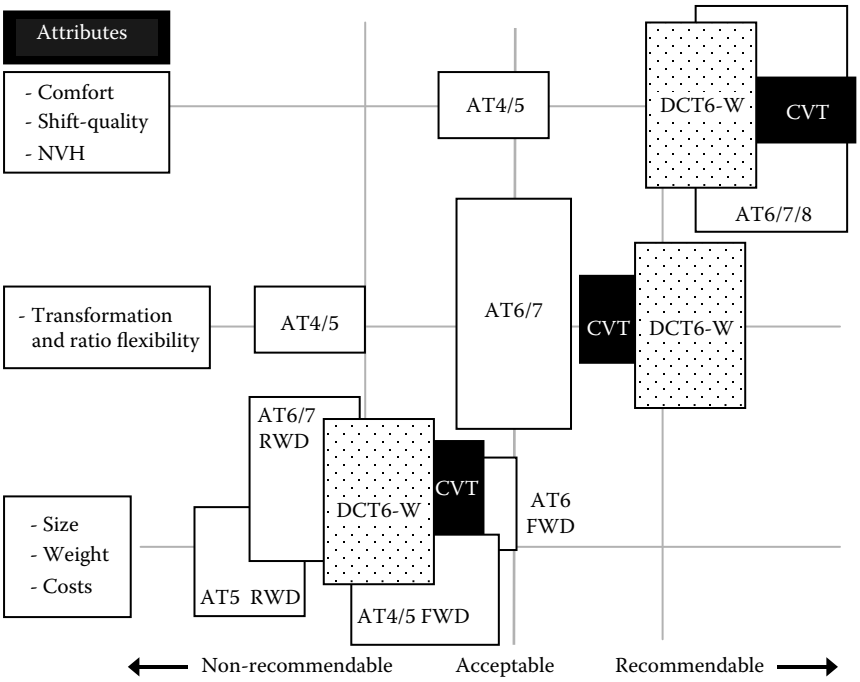

FIGURE 23.32 Customer attributes concerning existing AT concepts. (AT with a torque converter, DCT [W = wet clutch], CVT, and 4/5/6/7/8 = number of gears).

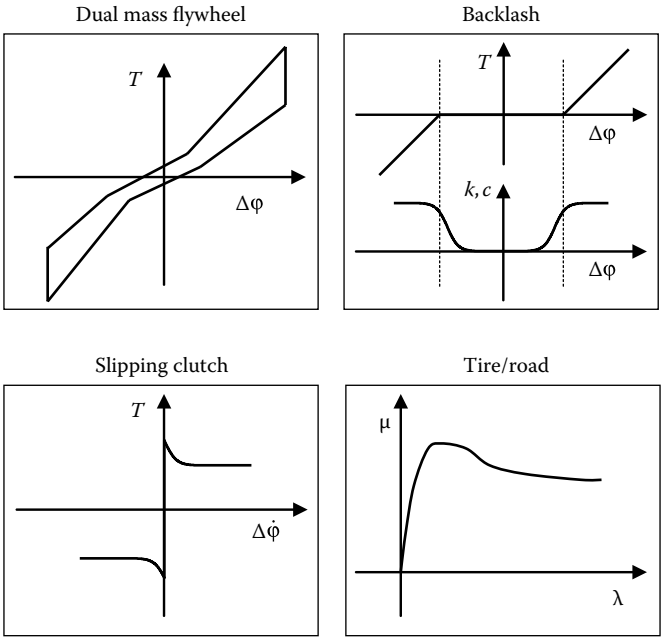

FIGURE 23.33 Examples of nonlinear effects inside a driveline.

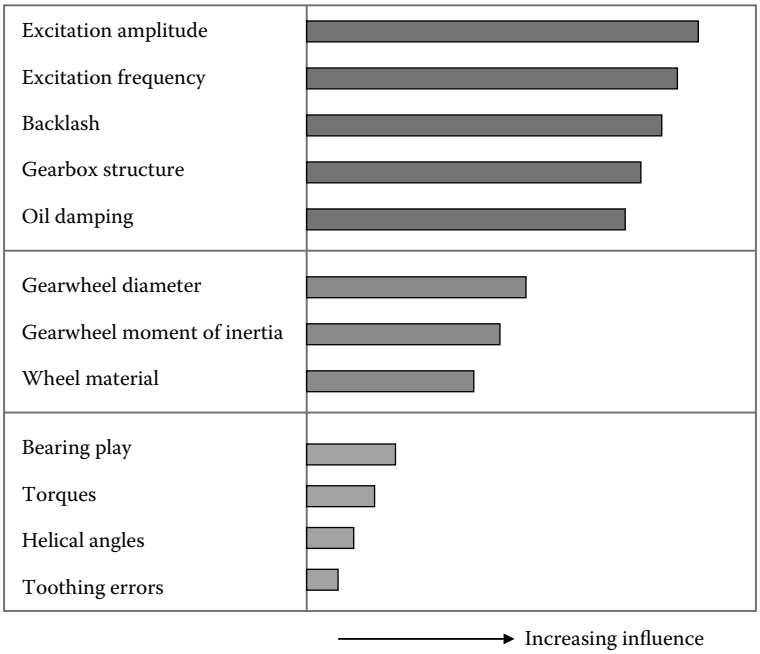

FIGURE 23.34 Influence of rattling effects depending on typical parameters. (From Küçükay, F., Berechnung und Optimierung der Rasselschwingungen bei Schaltgetrieben, in: *Berechnung im Automobilbau*, VDI Report No. 699, Düsseldorf, Germany, pp. 593–630, 1988.)

The calculation of the rattling factor R is based on the summation of the impact power over all p loose gear wheels in the total transmission. First, it is recommendable to normalize the input speeds n_{ej} of all loose "driving" gear wheels with the radius r_e (index = j) to the input speed n_{e1}. Taking r for the radius and J for the inertia of the "driven" loose gear wheel, we get the rattling number R_z as follows:

$$i_j = \frac{n_{e1}}{n_{ej}} \tag{23.12}$$

$$R_z = \sum_{j=1}^{p} J_j \frac{r_{ej}}{r_j^2} \frac{1}{i_j} \tag{23.13}$$

With the help of R_z, gearboxes with different structures on the one hand but same attributes (like backlash, transmission oil) on the other hand can be compared according to their principal rattle sensitivity. For the comparison, it is useful to choose a reference gearbox, whose rattling number in idle state R_{z0} is used as reference number. If the rattling number R_z is now normalized with R_{z0}, we get the dimensionless rattling factor R:

$$R = \frac{\sum_{j=1}^{p} J_j \, (r_{ej}/r_j^2)(1/i_j)}{R_{z0}} \tag{23.14}$$

Further details of this method are described in Ref. [59].

23.6.2.2 Simulation Models to Analyze the Gear Rattle Behavior

Further calculation steps supported by advanced simulation models are required, if the total driveline is optimized concerning the gear rattle effects but also with reference to other NVH effects that may lead to target conflicts when introducing any improvements or innovations. In order to analyze most of the NVH problems, a reduced simulation model can be used as shown in Figure 23.35 before creating comprehensive models [17]. See Section 23.4.1 for more explanations referring to the understanding of the energy presentations of vibration modes.

Based on the reduced model, the important gear branches with the loose gear wheels are integrated in the simulation model (Figure 23.36) in order to calculate some typical NVH rating functions [17,48] such as the following:

- RMS values (RMS = root mean square)of the loose gear wheel accelerations and fluctuations
- Number of impacts and classifying the time signals to identify NVH patterns
- RMS values of the impact energy, also the summation of all impact energies for every gear stage
- Superimposed analysis of the total system also considering statistical parameters and distributions standing for the variation of backlash but also for the clutch/DMF characteristics, further elasticities in the driveline, etc.

Statistical methods [17] are useful to consider

- Data variations
- Data uncertainties
- Data sensitivities
- Tolerances due to the manufacturing process
- Parameter range that is acceptable (and realizable) and can be taken for any further improvements

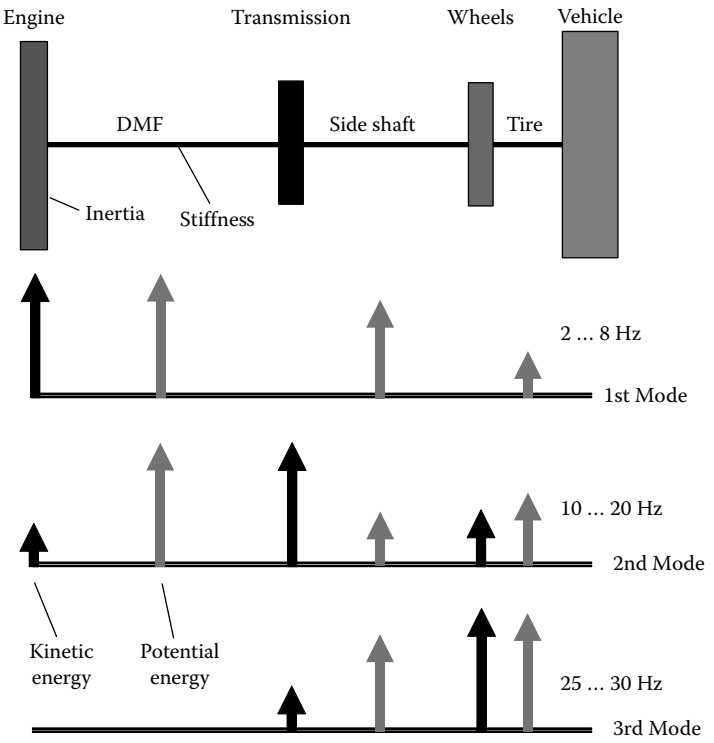

FIGURE 23.35 Reduced torsional vibration model of a driveline to discuss the basics of NVH problems. (From Laschet, A. and Fan, J., Ermittlung der NVH-Sensitivität durch geeignete CAE-Modellierung, in: S. Pischinger and H. Wallentowitz (eds.), *12. Aachener Kolloquium Fahrzeug- und Motorentechnik*, Technical University, Aachen, Germany, pp. 719–733, 2003.)

Therefore, the rating of NVH phenomena should also lead to a statistically based rating function [17]. The input values are no longer fixed parameters but parameter distributions (e.g., Gaussian, rectangular distributions). The sharper the rating distribution, the better the quality repeatability.

23.6.2.3 Advanced Evaluation of Superimposed Nonlinear Characteristics

As NVH effects cannot be rated just by taking single phenomena independently of other effects, it is crucial to create a rating matrix with the most significant characteristics including some aspects on efficiency and costs (Figure 23.37) [60]. Therefore, a more-dimensional rating system is required to investigate all typical target conflicts in order to come to an optimized solution. For this kind of computation studies, statistical methods are mandatory.

23.6.3 Driveline Modeling and Simulation of the Shifting Behavior

23.6.3.1 Targets and Benefits of Shifting Simulation

In manual gearboxes, each gear stage contains at least one pair of gears with different transmission ratios. Changing gears and implies the engagement disengagement of dog clutches, which positively connect idler gears to the gearbox shafts. The same principle takes place in many automated gearbox types (e.g., in DCTs). The required speed synchronization before engaging the dogs is achieved either by mechanical synchronizers (MT, DCT) or by external means such as the engine or gearbox brakes in heavy-duty vehicle powertrains.

The opening and closing of the dog clutches is the most important part in the shifting process. The quality of these operations has significant influence on the shift quality and comfort. Some aspects are of importance as presented in Table 23.3.

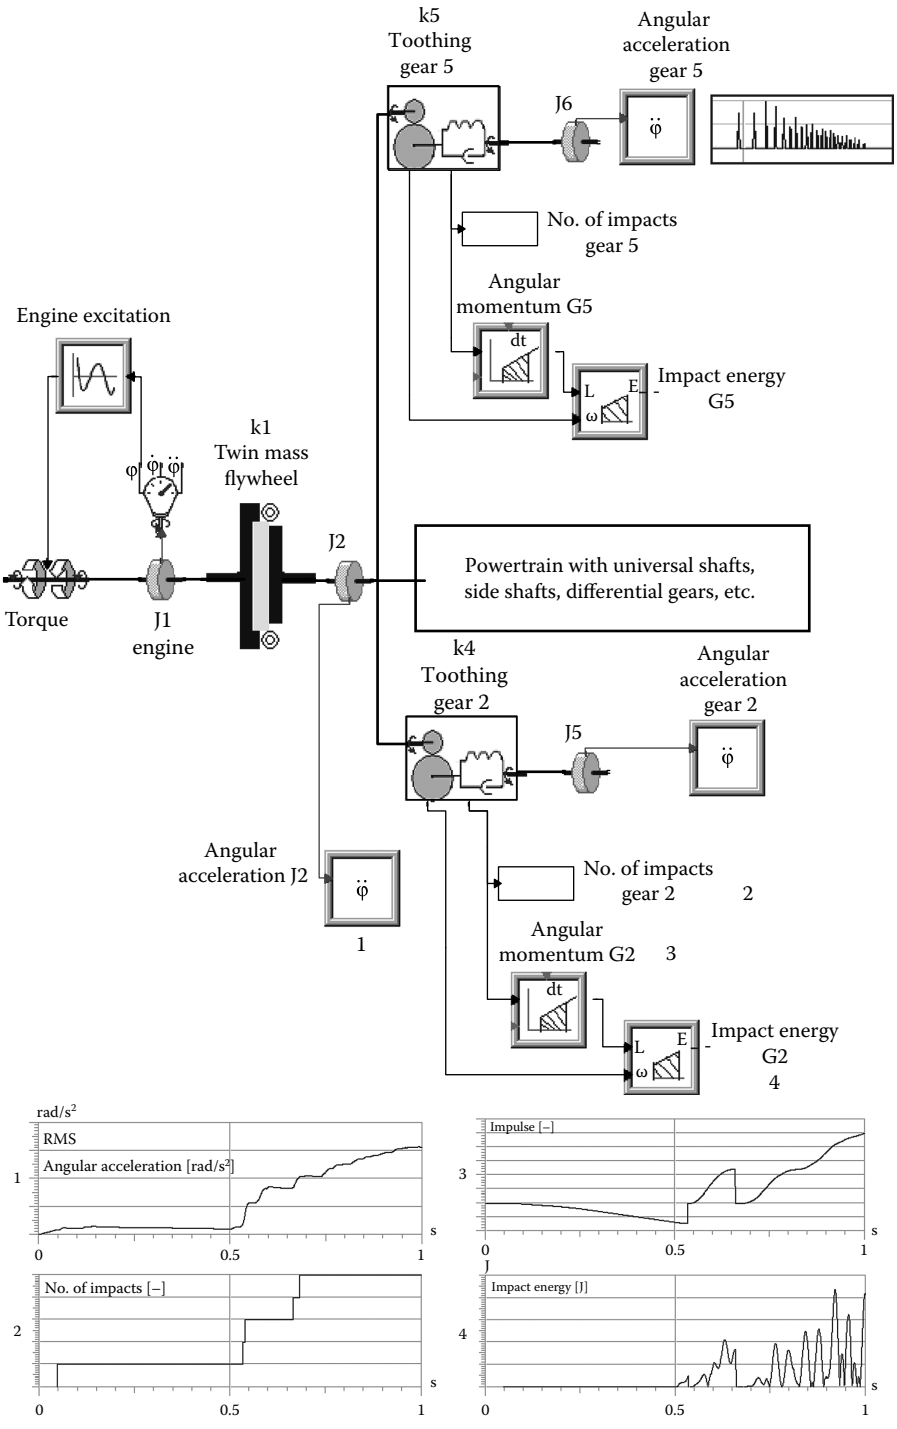

FIGURE 23.36 Simulation model realized by ITI®-SIM 3 to create typical NVH rating functions.

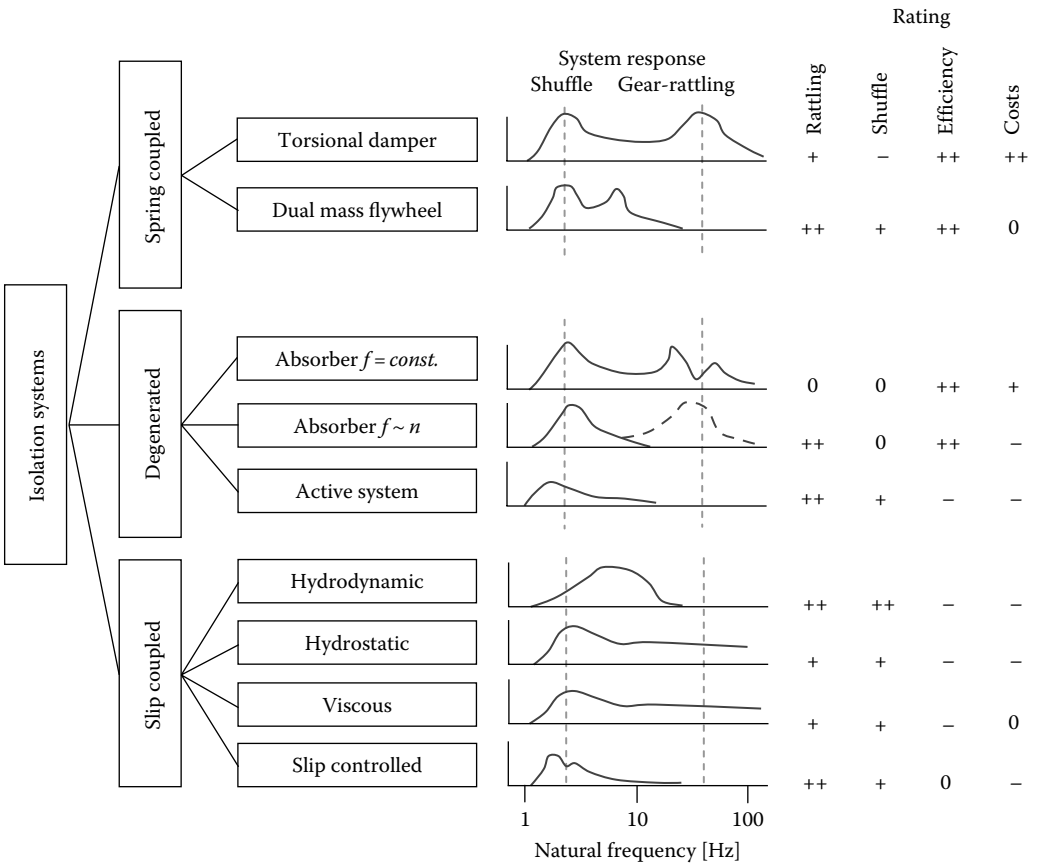

FIGURE 23.37 Rating of vibration damping and isolation in order to improve more than one NVH phenomenon in drivelines. (From Reik, W., Torsionsschwingungsisolation im Antriebsstrang—ein Wertungsversuch, in: *Torsionsschwingungen im Antriebsstrang*, Baden-Baden, LuK, Bühl, Germany, pp. 119–138, 1990.)

TABLE 23.3
Opening and Closing of Dog Clutches: Criteria and Influences

Criterion	Influence On
Speed equality during dog engagement	Clashing, vibration excitation on the powertrain, noise excitation, component wear, comfort perception on the shifting lever
Response forces during dog clutch engagement	Comfort perception by the driver; smoothness and efforts of shifting
Load torques during dog clutch disengagement	Excitation of vibrations on the driveline; disturbance of the subsequent shift process

23.6.3.2 Development of Shifting Simulation Methods

Modeling a powertrain for shifting simulation purposes is a step-by-step procedure, which starts at the innermost component in the shift scenario—the dog clutches and synchronizers. The resulting models are validated against test data acquired from measurements on component test rigs. This ensures the proper behavior of the component and allows tuning of the limited number of not or hardly measurable parameters such as damping or friction characteristics.

In a next step, the component model is included into a larger-scale model, such as a gearbox model, for which the procedure of validation against test data is carried out in the same manner. Finally, a powertrain model is the result of the last stage of this process.

23.6.3.3 Example: Manually Shifted Powertrain

The following example considers the shifting in a manual gearbox. The aim of this simulation task [61] is the optimization of the shift through, in particular for the lower gears. Potential comfort problems such as scratching under low-temperature conditions are of particular interest as well.

The simulation task follows a three-stage outline according to the approach as described earlier:

- Synchronizer modeling and validation
- Gearbox modeling and validation
- Complete powertrain modeling and validation

The final stage of the model development leads to a reproduction of the gearshift behavior as observed on the real vehicle. Once validated, on this model base there is a high certainty that a change of system parameters in the model will affect the simulated shifting behavior in the same way as the shifting behavior observed on the real vehicle.

Figure 23.38 shows a particularly bad shift from the perspective of the moving sliding sleeve. The effect seen here is clashing, which appears for very low oil temperatures and small shift forces. The increased drag torque leads to the formation of a speed difference during the short time interval between the locking teeth giving way and the sleeve reaching the selector teeth. Due to the speed difference, the sleeve is pushed back several times before the teeth engage, which is felt as a typical NVH effect by the driver (so-called scratching or clashing).

23.6.3.4 Example: Dual-Clutch Transmission

Dual-clutch concepts integrated into the driveline design combine a synchronized gearbox with automated shifting and provide the additional benefit of uninterrupted traction, resulting in a symbiosis of efficiency, comfort, and performance.

DCTs have gearboxes with two input shafts, each having its own clutch, two separate countershafts being engaged for even or odd gears, respectively, and one common output shaft (Figure 23.39). When shifting, a gear on one of the countershafts is engaged and the respective clutch is closed. On the other countershaft (with the corresponding clutch open), the next gear can be engaged during normal drive. Once the dog clutch for the new gear became engaged, the torque flow is handed over from one countershaft to the other by opening one and closing the other clutch simultaneously. The comfort of the shift is mainly determined by the way how smoothly the transition between the two gears takes place. General descriptions are also given in Section 23.5.3.4.

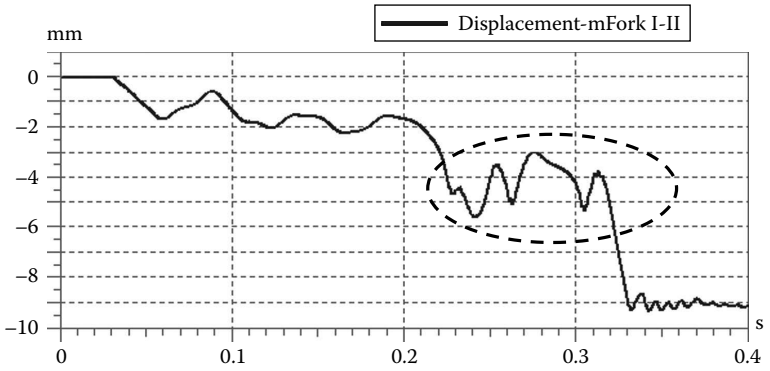

FIGURE 23.38 Clashing in a cold gearbox with low shift forces.

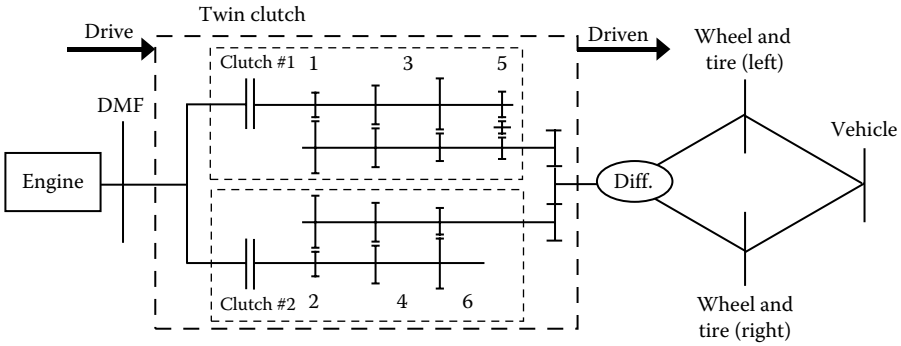

FIGURE 23.39 Example of a FWD driveline with dual-clutch transmission (=DCT).

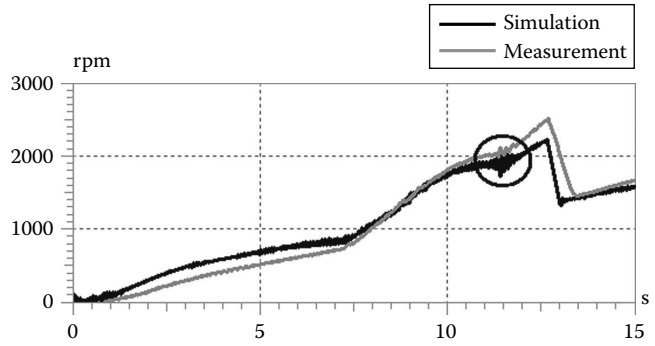

FIGURE 23.40 DCT gearbox input shaft speeds (simulation and measurement).

The example models and results are discussed in more details in Refs. [62,63].

A major analysis issue for shifting comfort in DCTs is the transition between the two branches in the transmission when shifting from one gear to the other. The simulation model is used in order to test the clutch actuation off-line and to evaluate the resulting quality of the gearshift at an early phase of the development cycle.

Figure 23.40 shows a comparison of measured and simulated input shaft speeds of the gearbox. The gear change takes place in the time interval from 10.5 to 12 s. The presented speeds correspond to the input shaft, which is disengaged during the shift. The focus of this analysis is principally on the gearbox vibrations excited during the gear change (marked by a black circle in the figure).

23.7 SUMMARY

The dynamic behavior of drivelines becomes critical when regarding stress, loads, excitations, and above all effects due to NVH. Such dynamic criteria stand for the level of quality and acceptance from the customer side. Therefore, it is crucial to compute the most important and critical dynamic effects in advance using simplified models on the one hand but also more comprehensive simulation methods and software tools on the other hand. Particularly, a practice-oriented rating system is required to evaluate the concepts as early as possible during the R&D process with best computing quality.

In spite of the advanced application of modern simulation technologies, one important connecting link must not be missing: the *engineer* is always the center of the product development chain. Engineerlike thinking and acting remain significant and central essential parts of the complex assessment of technical systems.

ACKNOWLEDGMENTS

The authors wish to thank Mr. Andreas Stöcker from ARLA Maschinentechnik GmbH, Wipperfürth, Germany for his assistance doing the calculations, the detailed analyses, and preparing the graphical presentations. The authors particularly thank Dr. Tobias Kassel from the Institute of Automotive Engineering (Braunschweig University of Technology, Germany) for his hard work, numerous ideas and suggestions in the development of this chapter and in addition also Mr. Gerrit Knabe and Mr. Jan Häfele for numerous technical suggestions and editorial notes. Furthermore the authors like to thank Mr. Andreas Abel from ITI GmbH, Dresden, Germany for his contribution for Section 23.6.3.

24.1 INTRODUCTION

Brakes are the most important safety subsystem of each ground vehicle. As for other subsystems of the vehicle such as engine, suspensions, and tires, brakes are very complex engineering devices. Material science, applied mechanics and thermo-fluid dynamics, manufacturing technology, and other engineering disciplines are all necessary to conceive and manufacture an effective brake system.

Brakes were first invented by the Romans and were applied to carts or wagons (Figure 24.1). Dissipating into heat the kinetic energy was at that time (and still today) the more effective way to stop a vehicle.

In this chapter, an overview of the main brake functions and constructive applications is given. Additionally, brake comfort (noise–vibration–harshness [NVH]) is dealt with in the second part of the chapter.

24.2 BRAKE FUNCTIONS

In a motor vehicle, the brake system has three main functions [1]:

- Reduce speed and, eventually, stop the vehicle (service brake)
- Prevent unwanted acceleration, for instance when driving downhill (retarders)
- Keep the vehicle at standstill (parking brake)

For common vehicles powered by internal combustion engines, the kinetic energy is normally dissipated into heat; this is a very efficient way to produce braking forces [1]. For hybrid or electric vehicles, regenerative braking is obtained by exploiting electric motors [2]. In this chapter, only common dissipative brakes will be dealt with.

On horizontal roads, the energy dissipated during braking is given by the difference between the initial and final kinetic energy:

$$E_d = \frac{1}{2} m \left(v_i^2 - v_f^2 \right) + \frac{1}{2} J_{rot} \left(\omega_i^2 - \omega_f^2 \right) \tag{24.1}$$

where

m is the mass of the vehicle

v_i and v_f are, respectively, the initial and final velocity of the vehicle

J_{rot} is the global rotational inertia of tires, transmission, and engine (for the computation of J_{rot}, both the gear ratio of the gear box and the gear ratio of the final reduction have to be taken into account [3])

ω_i, ω_f are respectively, the initial and final rotational velocities of the wheels of the drive axle (for sake of simplicity, we deal with the case of one single driving axle)

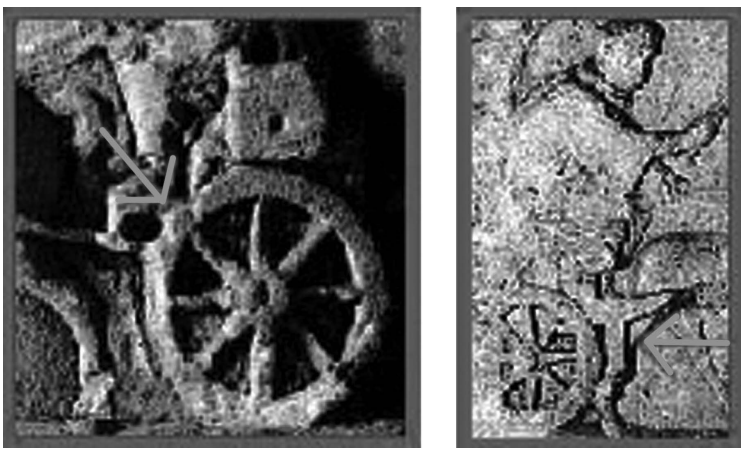

FIGURE 24.1 Ancient Roman carts or wagons with early brakes operated directly by the driver. (Adapted from Weller, J.A., Roman traction systems, www.humanist.de/rome/rts)

Often, the rotational energy is neglected, especially for non-driving axle(s). If other energy dissipation actions are neglected (aerodynamic drag forces, rolling resistance, engine resisting torque), all the kinetic energy must be dissipated by the brake system. In case of sloped roads, the potential energy of the gravitational field must be added to Equation 24.1:

$$E_d = \frac{1}{2} m \left(v_i^2 - v_f^2 \right) + \frac{1}{2} J_{rot} \left(\omega_i^2 - \omega_f^2 \right) - mg(h_f - h_i) \tag{24.2}$$

where

g is the gravitational acceleration

h_f and h_i are the initial and final height of the road

If $h_f > h_i$, the vehicle is braking uphill and part of its initial energy is turned into potential energy, thus reducing the energy dissipated by brakes. The more demanding situation is when $h_f < h_i$, the vehicle is braking downhill and the brake system has to dissipate both the kinetic and the potential energy. When driving downhill at a constant speed, the kinetic energy of the vehicle is constant; thus, the potential energy has to be completely dissipated by the brake system. In this case, retarders are employed [1,3].

The energy dissipated by the brake system is usually converted into heat that has to be evacuated from the brake system. The thermal resistance of the brake system is a crucial issue [1]. Moreover, different thermal behaviors are involved during speed reduction (service brake operation) or during driving downhill (retarder brake operation) [3]. In the first case, a great amount of thermal power is generated for a relatively small time. The thermal capacity of the brake accumulates the heat developed during braking and usually (for normal cars), a not very high-temperature increase occurs. In the second case, an almost constant thermal power is generated during the running of the vehicle at constant speed down a sloped path. The brake system is designed to reach a thermal equilibrium up to the admissible temperature limit of the components, such temperatures are generally much higher than those reached during service brake operation [1,3].

An estimation of the thermal power that the brakes have to dissipate when braking on a horizontal road can be given as follows. Considering an acceleration–braking cycle, the mean thermal power in the cycle can be computed as

$$W_d = \frac{1}{2} \frac{mv^2 + J_{rot}\omega^2}{t_a + t_b} \tag{24.3}$$

where t_a and t_b are the times needed to accelerate the vehicle from standstill to v and to brake from v to standstill, respectively. The mean power is null either when the velocity is null or when the velocity is equal to the maximum speed of the vehicle (in this case, $t_a \to \infty$ as the maximum speed is ideally an asymptotic value). A value of v can be computed for which the mean power reaches a maximum. This value depends on the mass of the vehicle and on its performance (performances of both engine and brakes).

The thermal power when driving downhill can be computed as

$$W_d = mgv \sin(\alpha) \tag{24.4}$$

α being the slope angle of the road. For a given slope angle, the thermal power linearly increases with the velocity. A limit velocity is imposed, at each slope angle, by the thermal dissipation performance of the brake system.

Usually, for light high-performance vehicles, the most critical condition is given by the service brake situation. For heavy commercial vehicles, the downhill situation is the most critical. For these vehicles, the friction brakes are devoted to the service brake and a dedicated subsystem realizing the retarder function is needed. Figure 24.2 shows the thermal power dissipated for level and sloped roads [4,5].

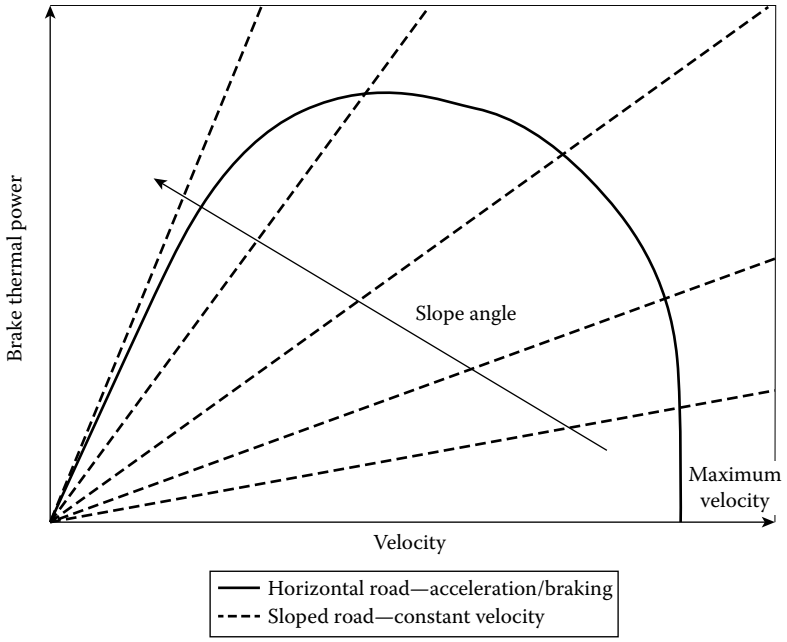

FIGURE 24.2 Brake thermal power dissipated as function of velocity for horizontal road (continuum line) and sloped road (dashed line).

24.3 BRAKING PROCESSES

24.3.1 Stopping Distance: Service Braking

The brake system has the task, especially in emergencies, of stopping the vehicle in the shortest possible distance. The stopping distance, however, does not depend on the braking system alone, but the following factors have to be considered.

Figure 24.3 shows the braking process over time [1,6,7]. At time zero, the driver sees an obstacle. After the reaction time t_r, the driver starts to apply the pedal force in order to brake the vehicle. The reaction time depends on many factors, among which driver attention and age play a very important role. The estimation of the reaction time is a very complex operation; a commonly accepted average value is around 1 s. In the figure, the pedal force is simplified as a linear function of time. The actual shape of the pedal force depends on the ability of the driver. More-skilled drivers are able to apply a steady rising pedal force, while unskilled drivers present strong oscillation in the pedal force.

After the reaction time, some more time has to be considered before vehicle deceleration begins due to the time needed by the braking system to start applying the braking force, that is, clearance taking up. This time is called brake application time (t_a) and is in the order of 0.1–0.2 s for hydraulic braking systems and up to 1 s for pneumatic braking systems [6,7].

In this first part of the maneuver (area 1 in the figure), with a total duration of $t_r + t_a$, the deceleration can be considered null; only a small deceleration could be present due to aerodynamic and motor drag but can be neglected [6]. The speed of the vehicle is constant and equal to the speed before the driver has seen the obstacle. The distance traveled in this phase can be of the order (if not greater) of the distance needed for the actual braking of the vehicle.

In phase 2 of Figure 24.3, the vehicle deceleration grows according to a law depending on the application of the pedal force and on the dynamics of the braking system. The maximum deceleration is reached, either because of tire locking or because the pedal force is kept constant. In this phase, vehicle speed begins to reduce; the deceleration can be considered a linear function of

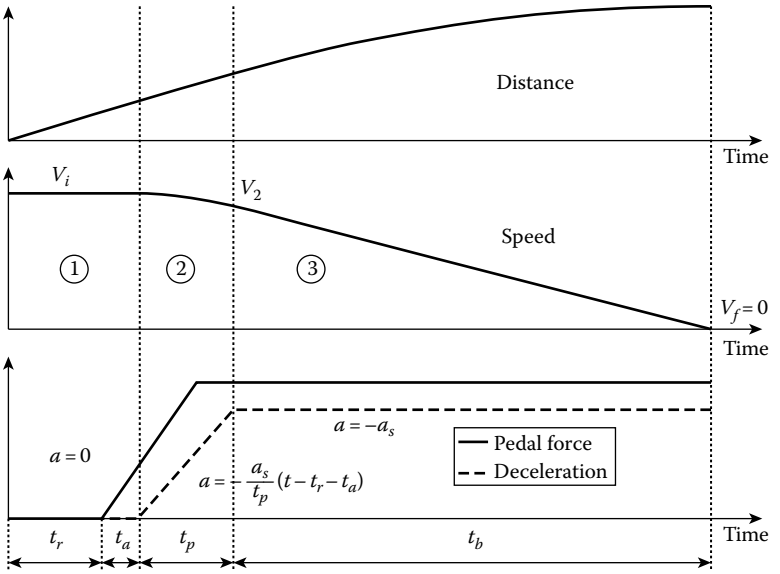

FIGURE 24.3 The braking process over time.

the time up to the stabilized value of deceleration a_s. At a_s (phase 3), the speed decreases linearly with time till the vehicle stops.

The total stopping distance is given by the sum of the distance traveled in the three different phases:

Phase 1: constant velocity motion, the traveled distance s_1 can be computed as

$$s_1 = V_i \cdot (t_r + t_a) \tag{24.5}$$

where V_i is the initial velocity of the vehicle. The velocity at the end of this phase is still V_i.

Phase 2: motion with linear rising deceleration. Considering a linear rising deceleration between zero and the stabilized value a_s in the time t_p, the traveled distance and the velocity variation in this phase can be estimated as

$$\begin{cases} a = -\dfrac{a_s}{t_p} \cdot t \\ V_2 = V_i - \displaystyle\int_0^{t_p} \frac{a_s}{t_p} t dt = V_i - \frac{1}{2} a_s t_p \\ s_2 = V_i \cdot t_p - \displaystyle\int_0^{t_p} \frac{1}{2} \frac{a_s}{t_p} t^2 dt = V_i \cdot t_p - \frac{1}{6} a_s t_p^2 \end{cases} \tag{24.6}$$

Phase 3: motion with constant deceleration, the traveled distance and the velocity are

$$\begin{cases} a = -a_s \\ V_f = V_2 - a_s t_b \\ s_3 = V_2 \cdot t_s - \dfrac{1}{2} a_s t_b^2 \end{cases} \tag{24.7}$$

where t_b is the time to stop the vehicle and can be computed by imposing $V_f = 0$. The resulting traveled distance is

$$s_3 = \frac{1}{2}\frac{V_2^2}{a_s} \tag{24.8}$$

when $t_b = V_2/a_s$.

By replacing the second of Equation 24.7 into Equation 24.8 and summing all of the three contribution, the total stopping distance reads

$$s = s_1 + s_2 + s_3 = V_i\left(t_r + t_a + \frac{t_p}{2}\right) + \frac{1}{2}\frac{V_i^2}{a_s} - \frac{1}{24}a_s t_p^2 \tag{24.9}$$

The last term of Equation 24.9 is usually small with respect to the other terms. Referring to a braking maneuver from 100 km/h, with $t_r = 1$ s, $t_a = 0.2$ s, $t_p = 0.3$ s, and $a_s = 8$ m/s^2, the total braking distance s is 85.3 m and the last term of the equation is less than 0.1 m.

A simpler expression for the estimation of the stopping distance can be obtained by considering only a phase with no deceleration and a phase with constant deceleration. To consider the time needed for the brake system to rise the braking force, a rising time to reach the 75% of the braking torque can be added to the reaction time. In this case, the stopping distance can be estimated as

$$s = \frac{1}{2}\cdot\frac{V_i^2}{a_s} + V_i \cdot t_{r_tot} \tag{24.10}$$

where

V_i is the initial velocity before braking
a_s is the constant deceleration during braking
t_{r_tot} is the total reaction time accounting for driver reaction time, brake activation time, and rising time

In case tire–road friction is fully exploited, the deceleration can be considered as $a_s = \mu g$, μ being the tire–road friction coefficient and g the gravity. Equation 24.10 can be rewritten as a function of the tire–road friction coefficient as

$$s = \frac{1}{2}\cdot\frac{V^2}{\mu g} + V \cdot t_{r_tot} \tag{24.11}$$

In Figure 24.4a, the respective total braking distances for decelerations on a high-friction road ($\mu = 0.8$) or on a low-friction road ($\mu = 0.4$) are reported as a function of the initial speed (ranging from 20 to 200 km/h) along with the distance traveled during the total reaction time (considered as 1.5 s). In Figure 24.4b, the percentage of the total braking distance traveled during the total reaction time is depicted for the two cases. In case of relatively small velocities and high road friction, the most part of the braking distance is traveled during the total reaction time, when the driver is not able to make any real action to prevent accidents (for more details on braking distances, see [1,6,8]).

24.3.2 Vehicle at Standstill: Parking Brake

In this section, a vehicle at standstill on a sloped road is considered. The brake system has to apply the braking force necessary to keep still the vehicle. Referring to Figure 24.5, the equilibrium of the vehicle can be written as

$$\begin{cases} mg\cos(\alpha) - F_{zF} - F_{zR} = 0 \\ mg\sin(\alpha) - F_{xF} - F_{xR} = 0 \end{cases} \tag{24.12}$$

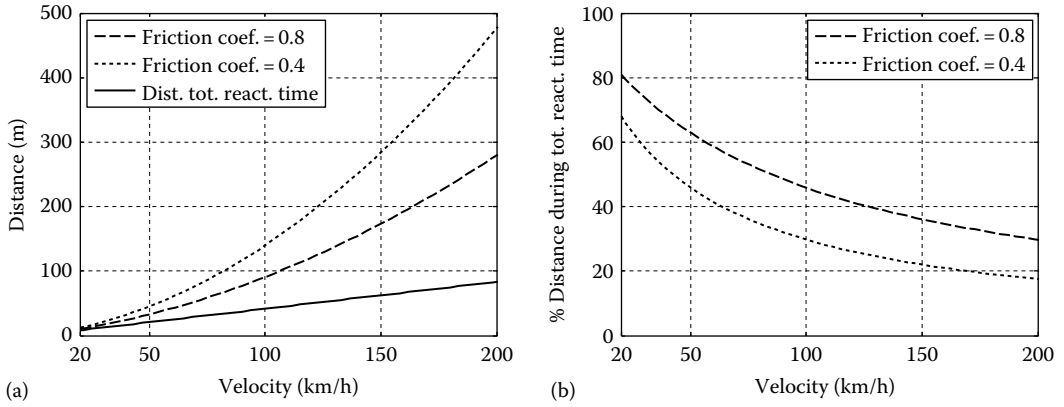

FIGURE 24.4 (a) Total braking distance for a high-friction and a low-friction road and (b) Percentage of the total distance traveled during the total reaction time in case of high-friction and of low-friction road.

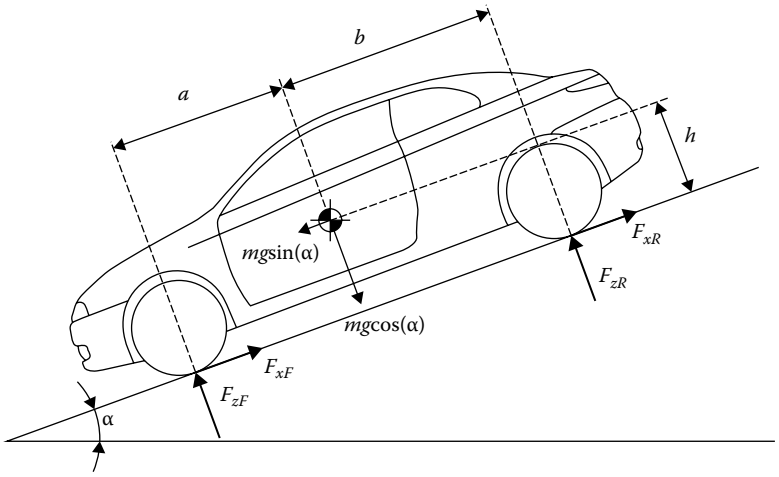

FIGURE 24.5 Braked vehicle standing on a sloped road.

If the tires have all the same friction coefficient μ, the limit condition to prevent sliding of the car along the slope is

$$mg\sin(\alpha) \le F_{xF} + F_{xR} = \mu(F_{zF} + F_{zR}) = \mu(mg\cos(\alpha)) \tag{24.13}$$

and the limit slope angle results

$$\tan(\alpha_{lim}) = \mu \tag{24.14}$$

For slope angles $\alpha > \alpha_{lim}$, the vehicle cannot be hold at standstill but it will slide downhill. In most cases, the parking brake acts on the rear axle only. In this situation, $F_{xF} = 0$ and the limit slope angle can be computed as

$$\begin{cases} mg\cos(\alpha) - F_{zF} - F_{zR} = 0 \\ mg\sin(\alpha) - F_{xR} = 0 \end{cases} \tag{24.15}$$

$$mg\sin(\alpha) \le F_{xR} = \mu F_{zR} = \mu mg\frac{a\cos(\alpha) - h\sin(\alpha)}{a+b} \tag{24.16}$$

And the resulting limit slope angle

$$\tan(\alpha_{lim}) = \mu \frac{a}{a + b + \mu h} \tag{24.17}$$

(For more details on such topic, see [9].)

24.3.3 Straight Braking and Stability

In order to get the best possible performance from a brake system, that is, achieving the shorter stopping distance, all of the available road–tire friction of each tire should be exploited. This means that if all of the tires have the same friction coefficient, the braking torque should be distributed to the tires according to the actual vertical load acting on each tire. Considering a symmetric vehicle, the load on tires on the same axle is the same and the braking torque should be distributed according to the load transfer from the rear axle to the front axle during braking. If the brake torque rises during braking, one of the following conditions occurs:

- The rear tires lock first.
- The front tires lock first.

These two situations have very different effects on vehicle stability. A quasi-static simplified analysis of the two scenarios can be carried out as follows [6,10]. Figure 24.6 depicts the two situations of front (left) and rear (right) locked tires. If the rear tires are locked first, the rear tire can react with a force opposite to the sliding velocity vector. If a disturbing lateral force is applied to the center of gravity of the vehicle, a slip angle appears between the longitudinal axis of the vehicle and the direction in which the center of gravity is moving. A reacting force can arise only at the front axle, thus generating a yaw moment that increases the slip angle of the vehicle, that is, the longitudinal axis of the vehicle rotates as to increment its angle with respect to the velocity direction. The system of forces is thus diverging and tends to increase the slip angle, which implies a very difficult handling of the vehicle. Only very skilled, and professional, drivers could control a vehicle in such a situation. A normal driver will lose control of the vehicle and very dangerous accidents can happen.

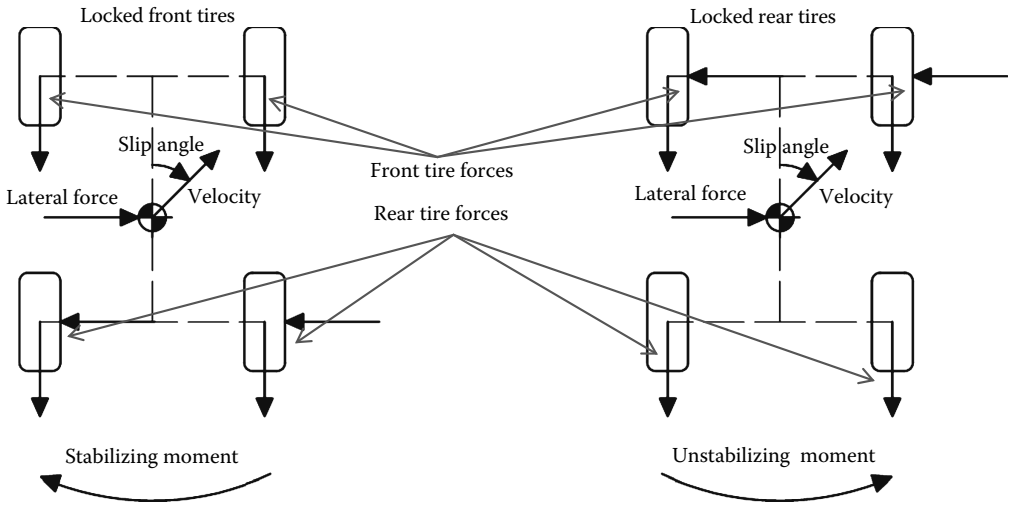

FIGURE 24.6 Vehicle behavior with rear and front wheels locked.

If the front tires lock first, the reaction force appears at the rear axle and the consequent yaw moment aligns the vehicle to the velocity vector of the center of gravity, thus reducing the slip angle of the vehicle. The resulting system of forces is converging and the handling of the vehicle is good.

A deeper understanding of the dynamics of the vehicle when the tire locking is reached can be achieved by considering the so-called *handling diagrams*. The theory leading to the definition and computation of the handling diagrams has been described in Sections 11.4 and Section 27.3, where the most important considerations on vehicle stability have been explained into details. A very important result of such discussions is that oversteering vehicles become unstable for velocities over a certain critical velocity. The instability can occur even on a straight road. The characterization of a vehicle as understeering or oversteering is given according to the understeering gradient and can be defined as (see Equation 11.47 or Equation 26.88)

$$K_{US} = \frac{m(C_R b - C_F a)}{(a+b)C_R C_F} \tag{24.18}$$

where

m is the mass of the vehicle

C_F and C_R are front and rear *cornering* stiffness, respectively

a and b are the dimensions of the vehicle as shown in Figure 24.5

A vehicle is said to be oversteering when $K_{US} > 0$ that implies $C_R b < C_F a$.

When a tire is locked, the lateral force is rather small, but not vanishing; it can be computed as $F_y = \mu F_z sin(\alpha)$ [11]. Figure 24.7 shows the handling diagrams for a vehicle either with all tires rolling or with locked front tires or with locked rear tires. Also, the characteristics of the unlocked axles are much lower than their pure lateral characteristics due to the presence of the braking force in longitudinal direction [11]. Let us consider rolling tires (Figure 24.7a), every vehicle is designed to be understeering. A vehicle with locked front tires (Figure 24.7b) is understeering, while a vehicle with locked rear tires (Figure 24.7c) is oversteering (see Chapter11). In fact, the cornering stiffness (C_α) for small values of α for locked tires is $C_\alpha = \mu F_z$ ($\mu = 0.6/1.2$ for dry pavements) instead $C_\alpha/F_z = 10/25$ for rolling tires ($C_\alpha/F_z = 4/7$ for truck tires) [3]. Thus, if the rear tires are locked, K_{US} (Equation 24.18) becomes negative. In [11], the interested reader can find the full discussion of this topic along with the computation of the critical velocity for a vehicle with locked rear tires.

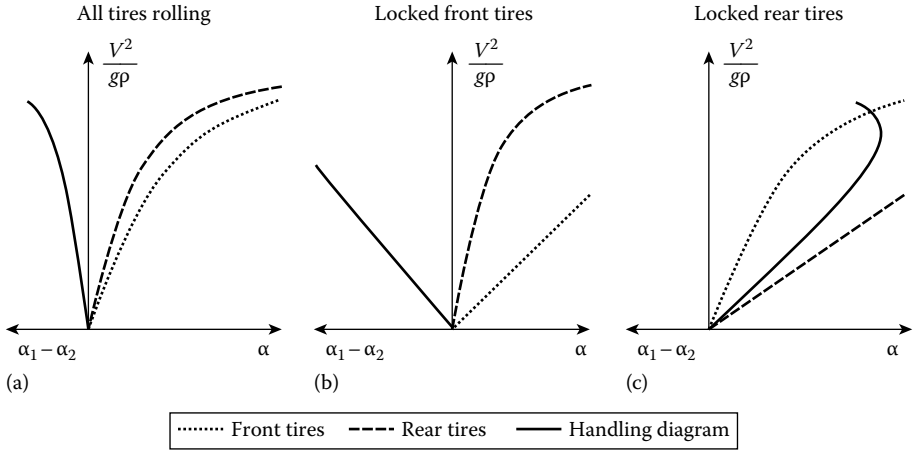

FIGURE 24.7 Handling diagrams (for the computation of the diagrams, see Section 11.4). Locked front tires produce high understeering; locked rear tires produce high oversteering and possibly instability even at straight driving. a: all tires rolling. b: locked front tires. c: locked rear tires.

The brake system has to be designed in order to lock the front tires first. In this case, if the locking of the front tires is reached, the vehicle will slide straight without responding to steering inputs by the driver. If a collision is unavoidable, a frontal crash typically will result in fewer injuries than a side crash due to better occupant protection.

24.3.4 Optimum Straight Braking and Brake Balance

In Chapter 11, the fundamental relationships between front and rear braking forces to have the optimal braking balance have been derived and discussed. Referring to Figure 24.8, these relationships can be written as

$$\frac{F_{xF}}{mg} = \frac{\mu}{L} \cdot \left(b + \frac{a_x}{g} h \right) \tag{24.19}$$

$$\frac{F_{xR}}{mg} = \frac{\mu}{L} \cdot \left(a - \frac{a_x}{g} h \right) \tag{24.20}$$

where μ is the friction coefficient. The loads on the front and rear axles depend on the actual value of acceleration and on the position of the center of gravity

$$\frac{F_{xR}^2}{m^2 g^2} + 2\frac{F_{xR}F_{xF}}{m^2 g^2} + \frac{b}{h}\frac{F_{xR}}{mg} - \frac{a}{h}\frac{F_{xF}}{mg} + \frac{F_{xF}^2}{m^2 g^2} = 0 \tag{24.21}$$

Equation 24.21 is a parabola and represents the ideal ratio between front and rear longitudinal forces to have optimum braking if the friction is equal at front and rear tires. In Figure 24.9, this relationship is depicted for a laden and an unladen vehicle [1–6,12,13]. The points on the parabola represent the front and rear forces to have the simultaneous locking of all of the tires. At the points located under the parabola, the front tires lock first and at the points located over the parabola, the rear tires lock first (see Figure 24.9).

The design corridor for the brake distribution can be found as the area between the most critical condition to avoid rear tire locking (usually unladen vehicle configuration) and the maximum acceptable braking distance (for Europe, this distance is defined by the Union Directive 71/320 [14]). For a typical hydraulic brake system employed on cars, the ratio between front and rear braking forces is fixed and it is depicted as a straight line in Figure 24.9 (fixed brake force distribution [BFD]). It appears that a fixed BFD is not effective in obtaining high braking performances. In fact, at low longitudinal acceleration, such a distribution gives much smaller forces than the ideal distribution.

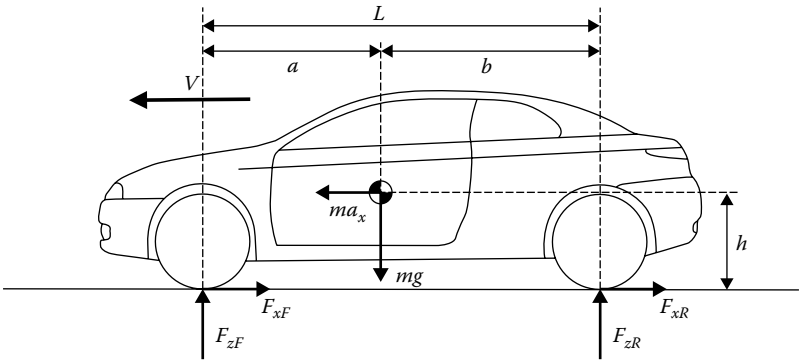

FIGURE 24.8 Vehicle braking on a horizontal road.

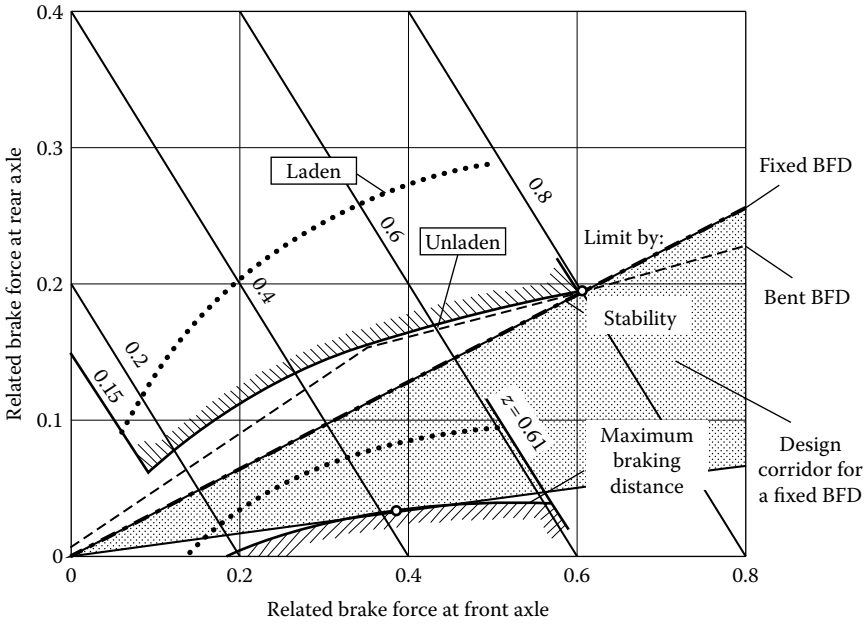

FIGURE 24.9 Fixed, bent, and load-sensitive brake force distribution (BFD). (Adapted from Breuer, B. and Bill, K.H., *Brake Technology Handbook*, SAE International, Warrendale, PA, 2008, ISBN 978-0-7680-1787-8.)

At high longitudinal acceleration, the vehicle tends to lock the rear tires first. Better results are obtained with a bent BFD in which a limit valve is employed for limiting the rear brake pressure at high longitudinal acceleration. In this way, a more convenient balance can be used at low longitudinal acceleration and the locking of the rear tires can be avoided at high longitudinal accelerations. In case of a laden vehicle, the brake system performances can be improved by varying the limit valve operation point as to allow for higher rear braking forces (load-sensitive limit valve, see Section 24.4.2.4).

In a hydraulic brake system without proportioning valve, the pressure is equal at the front and rear axles; thus, a fixed ratio exists between the front and rear brake forces and depends on the different brakes installed on the two axles. The brake distribution (φ), or brake balance, of a vehicle can be defined as the ratio between the rear braking force and the total braking force

$$\phi = \frac{F_{xR}}{F_{xF} + F_{xR}} \tag{24.22}$$

F_{xF} and F_{xR} being the braking forces at the front and rear axle, respectively. The best compromise brake distribution is obtained by proper design of the front and rear brakes. As shown in Figure 24.9, a fixed brake balance is not an optimal choice for the brake system. To improve the brake performance at low accelerations, a pressure-limiting or pressure-reducing valve is employed at the rear axle. At a given pressure, the valve intervenes either limiting or reducing the rear pressure, changing the slope of the balance curve.

It should be noted that the transmission drag and rotary inertia have practical interest when designing the BFD of the vehicle. The effect of the transmission drag is to add a braking torque generated to the driving axles. The effect of the rotary inertia is to use part of the brake torque to reduce the rotational speed of the rotating parts. Both driving and not driving wheels are affected by this phenomenon, but it is more relevant for driving axle where the rotational velocity of wheels and transmission has to be reduced.

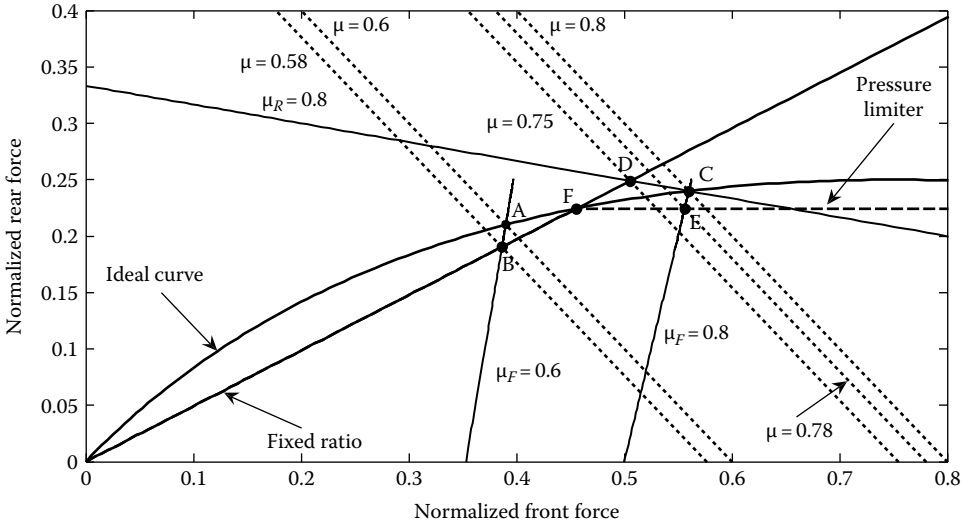

FIGURE 24.10 Optimum and real brake balance.

Aerodynamic effects on the brake balance should be considered when aerodynamic foils are employed on the vehicle (see Chapter 15). For standard vehicles, the effect of aerodynamic force is negligible in most practical situations.

Figure 24.10 shows the situation of a braking system with a fixed brake balance. If a friction coefficient of 0.6 is considered at all tires, point A represents the ideal brake distribution to obtain a deceleration of 0.6 g. If a fixed brake balance is considered as depicted in the figure, for this level of friction coefficient, the front tires lock first. The brake forces, front and rear, increase during pedal force application along the line representing the fixed brake balance up to point B. At this point, the fixed balance line crosses the line representing a constant front friction of 0.6 (for the definition of the lines at fixed front or rear friction, see Figure 11.30) and the front tires approach locking condition with a vehicle deceleration equal to 0.58 g. If more pedal force is applied, point A is reached with the front tires locked and the increase in the front force is due to load transfer.

If a friction coefficient of 0.8 is considered, for the depicted vehicle, the rear tires lock first. Point C represents the ideal brake balance to obtain a deceleration of 0.8 g. The actual brake forces follow the line representing the fixed brake balance up to point D where there is the intersection with the line representing a fixed rear friction coefficient of 0.8. At this point, the vehicle deceleration is equal to 0.75 g and the rear tires approach locking condition. The vehicle is in an unstable braking situation (continuing depressing the brake pedal from point D, point C would be reached; at C, both of the front and rear tires are locked). To avoid the locking of rear tires, a pressure-limiting or reducing valve can be employed. If a pressure-limiting valve is employed with a cut pressure equal to the rear pressure at point F, the brake forces have to increase according to the dashed line of figure from point F to point E where there is the intersection with the line of constant front friction of 0.8. At this point, the front tires approach locking condition at a deceleration of 0.78 g with a stable braking configuration.

The brake efficiency (E) can be defined as the ratio between the actual longitudinal deceleration a_x and $\mu \cdot g$

$$E = \frac{a_x}{\mu g} \tag{24.23}$$

Similarly, E can be defined for the front and rear axle as the ratio between the longitudinal deceleration and the friction coefficient at that axle times g. The friction coefficients at the front (μ_F) and rear (μ_R) axle can be computed as the ratio between the actual longitudinal force and vertical force

at that axle. For a fixed brake balance, with the notation of Figure 24.8, the front and rear friction coefficients can be computed as [6]

$$\mu_F = \frac{F_{xF}}{F_{zF}} = \frac{(1-\phi)(a_x/g)}{(b/L)+(a_x/g)(h/L)} \tag{24.24}$$

$$\mu_R = \frac{F_{xR}}{F_{zR}} = \frac{\phi(a_x/g)}{(a/L)-(a_x/g)(h/L)} \tag{24.25}$$

$$\text{beings with } F_{xF} = (1-\phi)\cdot a_x m, \quad F_{zF} = mg\left(\frac{b}{L}+\frac{a_x}{g}\frac{h}{L}\right), \quad F_{xR} = \phi\cdot a_x m,$$

$$\text{and } F_{zF} = mg\left(\frac{a}{L}-\frac{a_x}{g}\frac{h}{L}\right)$$

The front and rear brake efficiencies read

$$E_F = \frac{a_x}{\mu_F g} = \frac{(b/L)}{1-\phi-(h/L)\mu_F} \tag{24.26}$$

$$E_R = \frac{a_x}{\mu_R g} = \frac{(a/L)}{\phi+(h/L)\mu_R} \tag{24.27}$$

Only values smaller than 1 are physically meaningful.

24.3.4.1 Vehicles with More than Two Axles

The analysis of brake dynamics of vehicle with more than two axles is important to define the correct brake balance between the axles of the vehicle. Typical vehicles with more than two axles are three-axle trucks or buses with a single front axle and a tandem rear axle. For this type of vehicles, the dynamic equilibrium of the tandem rear axle has to be considered in order to compute the load transfer between the three axles. The equation involved is generally complex and computer programs can be employed for the solution. In some cases, such as walking beam or leaf spring tandem axle suspensions, the equation can be solved in a closed form [6].

In general, the load transfer increases the load on the front axle and reduces the load on the rearmost axle. The load on the central axle has smaller variations. The brake system has to be realized in order to optimize the brake torque application as a function of the vertical load variation.

24.3.4.2 Articulated Vehicles and Vehicle–Trailer Combinations

In case of articulated vehicles or vehicle–trailer combinations (Figure 24.11), the brake balance is crucial for stability [3,6]. Figure 24.11a refers to a tractor and trailer combination. The trailer has two axles and can support its own weight. Referring to the symbols in the figure, just formally, the respective decelerations of the tractor (a) and of the trailer (a_t) can be denoted as

$$a = \frac{F_x}{mg} \quad a_t = \frac{F_{xt}}{m_t g} \tag{24.28}$$

The deceleration (a_s) of the tractor and trailer combination can be expressed as

$$a_s = a\frac{mg}{mg+m_t g} + a_t\frac{m_t g}{mg+m_t g} \tag{24.29}$$

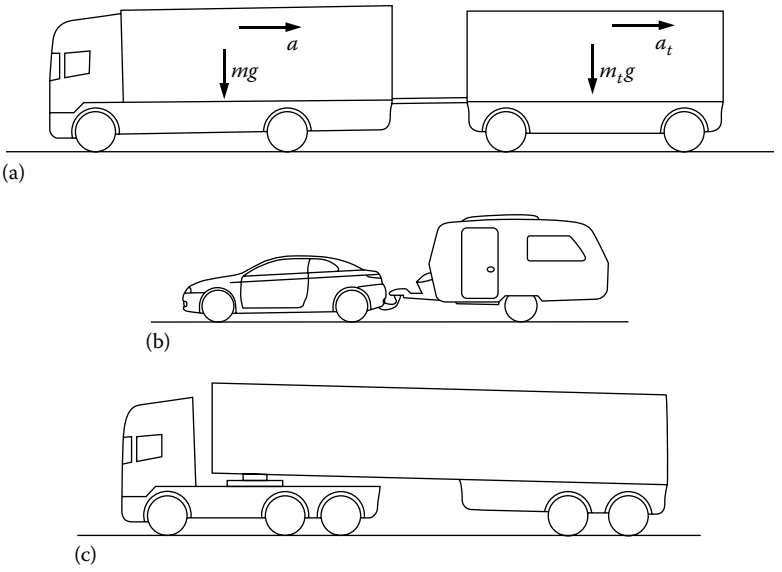

FIGURE 24.11 Articulated vehicles: (a) tractor and trailer, (b) car and caravan, and (c) tractor and semitrailer.

Two dangerous situations can arise. If the deceleration of the tractor is higher than the deceleration of the trailer ($a > a_t$), the trailer exerts a horizontal force on the tractor in the direction of the motion. The link between the tractor and the trailer is compressed and an instability may occur. In case the deceleration of the trailer is higher than the deceleration of the tractor ($a_t > a$), there is a risk of locking of the tires of the trailer. In this case, the trailer is no longer able to follow the tractor during curve negotiation, that is, the trailer can slide outside the curve [3]. To avoid these two opposite situations, the tractor and trailer must have the same deceleration, that is, forces F_x and F_{xt} must be tuned in order to have $a = a_t$. The horizontal force between tractor and trailer has to vanish during braking.

Figure 24.11b shows an articulated vehicle realized by a car and a caravan. In this case, the caravan is not able to support its own weight and a vertical force is acting at the hitch. Also, a certain amount of horizontal force cannot be avoided. The forces acting between car and caravan change the vertical loads acting at the front and rear axles of the car. In particular, the vertical load at the rear axle is increased, while the vertical load at the front axle is decreased. The brake balance of the car has been set in order to have the best performances when the car is riding alone. In this case, the balance should be shifted toward the rear axle. If this cannot be done, bad performances are to be expected. If an electronic system is present, the brake balance can be adjusted for this situation. Moreover, if the caravan does not have a braking system, the system can become unstable in a similar way of the previous case when the trailer has less deceleration of the tractor. If the caravan can brake, given the differences in the adherence of the tires of the caravan and of the car, there is the risk of locking the tires of the caravan [3].

A tractor and semitrailer combination is depicted in Figure 24.11c. This situation is very similar to the car–caravan situation. However, the risks of instability are limited by the positioning of the connecting hitch between the axles of the tractor, by designing the braking systems of the tractor and of the trailer as to work together, and by the presence of a mandatory electronic system for the regulation of the braking force balance between the tractor and trailer. (More information on this topic can be found in [15,16].)

24.3.5 Vehicle Body Attitude When Braking

In conventional vehicles, with front and rear suspension systems, the body pitch attitude during braking or acceleration varies due to the effects of the longitudinal acceleration. In general, important pitch of the body occurs, which is strongly related to the geometry of the suspension system. This

section is devoted to the analysis of the forces transmitted by front and rear suspensions to the body of the vehicle in order to derive the geometrical features of the suspension system required to avoid the pitching of the body. The feature of the suspension system that prevents the pitching of the car body when braking is called anti-dive characteristic. A suspension system that totally avoids brake pitch rotation has a 100% anti-dive.

For a car with two axles and brakes located on the wheels, following the comprehensive work reported in [3], the braking dive phenomenon can be described as follows.

In Figure 24.12, a suitable model for the definition of the anti-dive characteristics of a suspension system is depicted. The model has 3 degrees of freedom (DOFs), namely, longitudinal displacement x, vertical displacement z, and pitch rotation φ. The front and rear elastokinematics are described by equivalent stiffness and damping and additionally by equivalent longitudinal arms with given inclinations. By such a model, every kind of suspension systems can be taken into account. The brakes are located at the wheels hub carriers, that is, the reaction torques of the brakes act directly at the hub carriers. Referring to the symbols reported in the figure, the dynamic equilibrium while braking reads

$$ma_x = -F_{xcf} - F_{xcr} \tag{24.30}$$

$$m\ddot{z} = F_{zcf} + F_{zcr} + F_f + F_r \tag{24.31}$$

$$J\ddot{\varphi} = -F_{zcf}(a - L_f) + F_{zcr}(b - L_r) - F_f a + F_r b - F_{xcf}(h - h_f) - F_{xcr}(h - h_r) \tag{24.32}$$

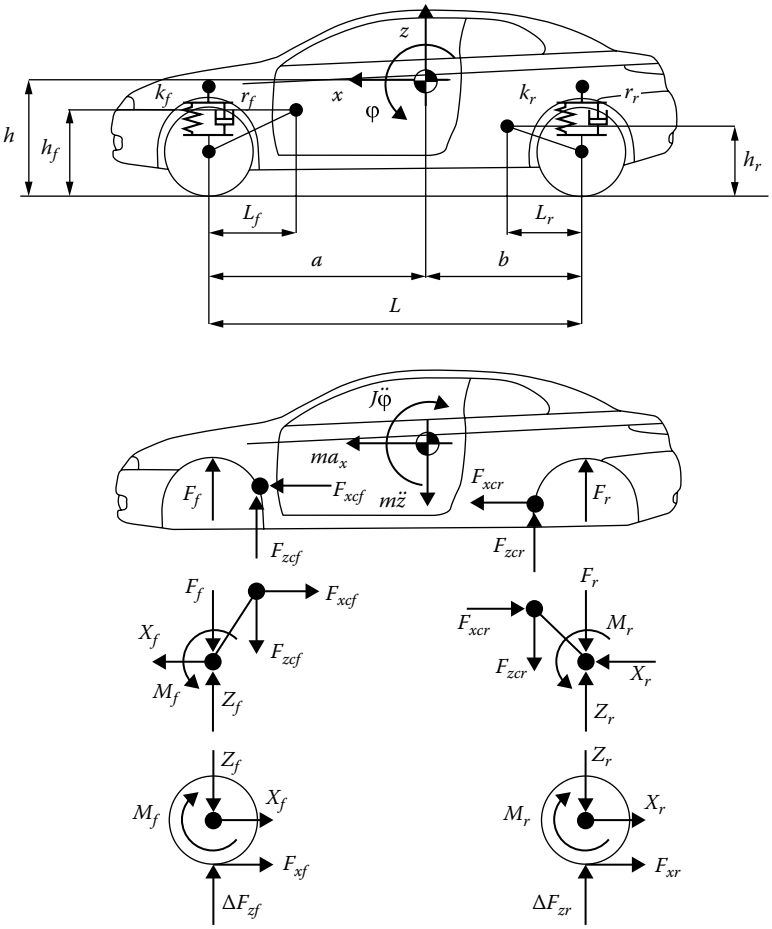

FIGURE 24.12 Vehicle model for anti-dive characteristic computation.

m being the mass of the body of the vehicle and J its moment of inertia with respect to the pitch axle. For the (massless) suspensions arms,

$$F_{xcf} = X_f \qquad F_{xcr} = X_r \tag{24.33}$$

$$F_{zcf} = Z_f - F_f \qquad F_{zcr} = Z_r - F_r \tag{24.34}$$

$$F_{zcf} L_f - F_{xcf}(h_f - r) - M_f = 0 \qquad F_{zcr} L_r + F_{xcr}(h_r - r) - M_r = 0 \tag{24.35}$$

r being the tire radius. For the (massless) tires,

$$F_{xf} = -X_f \qquad F_{xr} = -X_r \tag{24.36}$$

$$\Delta F_{zf} = Z_f \qquad \Delta F_{zr} = Z_r \tag{24.37}$$

$$M_f = F_{xf} r \qquad M_r = F_{xr} r \tag{24.38}$$

The forces due suspension stiffness and damping can be computed as

$$F_f = -k_f(z - L_f\varphi) - r_f(\dot{z} - L_f\dot{\varphi}) \tag{24.39}$$

$$F_r = -k_r(z + L_f\varphi) - r_r(\dot{z} + L_r\dot{\varphi}) \tag{24.40}$$

From Equations 24.30, 24.33, and 24.36,

$$ma_x = -F_{xcf} - F_{xcr} = X_f + X_r = F_{xf} + F_{xr} \tag{24.41}$$

By replacing Equation 24.41 into Equations 24.31 and 24.32, remembering Equations 24.34, 24.35, and 24.37 through 24.40, and rearranging, the vertical and pitch dynamic equilibrium of vehicle body can be rewritten as

$$m\ddot{z} + (r_f + r_r)\dot{z} - (r_f L_f - r_r L_r)\dot{\varphi} + (k_f + k_r)z - (k_f L_f - k_r L_r)\varphi = ma_x\left(\frac{F_{xf}}{F_{xf} + F_{xr}}\frac{h_f}{L_f} - \frac{F_{xr}}{F_{xf} + F_{xr}}\frac{h_r}{L_r}\right) \tag{24.42}$$

$$J\ddot{\varphi} - (r_f L_f - r_r L_r)\dot{z} + \left(r_f L_f^2 + r_r L_r^2\right)\dot{\varphi} - (k_f L_f - k_r L_r)z + \left(k_f L_f^2 + k_r L_r^2\right)\varphi = ma_x\left(h - \frac{F_{xf}}{F_{xf} + F_{xr}}\frac{h_f}{L_f}a - \frac{F_{xr}}{F_{xf} + F_{xr}}\frac{h_r}{L_r}b\right) \tag{24.43}$$

If the respective right expressions of Equations 24.42 and 24.43 were to vanish, both the heave (z) and the pitch (φ) would vanish. This occurs if

$$\frac{h_f}{L_f} = \frac{F_{xf} + F_{xr}}{F_{xf}}\frac{h}{L} \tag{24.44}$$

$$\frac{h_r}{L_r} = \frac{F_{xf} + F_{xr}}{F_{xr}}\frac{h}{L} \tag{24.45}$$

Please notice that if Equations 24.44 and 24.45 hold, no heave (z) and pitch (φ) occur both during steady-state braking and during transients, no matter which brake history is applied [3]!

If the steady-state equilibrium is considered, Equations 24.42 and 24.43 read

$$(k_f + k_r)z - (k_f L_f - k_r L_r)\varphi = ma_x\left(\frac{F_{xf}}{F_{xf}+F_{xr}}\frac{h_f}{L_f} - \frac{F_{xr}}{F_{xf}+F_{xr}}\frac{h_r}{L_r}\right) \tag{24.46}$$

$$-(k_f L_f - k_r L_r)z + \left(k_f L_f^2 + k_r L_r^2\right)\varphi = ma_x\left(h - \frac{F_{xf}}{F_{xf}+F_{xr}}\frac{h_f}{L_f}a - \frac{F_{xr}}{F_{xf}+F_{xr}}\frac{h_r}{L_r}b\right) \tag{24.47}$$

Solving the system of Equations 24.46 and 24.47, the steady-state pitch angle φ can be computed as

$$\varphi = \frac{ma_x}{L}\left(\frac{h}{L}\left(\frac{1}{k_f}+\frac{1}{k_r}\right) - \frac{F_{xf}}{F_{xf}+F_{xr}}\frac{h_f}{L_f}\frac{1}{k_f} - \frac{F_{xr}}{F_{xf}+F_{xr}}\frac{h_r}{L_r}\frac{1}{k_r}\right) \tag{24.48}$$

Figure 24.13 gives a graphical representation of the previous conditions for 100% anti-dive. The pitch rotation center, which can be obtained by the intersection of the lines passing through the tire contact points and the hinges between the suspensions arms and the car body, has the same height of the center of gravity. In this way, the inertia forces due to the deceleration pass through the pitch rotation center and no pitch moment is applied to the car body.

In case the brakes are located on the chassis of the car, the previous formulation has to be modified. In this case, the brake reaction torques act on the car body. The anti-dive conditions of Equations 24.47 and 24.48 can be recomputed and read

$$\frac{h_f}{L_f} = \frac{F_{xf}+F_{xr}}{F_{xf}}\frac{h}{L} + \frac{r}{L_f} \tag{24.49}$$

$$\frac{h_r}{L_r} = \frac{F_{xf}+F_{xr}}{F_{xr}}\frac{h}{L} + \frac{r}{L_r} \tag{24.50}$$

The graphical representation of the 100% anti-dive conditions for the case of brakes located on the car body is depicted in Figure 24.14. In this case, the pitch rotation center can be found by intersecting the lines passing through the center of the tires and the suspension arm hinges with the chassis and it is above the center of gravity. The consequent moment due to the inertial force during braking is equal to the reaction moment that the brakes apply to the car body.

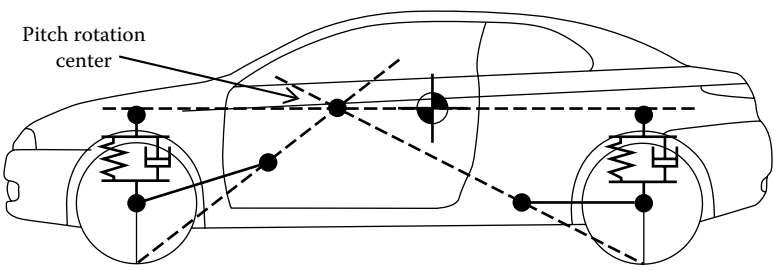

FIGURE 24.13 Front and rear suspension arms inclinations to have a 100% anti-dive configuration (brakes reacting on suspension arms).

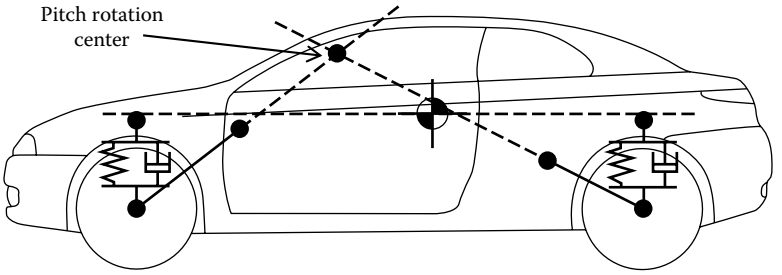

FIGURE 24.14 Front and rear suspensions arms inclinations to have a 100% anti-dive configuration (brakes on the car body).

24.4 HYDRAULIC BRAKE SYSTEM AND COMPONENTS

For cars, a hydraulic system is commonly used to transfer from the driver to the brakes both the actuation energy and the information on the amount of brake torque to be applied. Actually, the hydraulic system is rather flexible to be fitted into the car body and stiff enough to prevent undesired energy storage into the pipeline [1,3,8].

Brake by wire could be a widely adopted option in the future provided that brake mass and actuation energy will be kept as low as possible [1,8].

Figure 24.15 shows a schematic representation of a standard brake circuit. The driver force (F_P) applied at the pedal is multiplied by the lever ratio of the pedal (pedal ratio i_p) and transmitted to the master cylinder. Often, a brake booster is interposed between the pedal and the master cylinder as to increment the input force in the master cylinder. The pressure generated by the master cylinder is transmitted by a hydraulic circuit to slave pistons generating the clamping force (F_c). In this operation, the force applied to the master cylinder (F_i) is multiplied by the hydraulic circuit. In case of a circuit with an input area A_{in} at the master cylinder and an output area at the slave cylinder A_{out}, the clamping force can be computed as

$$p = \frac{F_i}{A_{in}} = \frac{F_c}{A_{out}} = const \Rightarrow F_c = \frac{A_{out}}{A_{in}} F_i = i_H F_i \tag{24.51}$$

where p is the pressure of the fluid, constant through the hydraulic circuit, and $A_{out} > A_{in}$, $F_c > F_i$, and $i_H > 1$. i_H is called hydraulic ratio and multiplies the input force. The maximum value of i_H is limited by the condition that the master cylinder must deliver the fluid needed to move the brake actuators (both for closing the clearances and for applying the force) plus the fluid absorbed by the deformation of the hydraulic circuit and maintain a residual travel. The fluid delivered by the master cylinder is equal to its volume, which can be computed as A_{in} times the travel of the master cylinder piston.

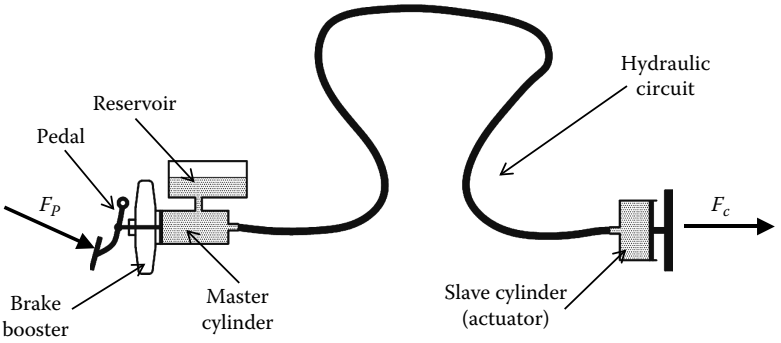

FIGURE 24.15 Schematic representation of a hydraulic brake circuit.

The travel of the piston is limited by the travel of the pedal and the pedal ratio (which is defined by the maximum force equal to 500 N for vehicles up to eight passengers and 700 N for more passengers [14]); thus, the minimum value of A_{in} is limited by the amount of fluid required. Incrementing A_{out} leads to an increment on the required fluid volume and thus is limited by A_{in}. To maximize i_H, all the component of the hydraulic circuit have to be very stiff in order to reduce the amount of fluid absorbed by their deformation. Also, the clearance between pad and disk (brake disk) or shoe and drum (drum disk) must be reduced at the minimum as to reduce the actuators' travel needed to close the clearance.

Considering the pedal ratio i_p and a force increment i_b at the booster, the total multiplication from the applied force F_P to the clamping force F_c is

$$F_c = i_P \cdot i_b \cdot i_H \cdot F_P = i_{out} F_P \Rightarrow i_{out} = i_P \cdot i_b \cdot i_H = \frac{F_c}{F_P} \tag{24.52}$$

i_{out} is called external brake system gain, defined as the ratio between the clamping force and the pedal force. The overall brake system gain i_{og}, defined as the ratio between the brake circumferential force (F_B) and the pedal force, can be obtained by multiplying the external gain by the internal gain C^* typical of each brake type:

$$i_{og} = i_{out} \cdot C^* \tag{24.53}$$

The internal gains C^* can be computed for each brake type (disk brake, drum brake) and are summarized in ISO 611 [17] for the different constructions.
For a disk brake with two friction surfaces, the internal gain can be computed as

$$C^* = \frac{F_B}{F_c} = \frac{F_{B,sch1} + F_{B,sch2}}{F_c} = \frac{F_c \mu_{lining} + F_c \mu_{lining}}{F} = 2\mu_{lining} \tag{24.54}$$

where

μ_{lining} is the friction coefficient between pad lining and disk
$F_{B,sch1}$ and $F_{B,sch2}$ are the tangential forces acting on the two surfaces of the disk

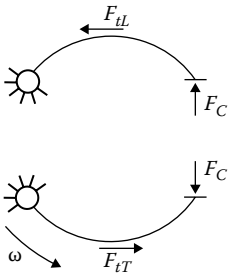
A typical value of C^* for a brake disk is 0.8 [17]. For drum brakes, the value of C^* depends on the type of construction and ranges between 1 and 5.5 [1,17,18] as reported in Table 24.1. Construction types with high values of C^* should not be employed as service brakes in order to avoid left-to-right and front-to-rear brake unbalances. These constructions are employed mostly as parking brakes.

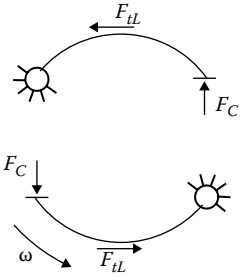
By considering the efficiencies of the force–pressure transformation in the master cylinder (η_{act}) and of the pressure–force transformation in the slave cylinder (η_B), the brake friction radius (r_B), and the tire rolling radius (r_t), the following formula can be derived that relates the braking force (F_x) to the pedal force:

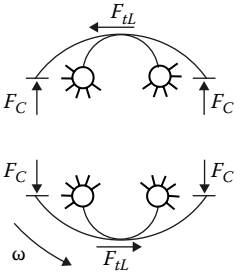
$$F_x = \underbrace{i_P \cdot i_b \cdot \eta_{act}}_{\substack{\text{Actuation} \\ \text{mechanism}}} \cdot \underbrace{i_H \cdot \eta_B}_{\substack{\text{Hydraulic} \\ \text{system}}} \cdot \underbrace{C^* \cdot \frac{r_B}{r_t}}_{\substack{\text{Brake} \\ \text{mechanism}}} \cdot F_P \tag{24.55}$$

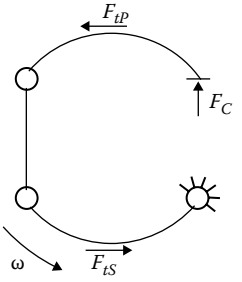
Equation 24.55 is very approximate and can be used only under restrictive conditions, but it gives an overview of the effects of the three subsystems composing the brake system.

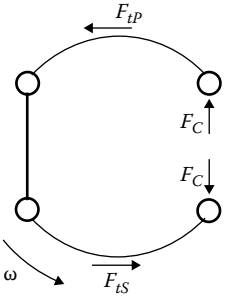
TABLE 24.1
Internal Gain C^* for Various Types of Brakes

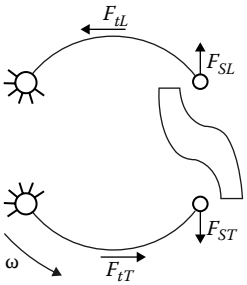


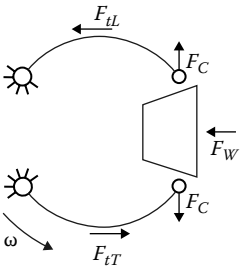


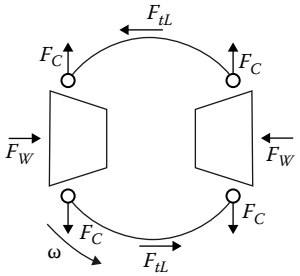


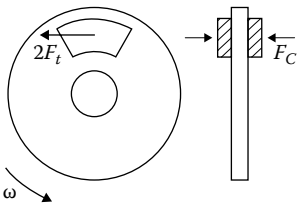












Brake Type	Force Scheme	Typical Friction Coefficient μ (from [17])	Internal Gain C^*

24.4.1 Brake System Configurations

The legal requirements on the safety of the brake system impose the use of two separate hydraulic circuits. In case of failure of one of the circuits, a certain amount of braking power has to be still available on the vehicle. In the DIN 74000 standard [19], the five circuit configurations that can be employed on a car are described (here depicted in Figure 24.16).

Among the five possible configurations, the most employed on passenger cars are the first two (II and X configurations) [1,8]. In the last three configurations (HI, LL, and HH configurations), two different circuits reach two or more brake calipers. The calipers have to be designed in order to have two separate pistons and two inlet pipes. This construction is more expensive and thus rarely used for passenger cars and adopted only for light to heavy commercial vehicles.

Referring to the first two configurations, the II configuration is adopted for vehicles with a high load on the rear axle. In this case, if the front axle circuit has a failure, a high load is present at the rear axle and sufficient brake force is still available. By separating the front and rear circuit, rear axle brakes remain effective in the event of thermal overload on the front axle (e.g., if vapor bubbles form in a hydraulic brake). The X configuration is adopted for most vehicles with forward or none weight bias. With this arrangement, each pair of brakes diagonally opposite each other are supplied from one brake circuit. This way, if one circuit fails, the greater proportion of the braking force at the front axle is still exploited at one wheel. It is possible to compensate for the brake pull that occurs if a circuit fails as a result of the asymmetrical distribution of braking force between the left and right of the vehicle by designing the axle appropriately (e.g., with a negative scrub radius).

24.4.2 Brake System Components

The main components of the brake system are similar for all passenger vehicles. Figure 24.17 shows the scheme of a braking system (II configuration). The driver exerts a force on the pedal (1), moving the piston rod connecting the pedal to the tandem master cylinder (3) through the brake booster (2).

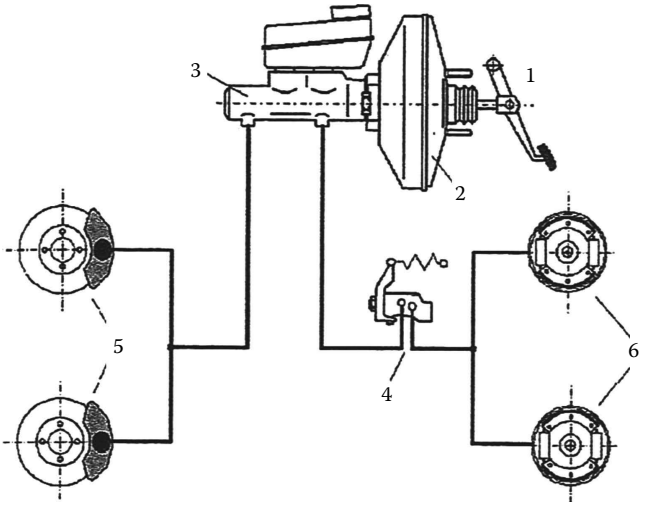

FIGURE 24.17 Brake circuit: (1) pedal, (2) vacuum brake booster, (3) tandem master cylinder with reservoir, (4) brake pressure regulator, (5) front axle wheel brakes, and (6) rear axle wheel brakes. (Adapted from Breuer, B. and Bill, K.H., *Brake Technology Handbook*, SAE International, Warrendale, PA, 2008, ISBN 978-0-7680-1787-8.)

The brake booster amplifies the force applied by the driver by introducing energy into the system. The tandem master cylinder transforms the mechanical force into pressure and feeds both of the two separate hydraulic circuits. A reservoir is connected to each chamber of the tandem master cylinder in order to provide the required brake fluid. One or two (depending on the circuits configuration) pressure regulators (4) are located on the line or lines to the rear axle brakes in order to reduce the rear pressure for high values of deceleration. Brakes (5 and 6) are located to the front and rear wheels. Disk (5) or drum (6) brakes are employed. Disk brakes can be used both at the front and rear axles, while the use of drum brakes is limited to the rear axle of low performances vehicles.

In the following sections, a brief description of each component of the brake system will be provided.

24.4.2.1 Pedal

The pedal is the interface between the braking system and the driver. The braking action can be sought of as a closed-loop control system in which the driver is the main controller (actually some control operations are demanded to the electronic control of the system, if present). In this control loop (Figure 24.18), the pedal has a double function. It is the actuator powered by the driver to

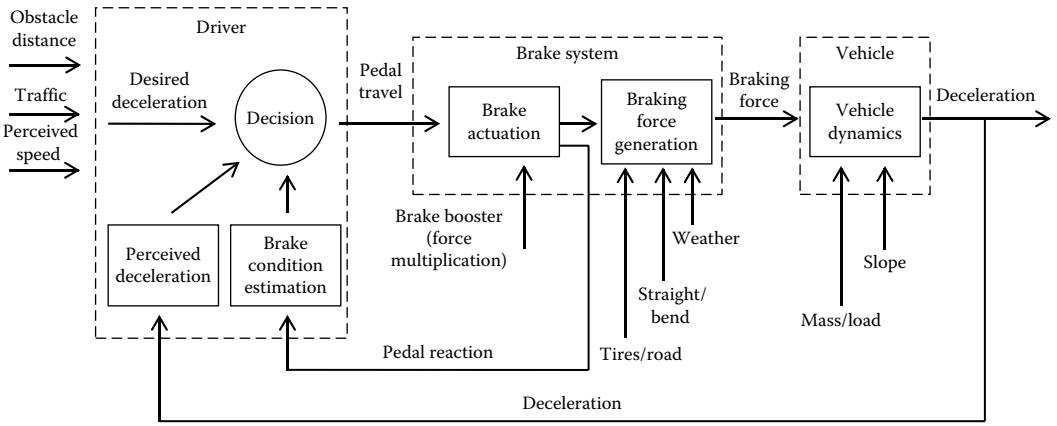

FIGURE 24.18 Brake control loop.

provide the braking energy and it is a sensor that the driver uses to estimate the state of the braking system. The ergonomics of the pedal and its force characteristics are of fundamental importance for the driver confidence and for safety. The driver force is multiplied by the pedal by a factor between 3 and 5. A correct positioning of the pedal can contribute to reduce the stopping distance, minimizing the time needed to reach the command in emergency situations.

24.4.2.2 Brake Booster

The function of the brake booster is to increment the force applied by the driver reducing the physical effort required for braking. Safety requirements prescribe that in case of booster failure, the driver must be still able to stop the vehicle by its own strength. As a consequence, very high values of boost ratio i_b cannot be employed, being difficult in this case to match this requirement. The booster has to function as a follower of the driver inputs, that is, the booster must apply its action after the driver has displaced the pedal and finish its action when the position defined by the driver is reached. Two types of brake booster are currently implemented, namely, vacuum brake booster and hydraulic brake booster [1,8,20].

24.4.2.2.1 Vacuum Brake Booster

Figure 24.19 shows the scheme of a vacuum brake booster able to comply with the requirements stated earlier. The driver action, through the pedal, is applied to the piston rod (7). The output force is transmitted to the master tandem cylinder by the push rod (1). Notice that if the system is not working, the piston rod can directly push the tandem rod allowing the driver to fulfill the braking action, even if without any boosting aid.

The operating principle is based on the difference of pressure between the vacuum chamber (2) and the working chamber (8). The vacuum chamber is connected to a void generator, either a void pump (diesel engines) or the inlet manifold (gasoline engines). A non-return valve is employed to avoid the vacuum chamber to release the void when the void generator is not functioning. When the

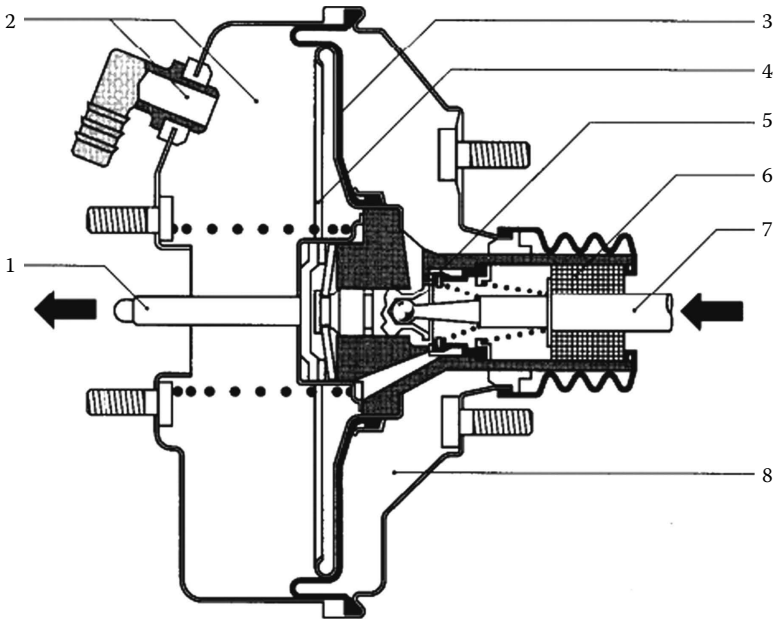

FIGURE 24.19 Vacuum brake booster: (1) push rod (output force to tandem cylinder), (2) vacuum chamber with vacuum connection, (3) diaphragm, (4) working piston, (5) double valve, (6) air filter, (7) piston rod (pedal force), and (8) working chamber. (Adapted from Bosch, *Automotive Handbook*, 7th edn., SAE, Warrendale, PA, 2007.)

system is at rest, the vacuum chamber and the working chamber are connected through the valve housing. The pressure is equal in the two chambers and no action is present. When the piston rod is displaced, the connection between the two chambers is closed, and the working chamber is connected to the atmospheric pressure by means of the double valve (5). The higher pressure in the working chamber acts on the diaphragm (3) connected to the working piston (4) that acts on the push rod adding the pressure force to the force applied by the driver, overcoming the reaction force of the returning spring. The valve housing is connected to the working piston, and when the final position is reached, the working chamber and the vacuum chamber are connected again to stop the booster action.

The active brake booster has an electrically actuated solenoid drive integrated into the housing to actuate the valve, providing support for additional functions (ESC priming, electronic brake assist, and ACC) [1].

Despite their larger dimensions, vacuum brake boosters have until now been preferred to hydraulic brake boosters. They are generally used for master cylinder volumes up to about 25 cm^3 [6], due to their limitation in booster pressure and size. The main reasons for their employment are their low manufacturing costs, a free source of vacuum at disposal in gasoline engines, and a better return feeling to the pedal [6].

24.4.2.2.2 Hydraulic Brake Booster

The hydraulic boost system uses as energy source a pressurized fluid. The brake system is a conventional brake system with the booster and plumbing added. In most cases, the source of pressurized fluid is the steering pump. A pressure-controlled flow volume regulator is employed for taking a small portion of flow supply from the power steering and charging a hydraulic pressure accumulator. The accumulator has, also, the function of providing the pressurized fluid for a certain number of brake applications in case of pump failure.

The hydraulic brake booster, compared with the vacuum brake booster, requires less installation space and it is able to furnish higher booster actions. However, it has a much worse pedal feeling and higher costs. The hydraulic brake booster is employed when a high brake boost is needed (heavy passenger cars such as limousines) [8,20].

24.4.2.3 Tandem Master Cylinder

The requirement of two distinct hydraulic circuits imposes the use of two master cylinders or a tandem master cylinder in order to pressurize both circuits. On most vehicles, the master tandem cylinder is adopted, while two master cylinders connected via a balance lever is relegated to race car applications (see Chapter 15 for details).

The tandem master cylinder must be constructed as such to provide the required pressure to the two hydraulic circuits and in case of failure of one circuit, it must be able to deliver the pressure in the other circuit. Figure 24.20 shows a typical construction for a master cylinder and its reservoirs. The reservoirs are needed in order to provide the hydraulic fluid absorbed by the displacement of the actuators, to compensate for the worn of the lining and for thermal dilatations.

The two pistons A and B are located in the same bore. Piston A is connected to the pedal, either directly or through the brake booster. The pedal displacement causes piston A to move left, and pressure is built in the chamber between the two pistons connected to the first hydraulic circuit. By effect of the pressure, a force arises on piston B that starts moving left winning the reaction force of the restoring spring and building up pressure in the last chamber connected to the second hydraulic circuit. By a proper design of the pistons areas, the same pressure can be given to the two circuits.

In case of failure of one of the two circuits, the tandem master cylinder is still able to provide pressure to the other circuit. If the circuit connected to port F fails, piston B will slide till the stop is reached without building up any pressure. As soon as the stop is reached, some reaction is present and pressure can build up in the other chamber. If the circuit connected to port G fails, piston A

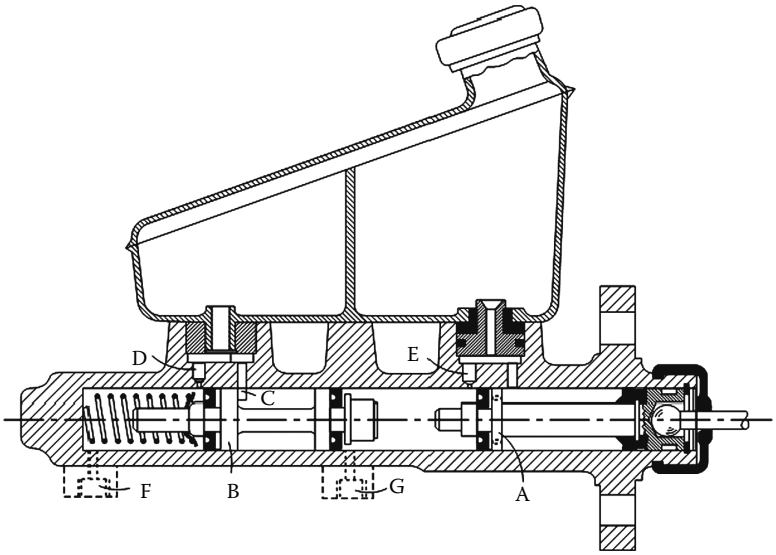

FIGURE 24.20 Master tandem cylinder. A and B, pistons; C, D, and E, reservoirs holes; F and G, connections to the two hydraulic circuits. (Adapted from Garrett, T.K. et al., *The Motor Vehicle*, Butterworth-Heinemann, Oxford, U.K., 2001.)

slides without building up pressure until it reaches piston B. At this moment, piston B is moved and pressure builds up normally in the chamber connected to port F [18,21].

24.4.2.4 Pressure Limiters and Reducers

As shown in the previous sections, the variation of the axle loads during braking is such that the braking action at the front axle increases and at the rear axle decreases. The ideal BFD is a nonlinear curve that can be conveniently approximated by limiting or reducing the brake pressure at the rear axle. Up to the mid-1990s, this operation has been realized by means of hydraulic–mechanical pressure limiters and reducers. Nowadays, these systems are increasingly replaced by electronic EBD, integrated into the ABS system [1].

In Figure 24.21, the typical characteristics of the three more diffused kinds of pressure distribution valves are shown.

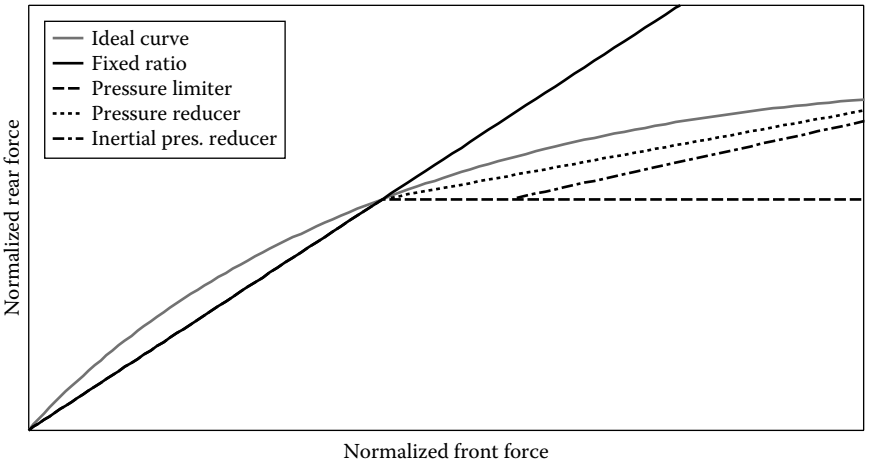

FIGURE 24.21 Characteristic of pressure limiter (dashed line), pressure reducer (dotted line), and inertial pressure reducer (dashed–dotted line).

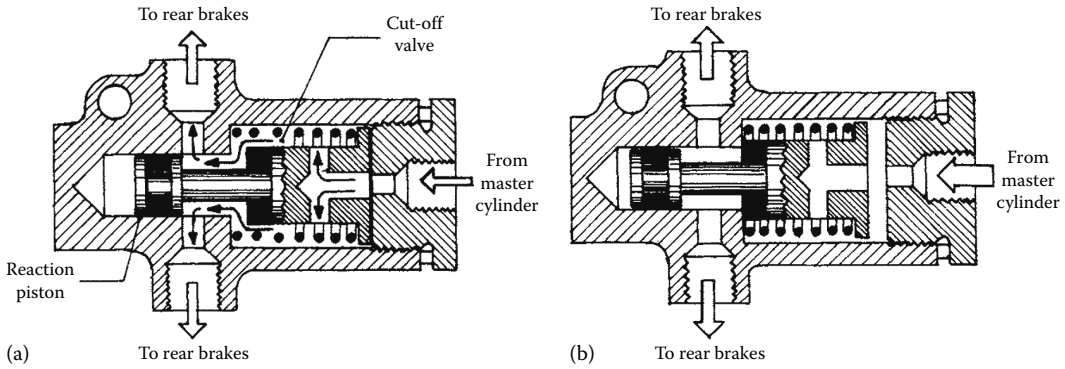

FIGURE 24.22 Pressure-limiting valve. (Adapted from Heisle, H., *Advanced Vehicle Technology*, Butterworth-Heinemann, Oxford, U.K., 2002.) (a) Low deceleration. (b) High deceleration.

In case of the pressure limiter (Figure 24.22), a cutoff pressure is defined at which the circuit of rear brakes is isolated from the master cylinder, that is, the rear brake pressure is kept constant regardless of the increase of pressure into the master cylinder. To this end, the limiting valve has an internal piston connected to a reaction spring that is moved by the pressure from the master cylinder till the manifold connecting the rear axle is closed.

Figure 24.23 shows a proportional valve reducer. In this case, the master cylinder pressure causes the reaction piston to move outward till it reaches the conical cutoff valve at the designed cutoff pressure, isolating the rear axle. Then, if the master cylinder pressure rises, the conical valve is moved inward, and the rear axle is again connected to the master cylinder. The pressure at the rear axle rises less than the pressure in the master cylinder, because as the two circuits are connected, the rise in pressure of the rear circuit makes the reaction piston to close the valve again. During high-pressure braking, this sequence is repeated and the valves continue to oscillate letting the rear pressure rise with a slower slope with respect to the master cylinder pressure. The proportional valve shown in the figure is also load sensitive. The reaction spring is connected to the suspension system of the vehicle and the preload varies as the load on the vehicle varies. In this way, the cutoff pressure can be varied and the characteristics of Figure 24.24 can be achieved [18,20,21].

In Figure 24.25 an inertial pressure reducer valve is depicted. In this case, an inertial ball is positioned on an inclined slope with respect to the direction of travel. When a certain amount of

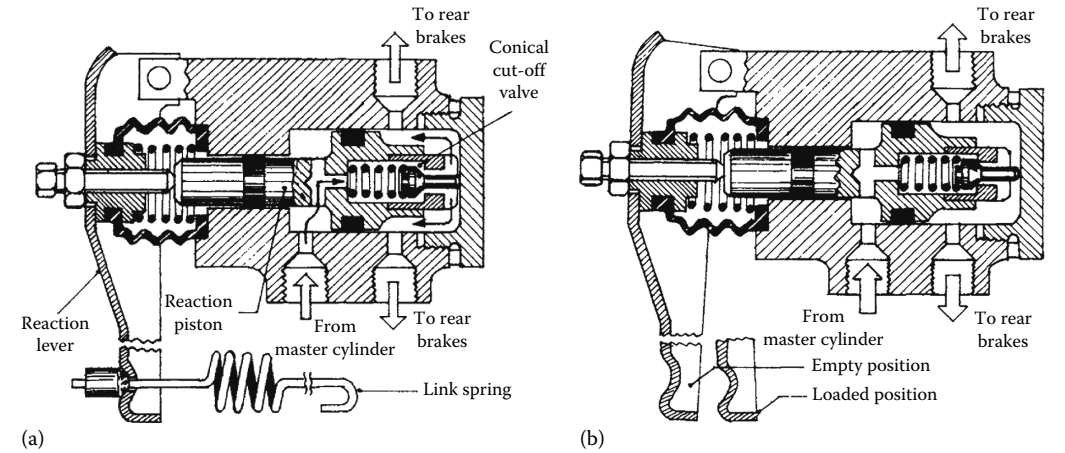

FIGURE 24.23 Load-sensitive pressure reducer valve. (Adapted from Heisle, H., *Advanced Vehicle Technology*, Butterworth-Heinemann, Oxford, U.K., 2002.) (a) Low deceleration. (b) High deceleration.

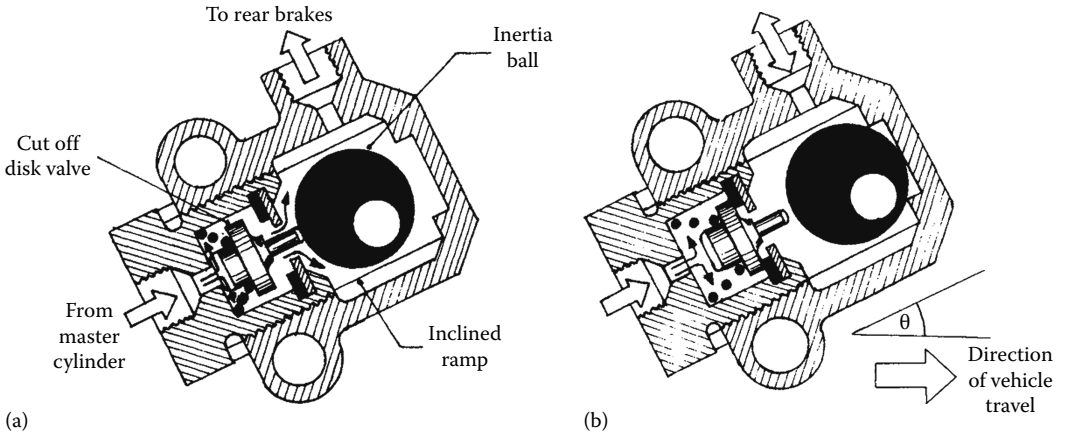

FIGURE 24.25 Inertial pressure reducer valve. (Adapted from Heisle, H., *Advanced Vehicle Technology*, Butterworth-Heinemann, Oxford, U.K., 2002.) (a) Low deceleration. (b) High deceleration.

longitudinal deceleration is reached, the ball is removed from the cutoff disk valve that closes and isolates the rear circuit. If a differential cutoff disk valve is employed, a proportional characteristic similar to the one of Figure 24.24 can be obtained [18].

24.4.3 Brake Types

For vehicle application, two different types of brakes are employed, drum brakes and disk brakes. Other types of bakes, such as band brakes, are used on tracked vehicles. Band brakes are employed in vehicle automatic transmissions with planetary gears for changing the planetary configuration and thus the transmission ratio [22] (for details on automatic transmissions, see Section 23.5.3.5).

Drum brakes have been firstly utilized on hydraulic actuated brake systems and have been the sole kind of brake in use until mid-fifties, when the disk brakes with part contact between disk and pads were employed by Jaguar [1] firstly in competition and then on mass production. Since then, disk brakes have become the common choice, while drum brakes have been relegated to the rear axle of low performances vehicles.

24.4.3.1 Drum Brakes

Drum brakes are realized by means of a drum located on the wheel hub and rotating with it. A pair of shoes, fixed with respect to the vehicle, is located inside the drum and is pressed to the drum by hydraulic actuators creating a tangential force on the drum. Different arrangements of the shoes are possible and shown in Table 24.1. Depending on shoe arrangements, the internal gain of the drum brake can be very high. In some arrangements, different internal gains are obtained for forward and reverse rotations [1,6,17,18].

Even if drum brakes have internal gains much higher than the disk brakes, their performances are poorer. This is due to many factors. Drum brakes have to be located inside the hub; thus, small brake diameters can be realized reducing the brake torque. For the same reason, the heat dissipation of these brakes is limited. Moreover, they greatly suffer thermal expansion that increases the internal diameter of the drum reducing the pressure between drum and shoes. The friction coefficient is not constant and, given the high internal gain, brake balancing problems can arise. A relatively high clearance is needed between shoes and drum, thus augmenting the volume of fluid needed to actuate the system and, consequently, reducing the hydraulic gain. Finally, drum brakes are prone to brake squeal.

Due to low manufacturing costs, drum brakes are employed on the rear axle of low-performance vehicles where thermal problems are much less relevant. Thanks to their high internal gain, they are also employed as parking brakes, even on heavy vehicles [1,6,18,21].

24.4.3.2 Disk Brakes

Disk brakes are composed of a rotating disk, called rotor, connected to the wheel hub and a couple of pads connected to a caliper attached to the stub axle. By means of hydraulic actuators, the pads clamp the disk generating a tangential force.

The caliper can be either fixed or floating. The fixed caliper (Figure 24.26a) has a fixed housing and the brake cylinders are located on both sides of the disk. This arrangement is highly stiff, ensuring low fluid displacements when operated. Since brake cylinder are located on both sides, large design space is required, and there are most employed on heavy passenger cars with rear drive with positive scrub radius.

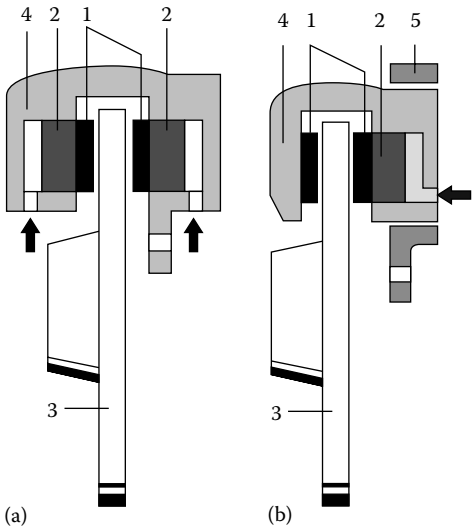

FIGURE 24.26 Disk brakes. (a) Fixed caliper and (b) floating caliper: (1) friction pads, (2) brake piston, (3) brake disk, (4) caliper, and (5) support. (Adapted from Bosch, *Automotive Handbook*, 7th edn., SAE, Warrendale, PA, 2007.)

In the floating caliper (Figure 24.26b), one or two hydraulic actuators are located at one side of the disk and the caliper is free to move axially. When the actuation force is applied, the reaction on the disk on the side of the actuators moves axially the caliper allowing for the contact between the other pad and the disk. Floating calipers require less design space and can be useful to locate properly the steering axis.

The clearance of disk brake is very small and it is guaranteed by the sealing ring of the piston that retracts the piston of a certain amount of space when the braking pressure is removed (rollback).

During braking, most of the released heat is absorbed by the disk, which can reach very high temperatures (up to 700°C). Most thermal problems of the disk brakes are related to the reduction of friction coefficient of the linings that can release vapor at high temperature (fading), to the damaging of localized zones of the disk due to microstructural modification (hot spots), to the development of bubbles in the fluid (especially for fixed calipers), and to the deformation of the rotor bell that inclines the disk with respect to the pads (dishing). To reduce disk temperature, ventilated disk can be employed [1,6,9,18,21,23].

A very important issue regarding brake disk is the vibration of the disk while braking. This problem can cause physically perceived low-frequency vibration or high-frequency vibration perceived as noise. This argument will be thoroughly explained in the last sections of this chapter.

24.5 RETARDERS

The speed regulation of heavy commercial vehicles driving downhill requires the dissipation of the potential energy of the vehicle. As shown in Equation 24.4, the thermal power that must be evacuated from the brake system is a linear function of the velocity and can be of the order of several hundreds of kilowatts. The friction brakes employed as service brakes are not able to dissipate this amount of thermal power for the time needed to run down the slope. In this situation, retarders (or continuous braking systems) are required.

Retarders are conceived in order to allow the driver to continuously regulate the speed of the vehicle when driving downhill without suffering any damage from thermal dissipation.

Three different types of retarders can be employed, namely, engine brake, hydrodynamic retarder, and electrodynamic retarder. The engine brake is also called primary retarder as it is applied to the drive input shaft, while the other two are called secondary retarders as they are applied to the drive output shaft.

Internal combustion engines, when the throttle is closed, are driven by the transmission and absorb some energy. To increase the negative torque of the dragged engine, it is sufficient to add a throttle in the exhaust pipe, as close as possible to the exhaust manifold. When required, the throttle can close the exhaust manifold; the exhaust gas remains in the exhaust pipe and during the fourth cycle of the engine (exhaust stroke), the piston has to compress the gas. After the compression, the compressed air is trapped in the exhaust pipe by the closure of the exhaust valve and cannot do positive work in the expansion cycle of the engine. In case, by adding a decompression valve, also the second cycle of the engine (compression stroke) can be used to dissipate energy. By this simple device, the engine is able to absorb up to 80%–90% of the engine power, depending on the engine speed [1,3,5,6,18].

The hydrodynamic retarder heats a fluid to dissipate the kinetic energy of the vehicle. A hydrodynamic retarder has a design similar to the one of a fluid coupling. A rotor (which has the function of a pump in the fluid coupling) is connected to a drive shaft, while a stator (which has the function of the turbine) is connected to the retarder housing. The rotor, driven by the drive shaft, applies a torque to the stator as a function of the speed of the vehicle. The stator cannot rotate and all the energy is dissipated and transformed into heat. The heat is then evacuated through the cooling system of the engine. By regulating the level of the fluid in the rotor–stator system, it is possible to regulate the torque of the retarder. Up to the 200% of the nominal engine power can be dissipated by such retarders. However, for a long working period of the retarder, the cooling system performance

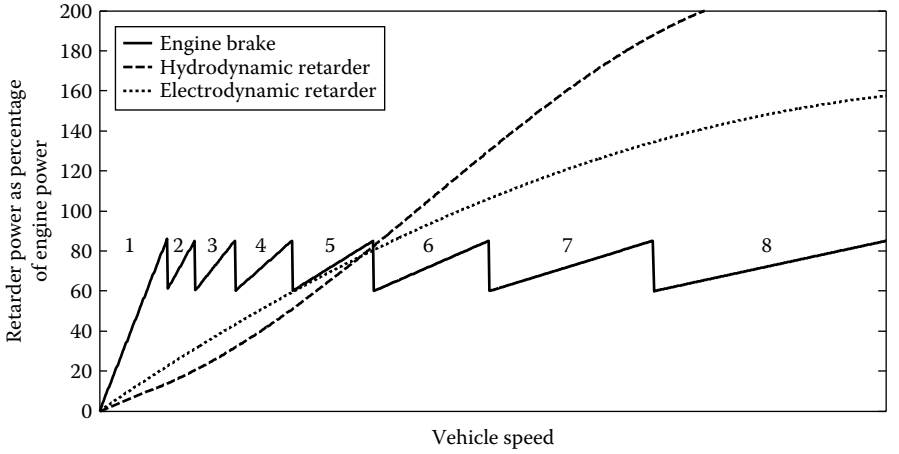

FIGURE 24.27 Retarders' braking power as a function of vehicle speed. Numbers refer to selected gear.

could be not sufficient and the retarder action has to be reduced. The advantages of such retarders are that it is impossible to lock the wheels as the torque vanishes when wheels approach locking, the retarder has virtually no wear, the load on the transmission is reduced, and the operation is less noisy than that of engine brake [1,3,5,6,18].

Electrodynamic retarders make use of eddy currents to dissipate energy. A disk, with excitation coils, is used as a stator. The rotor, connected to a drive shaft, is composed of two disks located at each side of the stator. When the coils are fed with current, a magnetic field is generated. The rotor, by rotating in the magnetic field, generates eddy currents in the coils of the stator. The current is then turned into heat and then dissipated. The amount of braking power depends on the excitation current of the stator and on the speed of the rotor [1,3,5,6,18].

Figure 24.27 shows the typical braking power of the three types of retarders as a function of speed. Notice that the engine brake, as it is applied to the input drive shaft, has a braking power depending on the chosen gear. This allows for good performances at lower speed and it is widely employed in public-transport buses. The secondary retarders have good performances at high speed, and they are mostly employed on long-distances truck for adjusting speed during high-speed downhill traveling.

24.6 NOISE VIBRATION HARSHNESS

The recurring studies on disk brake vibration and/or noise indicate that such a problem is still an elusive issue. Modeling brake vibration and/or noise involves many design variables; additionally, many harsh operational and environmental conditions have to be taken into account. Within such uncertain conditions, brake vibration and/or noise may be generated and occur. Understanding the contact mechanisms, the tribology, the nonlinear dynamics, the interactions between the brake system and the suspension system, and so forth is essential.

Even if a large amount of research has been performed and the main sources have been understood; a final solution for brake squealing seems to be far away. The only way to validate a noiseless brake system is an integrated process with a mixture of both experimental and analytical activities.

The only analytical approach available at the moment for an industrial application is the complex eigenvalue extraction in a full FEM braking system model. It seems to be (although the theoretical limitations), for practical issues, the only possibility for a robust design investigation. Brake squeal solutions in fact, can be better evaluated through a robust design approach.

Brembo has also adopted an FEM model and the complex eigenvalue analysis. This tool (conveniently tuned using experimental tests) is able to foresee the most critical situations and the tendencies.

The main goal of such a simulation is the "global" design of the components of the system (stiffness, mass distribution, modal participation, and so on) and should be used in a very early stage of the design and product development.

Unfortunately, a robust solution would frequently require that the whole suspension and braking system design would be oriented to this, especially for low frequencies squeals (1500–2500 Hz). This is not always possible: Suspensions and knuckles are designed for different targets and brake systems have to fulfill several constraints (weight, fluid consumption, thermal loads, performances in terms of friction, and, obviously, costs).

Moreover, the behavior of the friction material in terms of noise propensity is quite unpredictable because of the spread of operational conditions during braking (pressure, temperature, wear, etc.).

The global scenario is actually quite complex.

This leads to the necessity (in addition to analytical tools) of a product development made of bench and vehicle tests. During product development, in a reliable way, some countermeasures can be tested and selected that normally do not impact on global design and performances (added masses, chamfer on friction surfaces, shims, etc.) and a fine tuning with simulation results can be reached (tools as modal acquisitions and laser vibrometry are fundamental in order to reach a high correlation).

In conclusion, an integrated approach has to be implemented: analytical tools for the first design phase to get the global design of components and a fine bench and vehicle tuning in order to fix all possible squealing occurrences.

24.6.1 NVH State-of-the-Art Reviews

Many state-of-the-art reviews on vibration and/or noise generated by brakes have been produced. From these works, it is possible to understand that avoiding brake vibration and/or noise is still a cumbersome issue. Much progress has been made on understanding the brake vibration and/or noise mechanisms and causes. However, new mechanisms (unreferenced even in the recent state-of-the-art reviews) can still be found [24] or envisaged [25–27].

The following authors have written their respective state-of-the-art review, focusing on a particular point of view:

- North (seemingly the first review on brake vibration and/or noise [28])
- Nishiwaki (the first modern state-of-the-art paper on brake vibration and/or noise [29])
- Crolla and Lang (a comprehensive state-of-the-art review focusing on future issues regarding FEM [30])
- Ibrahim (two detailed state-of-the-art review focusing on disk vibration modes and nonlinear effects such as chaos [31] and [32])
- Yang and Gibson (a comprehensive review with emphasis on materials [33])
- Mottershead (a review on the dynamics of disks subjected to frictional loading, with particular emphasis on the mathematical modeling [34])
- Papinniemi et al. (a comprehensive review with emphasis on acoustics [35])
- Kinkaid et al. (a prominent state-of-the-art review on brake squeal [36])
- Ouyang et al. (a useful complement to the previous state-of-the-art review [37])
- Chen (a review from a OEM perspective [38])
- Hoffman and Gaul (a review stating well the objectives and the still open issues, with a timely focus on the future [25])
- Cantoni et al. (a comprehensive review on brake squeal modeling and testing techniques [39])

Two SAE (Society of Automotive Engineers) books [1,40] have been published focusing on brake vibration and/or noise.

In the appendix (Table 24.8), a table is presented where all of the papers cited in this chapter are sorted according to the sections in which this chapter has been subdivided.

24.6.2 Phenomena and Influencing Factors

In general, brake vibration and/or noise can be classified into many categories based on either the occurring frequencies or excitation sources (Papinniemi et al. [35], Kinkaid et al. [36], Ouyang [37], Chen [38], Dunlap [41]). We will here classify vibration and/or noise as a function of frequency. Excitations or mechanisms generating vibration and/or noise will be dealt with in the sequel.

According to [42], depending on the frequency of vibration and/or noise occurrence, there are three main categories, namely, low-frequency vibration and/or noise (0–1,000 Hz, subdivided into three subcategories), low-frequency squeal noise (1,000–3,000 Hz), and high-frequency squeal noise (3,000–15,000 Hz).

As shown in Figure 24.28, in the low frequency range (0–1000 Hz), there are two different types of structural vibrations, named judder and groan, and their associated airborne noise called moan and howl (or hum).

With respect to the huge number of publications dealing with high-frequency vibration and/or noise, (i.e., brake squeal, see Section 24.6.5.3), judder and groan received much less attention. However, this type of vibration and/or noise receives a growing interest from the automotive industry because it primarily affects the comfort (the driver experiences judder as vibrations in the steering wheel, brake pedal, and floor, see Table 24.2) and could lead, when impacting on inexperienced drivers for the first time, to faulty reactions and reduced driving safety [43–47].

The vibration frequency of the brake judder (0–100 Hz) is proportional to the wheel speed and therefore to the velocity of the vehicle. It is common to relate the judder frequencies to the wheel speed (e.g., frequencies at twice the number of wheel rotations per second are called second-order judder) [45].

Table 24.2 summarizes the judder phenomenon referring to excitation sources, transfer system, and effects.

Groan (often called creep groan [48]) generally occurs at low vehicle speed and occurs with cold brakes and high humidity (Figure 24.29). Figure 24.30 summarizes the factors that contribute to generate a creep groaning brake.

From literature [42], the squeal noise is classified as a function of frequency. There is a *low-frequency squeal* and a *high-frequency squeal* (see Figure 24.28). Low-frequency squeal is generally classified as a noise having a narrow frequency bandwidth in the frequency range above 1000 Hz, while high-frequency brake squeal is typically classified as a noise occurring at frequencies above 3 kHz. Since it is a range of frequency that affects a region of high sensitivity in the human ear, high-frequency brake squeal is considered the most annoying type of noise. The so-called wire brush noise occurs above 1 kHz.

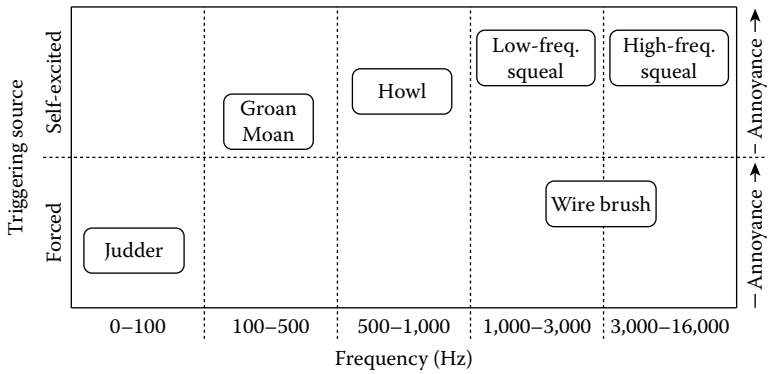

FIGURE 24.28 Brake noise classification based on the frequency of occurrence and excitation source. (From Dai, Y. and Lim, T.C., *Appl. Acoust.*, 69, 196, 2008.)

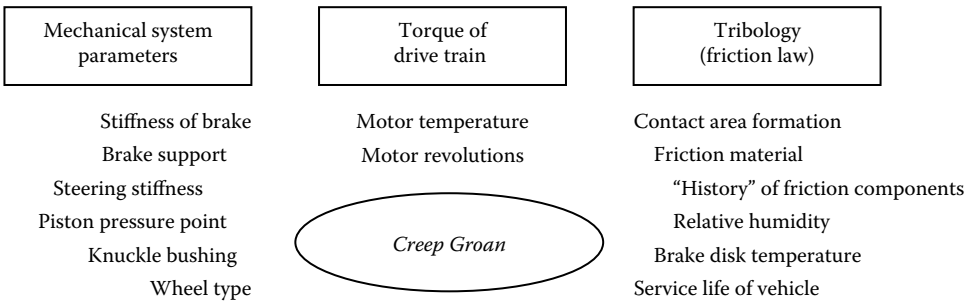

FIGURE 24.30 Factors influencing creep groan phenomenon. (Adapted from Brecht, J. et al., Mechanisms of brake creep groan, Technical Report, SAE, Paper No. 973026, Warrendale, PA, 1997.)

Nevertheless, there is no a unique idea about the frequency that divides the first phenomenon from the second one. For this reason, many authors [49,50] consider the number of the nodal diameters (which characterize the vibration modes of the disk) as a way of classification for the brake squeal noise.

In addition, the most significant difficulty in brake research is the fugitive nature of brake squeal (it can sometimes be non-repeatable) [36,51]. A brake system may not always squeal given the "same"

conditions [40]. Alternatively, small variations in operating temperature, brake pressure, rotor velocity, or coefficient of friction may result in differing squeal propensities or frequencies [38].

24.6.3 Experimental and Computational Activities

24.6.3.1 Experimental Activities

24.6.3.1.1 Displacement/Vibration

Brake tests represent a crucial method to characterize the vibrational behavior of a brake system and of its components in order to provide a ready solution for vibration and/or noise problems. However, it should be noted that the squeals cannot be reproduced or cannot be reproduced at all working conditions.

A number of different test procedures (often proprietary of OEM or brake manufacturers) exist to assess the vibration and/or noise propensity of a brake system. In such procedures, it is difficult to include all conditions under which a brake vibration and/or noise might occur due to the constraints of time and cost (e.g., it is difficult to reach some conditions of both cold and high humidity [38]).

A preliminary and fundamental analysis to detect brake vibration is just measuring displacements/velocities of the brake components. Such displacements are often very small and are of the same order of magnitude as the surface irregularities of the disk [52]. Such analyses begun few decades ago and are continuously updated. In Table 24.3, the measured displacements of a squealing disk are reported.

Optical techniques for deriving addressed displacements include

- Double-pulse holographic interferometry (DPHI) and speckle interferometry. In [36,53], many brief reports are given. These methods are used to examine the modes of squealing brakes. DPHI dominated the literature until the use of another optical technique (electronic speckle pattern interferometry [ESPI]) appeared.
- ESPI and laser vibrometer became popular in the late 1990s.
- Scanning laser vibrometer (SLV) is used to identify locations with large amplitude and ideal to identify hot spots (for more details, see [53]).

TABLE 24.3
Measured Displacements in a Vibrating Brake Disk

	Displacement Value (μm)		
Displacement Component	**Maximum**	**Minimum**	**Mean**
Upper disk section

Source: Fieldhouse, J.D. et al., *Proc. IMechE*, *Part D*, 222, 1121, 2008.

The recently developed laser vibrometers can measure 3-D velocity distributions with three laser vibrometer heads. The system is able to capture the out-of-plane motion during squeal inducing from any in-plane vibration. Similar to 3-D laser vibrometer, a 3-D pulsed-laser ESPI also uses three cameras to deduce 3-D.

Another approach is the combination of accelerometer with a laser technique. Small accelerometer can be instrumented inside rotor fins in three directions as reported in [38,51].

In the literature devoted to experimental studies of brake vibration and/or noise, few details are provided on the actual brake assembly under test. As a result, given the wide range of designs and material selections that are possible, it is almost impossible to compare the results derived from different research groups. Together with Kinkaid [36], we summarize the conclusions reached in the experimental literature on brake vibration and/or noise. A braking system can squeal at a number of distinct frequencies with amplitude of the order of microns (actual deformations due to sustained brake force can reach the order of 0.1 mm); standing or traveling wave can run along the disk, rotating speed, and brake pressure and coefficient of friction of the pad can influence brake vibration and/or noise (see Figure 24.31).

The definition of the parameter values to be introduced in the mathematical models is a typical experimental activity. A basic method for friction measurement is reported in [54]. Such a method implies friction to be a parameter and is more suited for tribological scientific studies than applications involving dynamical system models.

The orthotropic characteristic of the pad liner (Young's modulus higher in the vertical than in the horizontal—contact surface—direction) can be measured by means of nonstandard material testing techniques ([55], Chapter 12); five independent elastic constants (Equation 24.56) must be measured in order to completely determine the (linear) mechanical properties. Ultrasound techniques have been adopted successfully by D. Yuhas and M. Yuhas to measure the elastic constants that are reported in Figure 24.31.

$$\begin{bmatrix} \sigma_x \\ \sigma_y \\ \sigma_z \\ \tau_{xz} \\ \tau_{yz} \\ \tau_{xy} \end{bmatrix} = \begin{bmatrix} c_{11} & c_{12} & c_{13} & 0 & 0 & 0 \\ c_{12} & c_{11} & c_{13} & 0 & 0 & 0 \\ c_{13} & c_{13} & c_{33} & 0 & 0 & 0 \\ 0 & 0 & 0 & c_{44} & 0 & 0 \\ 0 & 0 & 0 & 0 & c_{44} & 0 \\ 0 & 0 & 0 & 0 & 0 & \frac{1}{2}(c_{11} - c_{12}) \end{bmatrix} \begin{bmatrix} \varepsilon_x \\ \varepsilon_y \\ \varepsilon_z \\ \gamma_{xz} \\ \gamma_{yz} \\ \gamma_{xy} \end{bmatrix} \tag{24.56}$$

Temperature has an important effect on stiffness parameters of Figure 24.32; a reduction ranging from 20% to 35% can be expected raising the temperature from 20°C to 200°C [40].

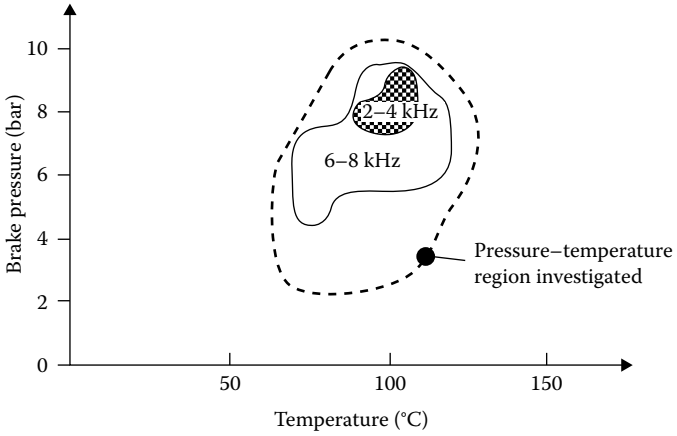

FIGURE 24.31 An example of the interaction of brake pressure and temperature on brake squeal. (Adapted from Bergman et al., *Tribotest J.*, 5(3), 265, 1999.)

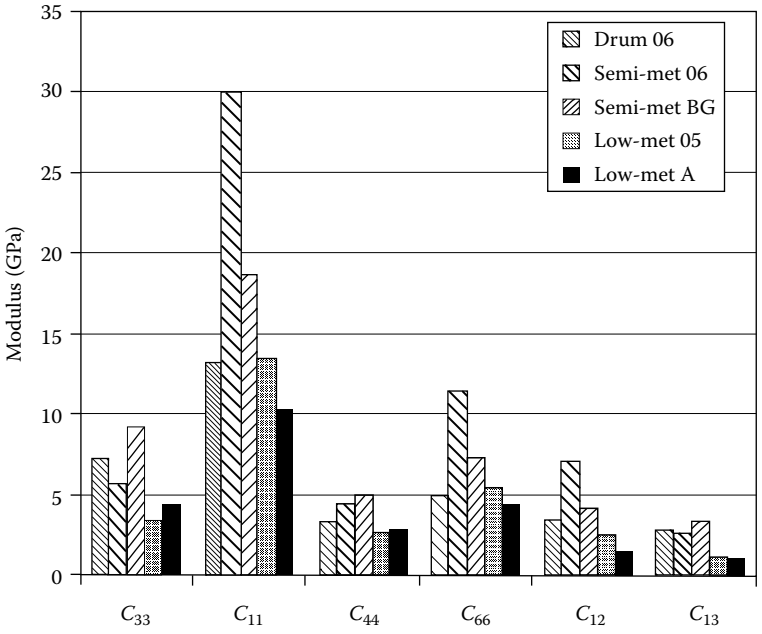

FIGURE 24.32 Comparison of moduli of friction material. (Adapted from Chen, F. et al., *Disc Brake Squeal—Mechanism, Analysis, Evaluation, and Reduction/Prevention*, SAE International, Warrendale, PA, December 2005, Chapter 12, ISBN 978-0-7680-1248-4.) The values c_{ij} $(i, j = 1, 6)$ refer to the components of the stiffness matrix in Equation 24.56 where $\sigma_x\sigma_x\sigma_x\tau_{xy}\tau_{yx}\tau_{xz}$ are the stresses and $\varepsilon_x\varepsilon_x\varepsilon_x\gamma_{xy}\gamma_{yx}\gamma_{xz}$ are the deformations.

A recent SAE test procedure (J2598, [56]) on pad damping measurement provides a robust procedure with a certain degree of reproducibility. It proposes using a small impact hammer, in order to avoid attachments like shakes (although the effect of the contact cannot be totally eliminated), and a small accelerometer. An alternative way to get test results with consistent repeatability is to use noncontact excitation (magnetic force, one of the first researchers that used it were Nishiwaki et al. [57]) and noncontact signal pickup (laser vibrometer).

24.6.3.1.2 Friction

Bergman, Eriksson, Jacobson, and coworkers correlated changes in μ_d (coefficient of friction) to the number of brakings and squeal generation. Their results are summarized in [58–67] and are consistent with what is reported in [26]. They noted that μ_d gradually increased from a value just above 0.2 and, after over 1000 brakings, began to plateau at a value below 0.6. As μ_d increased beyond a critical value, they observed that squealing behavior sharply increased (see Figure 24.33).

In [36], experimental results referring to the effects of various solid lubricants, influence of humidity, and pad morphology on brake squeal generation is reported.

24.6.3.2 Computational Activities

Computational activities are crucial for understanding brake vibration and/or noise. Simulation and analysis methods may be divided into two big categories: *complex eigenvalue analysis* in the frequency domain and *transient analysis* in the time domain [37]. The transient results can be converted to the frequency domain by a Fourier transform, provided that the phenomenon is periodic, which is not always the case.

The complex eigenvalue analysis studies the brake vibration and/or noise phenomenon at quasi-static steady sliding conditions. The equations of motion derived from a mechanical model are linearized.

When the effects of nonlinearities are present and effective, only a time-domain simulation is the proper way to analyze the dynamic behavior of the brake system. Table 24.4 summarizes the main aspects (positive and negative) of these two approaches that were stated and dealt with in [37,68–73].

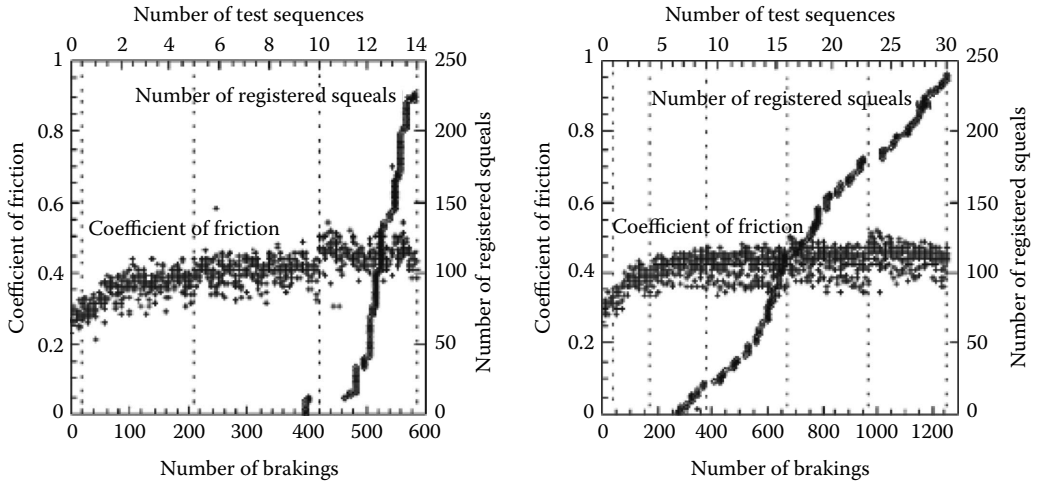

FIGURE 24.33 Cumulated occurrence of squeals and coefficient of friction μ_d as a function of the number of brakings. (From Bergman, F., Tribological nature of squealing disc brakes, PhD thesis, Uppsala University, Uppsala, Sweden, 1999; Eriksson, M. and Jacobson, S., *Tribol. Int.*, 33, 817, 2000.)

24.6.3.3 Both Experimental and Computational Activities

Since late 1930 until 1990, few contributions have been really effective in matching computation data and experimental results. In the last two decades, the ever-increasing computation power has allowed researchers to face the simulation of the complex problem of brake vibration and/or noise.

The appendix (Table 24.8) reports a list of papers dealing with both experiments and computer simulations.

A comprehensive study [74] aims at improving complex and simple brake models by means of experimental activities. In particular, it is found (by an FEM 3-D thermomechanical simulation together with a detailed analysis of experimental results) that the thermoelastic "buckling instability" is a significant factor causing hot spotting and hot judder [47].

A number of researchers have built laboratory brake assemblies in order to control the many uncertainties and shape details that are present in an actual brake and that are difficult to be modeled. In [75], a pin-on-disk (POD) system is used that provides desirable qualities of mechanical simplicity and controllable dynamic characteristics; the predicted unstable modes were actually unstable, but the stable modes could evolve toward instability. In [76], the interaction between a disk brake and its pads has been treated analytically and experimentally by means of a laboratory brake. Transverse and circumferential disk–pad oscillations were considered under deterministic and random friction coefficient. In [77], the authors study a simple lumped mathematical model and propose, by means of simple test rig (in which a simple L-shaped beam was used), two experimental methods for the prediction of squeal noise, the results rely on accurate definition of friction and tangential/contact stiffness. In [78,79], in-depth scientific analyses were undertaken focusing on a simple brake system built to control the parameters influencing brake vibration and/or noise. The crucial role of time-domain simulation was highlighted.

24.6.4 Models

24.6.4.1 Friction

In [36], an illuminating review on the relationship friction–braking systems is presented. Besides the classical books on tribology [80–83], recent contributions on friction for control application are reviewed in [84]. From [84], it appears that the historical friction models by Amontons, Coulomb, and Stribeck should be improved by state-dependent friction laws; indeed, friction has a dynamic behavior. Phenomena such as predisplacement, rate dependence, and hysteresis have been observed

experimentally and are reproduced only by dynamic models [84]. The Dahl model [85] is a state-dependent friction law defined by

$$F = F_c\left(1 - e^{-\sigma_0 |x|/F_c}\right)\mathrm{sgn}\left(\frac{dx}{dt}\right) \tag{24.57}$$

where
F is the force
F_c is the Coulomb friction
x is the displacement
σ_0 is the stiffness

After differentiation at $x = 0$,

$$\frac{dF}{dx} = \sigma_0\left(1 - \frac{F}{F_c}\mathrm{sgn}\left(\frac{dx}{dt}\right)\right) = \sigma_0\left(1 - \frac{F}{F_c}\mathrm{sgn}(\nu)\right) \tag{24.58}$$

Introducing $z = F/\sigma_0$ as a state variable (Equation 24.59),

$$\frac{dz}{dt} = \frac{1}{\sigma_0}\frac{dF}{dx}\frac{dx}{dt} = \frac{1}{\sigma_0}\frac{dF}{dx}\nu = \nu - \frac{\sigma_0}{F_c}|\nu|z \tag{24.59}$$

At steady state,

$$F_{ss} = \sigma_0 z_0 = F_c\,\mathrm{sgn}(\nu) \tag{24.60}$$

the Coulomb friction force is found. The Dahl model does not contain Stribeck effect (i.e., the coefficient of friction decreasing with increasing velocity) but the LuGre model does [85]. The LuGre friction model (to be compared with the Dahl model introduced before) reads

$$\dot{z} = \upsilon - \sigma_0\frac{|\upsilon|}{g(\nu)}z = \upsilon - h(\upsilon)z; \quad F = \sigma_0 z + \sigma_1\dot{z} + f(\upsilon) \tag{24.61}$$

where
υ is the velocity between the surface in contact
σ_1 represents microdamping
$f(\upsilon)$ represents macrodamping (typically $\sigma_0\upsilon$)

At steady state,

$$F_{ss}(\upsilon) = g(\upsilon)\mathrm{sgn}(\upsilon) + f(\upsilon) \tag{24.62}$$

The LuGre model may be considered a passive system if and only if

$$\sigma_2 > \sigma_1\frac{F_s - F_c}{F_c} \tag{24.63}$$

More details can be found in [85] with a discussion on the nonlinear dynamics of stick-slip phenomenon (Figure 24.34).

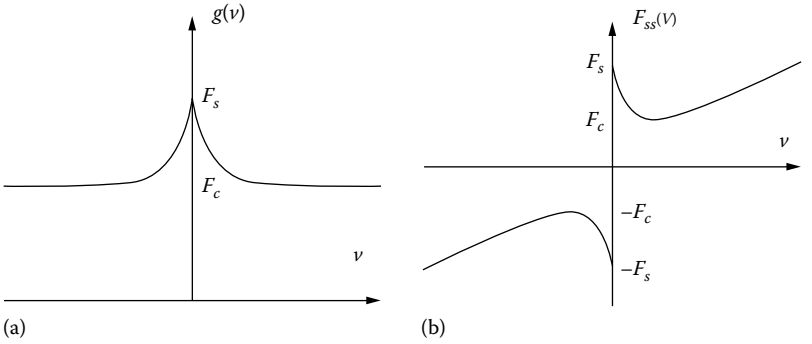

FIGURE 24.34 Functions that characterize the LuGre friction model. (a) shows the function $g(v)$ that captures Coulomb friction and the Stribeck effect, while (b) shows the steady-state friction function $F_{ss}(v)$, where $f(v)$ represents viscous friction, typically, $f(v) = \sigma_2 v$. F_c is the Coulomb friction force, whereas F_s sdenotes the stiction force. Asymmetric friction behavior can be obtained by letting $g(v)$ and $F(v)$ have different shapes for positive and negative velocities. (Adapted from Dahl, P.R., *AIAA J.*, 14, 1675, 1996.)

The measurement of friction is defined by a well-defined standard [54]. In [86], it was pointed out how difficult it is to derive the Stribeck characteristics from essentially quasi-static measurements.

From experience, the *mean* friction coefficient in the contact region between pad and disk ranges from 0.2 to 0.7, with more common values between 0.3 and 0.6. Such mean values refer to a broad contact area and are not to be expected to be smoothly distributed on the contact area. On single small contact regions, the friction coefficient measurement can be made with standard laboratory dynamometers, called tribometers. Such a measurement is interesting from the material science perspective; it has, at the moment, limited significance for common engineering applications, such as the measurement of the friction between the pad and the disk. The contact pressure ranges from 0 to 4 MPa within the contact area between pad and disk. It depends on rotor temperature that rises up to 500°C.

In [27,87], a stochastic approach was attempted to model friction brake forces, since it is evident the random nature of brake vibration noise. The contact surface and the relative speed were found to be random, leading directly to random friction force. A stochastic definition of friction was introduced as

$$\mu = \left(\mu_k + \frac{\mu_s - \mu_k}{\cosh(\alpha v_{rel})} \right) \tanh(\beta v_{rel}) \tag{24.64}$$

where

μ_s and μ_k are the static and kinetic friction coefficient, respectively
α and β are shape parameters
v_{rel} is the relative velocity
the friction coefficient is considered a random variable with a Gaussian white noise process of mean μ_k

The implementation of a stochastic equivalent (mean) friction coefficient might explain the elusive nature of brake vibration and/or noise, but the physical meaning could be lost. A much more interesting approach that captures the friction coefficient (random) variation by devoting attention to phenomena occurring in the micro- (micron) or meso- (micron millimeter) scale is due to the scientific research by Ostermeyer on the topic (see [26] where previous papers are cited). In [26], the variation of the friction force is related to the synchronized micro vibrations of the hard particles appearing on the contact surface between the pad and the disk. An example of a mechanical model is shown in Figure 24.35 where the hard particles are elastically connected both to the polymeric substrate and to each other. A macroscopically varying friction can be computed.

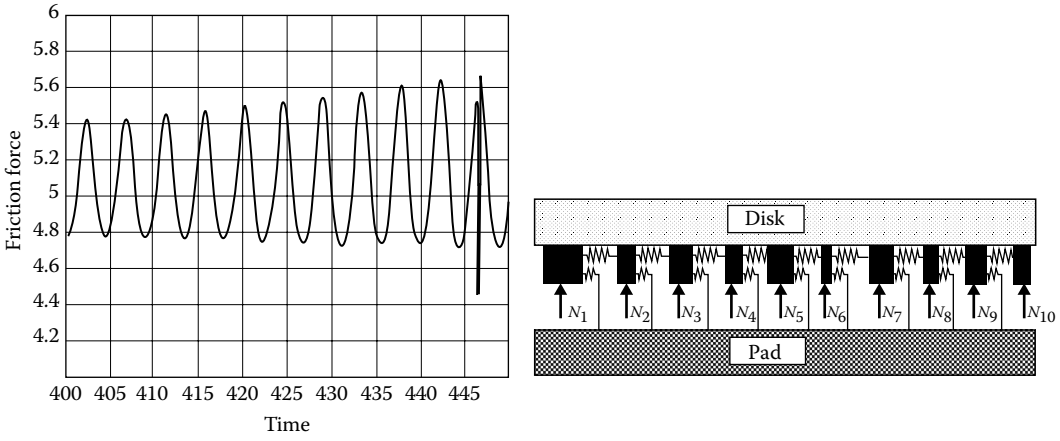

FIGURE 24.35 Variable friction force acting on the disk as a result of many interconnected vibrating masses. (Adapted from Ostermeyer, G.-P., On tangential friction induced vibrations in brake systems, Technical Report, SAE, Paper No. 2008-01-2580, Warrendale, PA, 2008.)

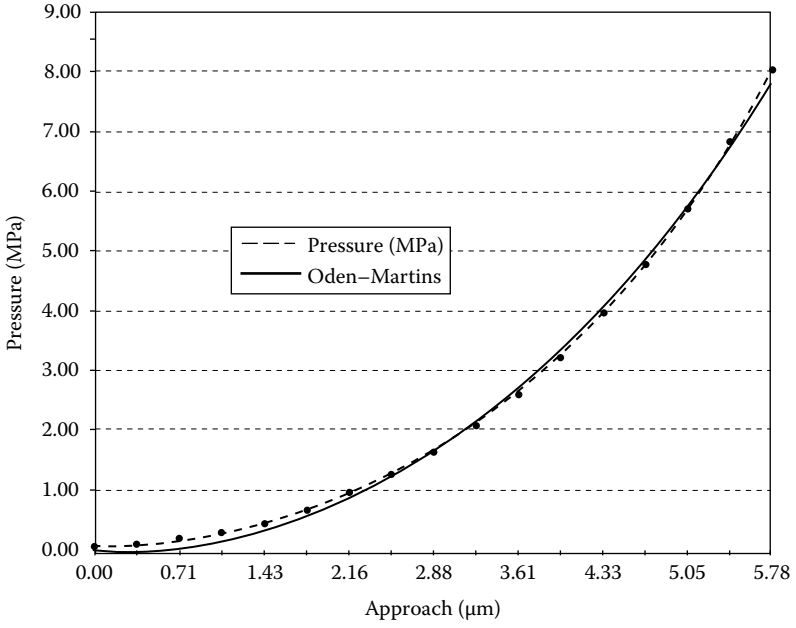

FIGURE 24.36 Increasing of contact pressure as a function of penetration. (Adapted from Chen, F. et al., *Disc Brake Squeal—Mechanism, Analysis, Evaluation, and Reduction/Prevention*, SAE International, Warrendale, PA, December 2005, Chapter 2, ISBN 978-0-7680-1248-4.)

In [40], Chapter 2 deals with surface topography and surface asperity deformation. A correlation between asperity-based contact models and phenomenological contact models is given. The Oden–Martins constitutive model for contact and friction is introduced that is based on normal compliance law. Such a model is very effective for capturing the nonlinear effect of increasing contact pressure with penetration (Figure 24.36).

24.6.4.2 Lumped-Parameter Models

The first attempts in understanding the causes of brake noise have been made through the study of simple analytical few DOF system models, called "minimal models" or "lumped-parameter models"

(Jarvis and Mills [88], Millner [89], Earles and coworkers [90–94], Nishiwaki [57,95], Brooks [96], Hultén and Flint [97], El-Butch and Ibrahim [32,98], Rudolph and Popp [99,100,], Popp et al. [101], Chowdhary [102,103], Hoffmann and Gaul [104]).

Such models are approximations of the actual system and aggregate components seen as discrete elements, like rigid bodies connected by springs and dampers. Literature is full of examples of minimal models ([25,36]) in particular for the study of brake squeal noise. A key issue concerns the information that we can extrapolate from these models and reliability of the results.

Basically, in [104], two possible categories of models were suggested: (1) analysis models for the understanding of vibration phenomena and (2) models derived from large-scale systems. The first group includes models that are used to reveal the physical mechanisms that lead to the brake vibration and/or noise, such models usually can give only qualitative and phenomenological results. Instead, the latter group includes models that have the aim to obtain quantitative results (often for control application [105,106]) but the derivation of such models is still an open question. The early academic studies (see Section 24.6.1) can be clearly placed in the first category because they tried to understand and to explain the phenomenon of vibration and/or noise; some models were validated with experimental analysis.

A number of "minimal models" are presented that appear in the literature. For the sake of simplicity, we will only describe, for each model, the general characteristics and, referring to the linearized equations of motion, we will report only the mass matrix [*M*], the damping matrix [*C*], the stiffness matrix [*K*], and related equations of motion:

$$[M]\cdot\underline{\ddot{z}}+[C]\cdot\underline{\dot{z}}+[K]\cdot\underline{z}=\underline{0} \tag{24.65}$$

The most widely studied model (not only within the brake noise problem) is depicted in Figure 24.37, where the single DOF model of friction oscillator is represented.

Many authors (i.e., [84,107,108]) have dealt with this simple model consisting of a mass *m* restrained by a linear spring (stiffness *k*) and by a linear viscous damping element whose constant is *c*. The mass is pressed by a vertical force *F* with a moving belt that runs at a *given* speed *v*. Obviously, we have a single equation of motion:

$$m_{TOT}\ddot{x}+c_{TOT}\dot{x}+k_{TOT}x=0 \tag{24.66}$$

Depending on the physical parameters of the system, this model can be unstable. Matsui et al. [109] proposed a simple model, represented in Figure 24.38, trying to explain the onset of squeal noise based on a friction law with μ depending on *v*.
Matrices of linearized equations of motion are

$$\underline{z}=x \qquad [M]=m \qquad [K]=k \qquad [C]=c-Nb$$

It is clear that the sign of the term $c-Nb$ determines if the system can be asymptotically stable or unstable. For Matsui and Murakami, the basic parameters that are affecting the stability of the system are the damping coefficient *c*, the vertical force *N*, and the friction slope *b*.

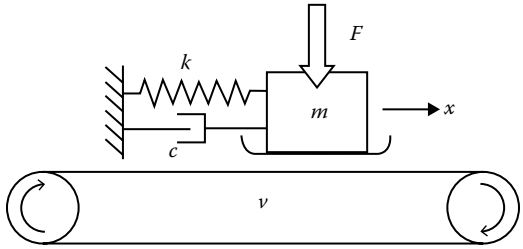

FIGURE 24.37 Single DOF model of friction oscillator.

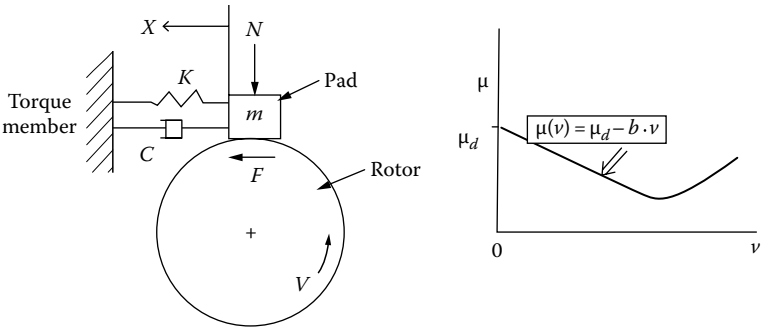

FIGURE 24.38 Model by Matsui and Murakami. (Adapted from Matsui, H. et al., Analysis of disc brake squeal, Technical Report, SAE, Paper No. 920553, Warrendale, PA, 1992.)

Hetzler et al. [110,111] found that the transition behavior between stable and unstable states of sliding motion is more complex than suggested by the classical stability analysis and involves bifurcation (sub- or supercritical) that depends on the system's parameters.

Despite its simplicity and the importance of certain phenomena that can be explained by means of it, the models in Figures 24.37 and 24.38 are definitely not suitable to describe brake vibration and/or noise.

One of the most important "minimal models" in the history of the study of brake squeal is the binary flutter model produced by North in 1972 [112]; such a model was simplified by the same author in 1976 [28]. The model in [28] is a 2-DOF (y and θ) disk, modeled as a rigid body of mass m, thickness $2h$, and moment of inertia J. The disk is assumed to be sandwiched between two layers of friction material, each of length L, of total and stiffness k_1 and $k_2 = k_1L^2/3$. N_0 is the static preload between the pads and the disk and the friction follower forces F_1 and F_2 acting on the disk are (Figure 24.39):

$$F_1 = \mu(k_1 y + N_0), \quad F_2 = \mu(-k_1 y + N_0) \tag{24.67}$$

As mentioned, this model was innovative because it was the first one to consider brake squeal as a self-excited vibration induced by friction forces with constant friction μ. The linearized equations of motion (referring to the steady equilibrium position $y = 0$, $\theta = 0$) are as follows:

$$\underline{z} = \begin{bmatrix} y \\ \theta \end{bmatrix} \quad [M] = \begin{bmatrix} m & 0 \\ 0 & J \end{bmatrix} \quad [K] = \begin{bmatrix} k_t + k_1 & 2\mu N_0 \\ -2\mu h k_1 & k_r + k_2 \end{bmatrix}$$

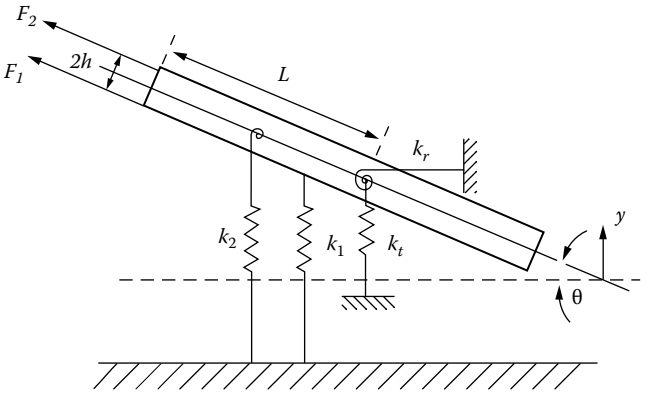

FIGURE 24.39 Model by North. (Adapted from North, M.R., Disc brake squeal, in *Braking of Road Vehicles*, Automobile Division of the Institution of Mechanical Engineers, Mechanical Engineering Publications Limited, London, U.K., pp. 169–176, 1976.)

North observed that the non symmetry of the matrix [*k*] could bring mode-coupling instability or binary flutter. Such an instability occurs if two conditions (Equation 24.68) are verified: The first condition always holds; the second depends on the system's parameter values:

$$(-2\mu h k_1)(2\mu N_0) < 0 \tag{24.68a}$$

$$\frac{1}{mJ}((k_t + k_1)J - (k_r + k_2)m)^2 \le 16\mu^2 h k_1 N_0 \tag{24.68b}$$

Despite the simplicity of this model, which does not include damping, an important result is achieved: Increasing the coefficient of friction μ causes a greater propensity to flutter instability and then to brake vibration and/or noise.

Another important model is the POD model presented by Earles and coworkers: in this model (Figure 24.40), the disk is represented by a rigid body mass *M*; the pad has a rigid body mass *m* and inertia moment J. The two bodies are in contact through a pin placed at characteristics lengths l_C and l_G. Before considering the contact constraint, this model has 3 DOFs (x_d, x_p, φ), but as the pin must remain always in contact with the disk, the model has only 2 DOFs. The coefficient of friction μ in this model is constant.

The equations of motion are

$$\begin{aligned} M\dot{x}_d + Kx_d &= -F \\ m\ddot{x}_p + k_t x_p &= F \\ J\ddot{\varphi} + k_\varphi \varphi &= \mu F l_G + F l_C \end{aligned} \tag{24.69}$$

The contact constraint equation is

$$x_d = x_p + l_C\varphi$$

$$\underline{z} = \begin{bmatrix} x_p \\ \varphi \end{bmatrix} \quad [M] = \begin{bmatrix} M+m & Ml_C \\ \mu l_G M + l_C M & J + \mu l_G l_C M + l_C^2 M \end{bmatrix} \tag{24.70}$$

$$[\boldsymbol{K}] = \begin{bmatrix} K + k_t & Kl_C \\ \mu l_G K + l_C K & k_\varphi + \mu l_G l_C K + l_C^2 K \end{bmatrix}$$

This model is based on the sprag-slip theory (introduced without a consistent mathematical formulation referring to equations of motion by Spurr [113]), and its greatest innovation has been to consider for the first time the rotational motion of the pad and not just its translational motion.

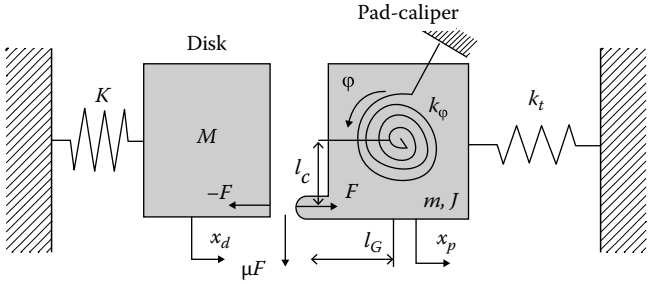

FIGURE 24.40 Model by Earles. (Adapted from Earles, S.W.E., A mechanism of disc-brake squeal, Technical Report, SAE, Paper No. 770181, Warrendale, PA, 1977.)

With a series of models, Earles et al. [90–94] were able to show the importance that the pad bending vibration has on the onset of brake vibration and/or noise. The analysis showed that squealing is generated when the natural frequency of the disk (f_d) and the pad-caliper (f_φ) are close to each other. However, the experimental results were not in good agreement with the results because, among other reasons, the pin–disk model cannot simulate the restoring moment in the rotational direction at the contact surface but only the reaction force in the translational direction. For this reason, Oura et al. [114], in a very recent work, developed a surface-contact model where the influence of the frictional contact surface (modeled as a distributed spring) on squealing has been examined. In this way, a better agreement with the experimental results has been obtained.

An important minimal model is Millner's [89], Figure 24.41. It is composed of a disk, a single brake pad, and half of the caliper. The model has 6 DOFs that are reduced to five including a constraint equation. It is characterized by a constant friction coefficient μ and based on the sprag-slip theory. This model is similar to North's one. With Millner's model, there is a greater instability likelihood increasing friction coefficient μ, but a minimum value for the instability onset is necessary. Other important results from [89] can be summarized as follows. For a constant friction value, the occurrence of squeal and squeal frequency depends on the stiffness of pad material (Young's modulus), caliper stiffness, and mass. Moving the center of pressure, between the piston and the brake pad, toward the leading edge of the brake pad reduced the propensity for squeal. A comparison between the minimal model and the experimental results has been conducted. The theoretical and the real μ values corresponding to squeal appearance are favorably comparable and an increase, at higher values, of the squeal amplitude with μ can be also noted in the model [89].

Murakami et al. developed a more complex model of a pin slider fist-type disk brake [115]. The torque members (at the trailing and leading side of the brake) act as a stiffness/damper system. In relation to Figure 24.42, the 7 DOFs of the model are represented by the rotations θ_o, θ_i,

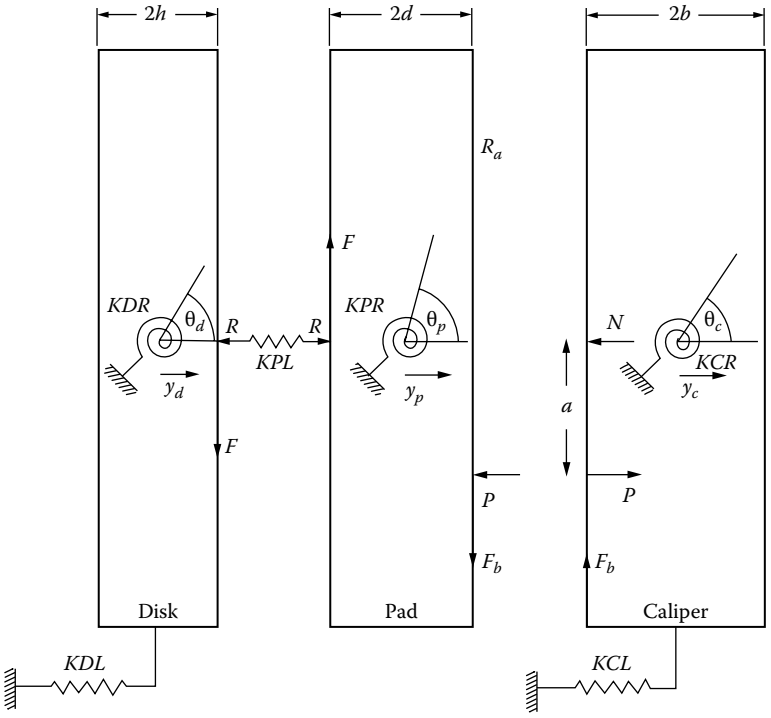

FIGURE 24.41 Model by Millner. (Adapted from Millner, N., An analysis of disc brake squeal, Technical Report, SAE, Paper No. 780332, Warrendale, PA, 1978.)

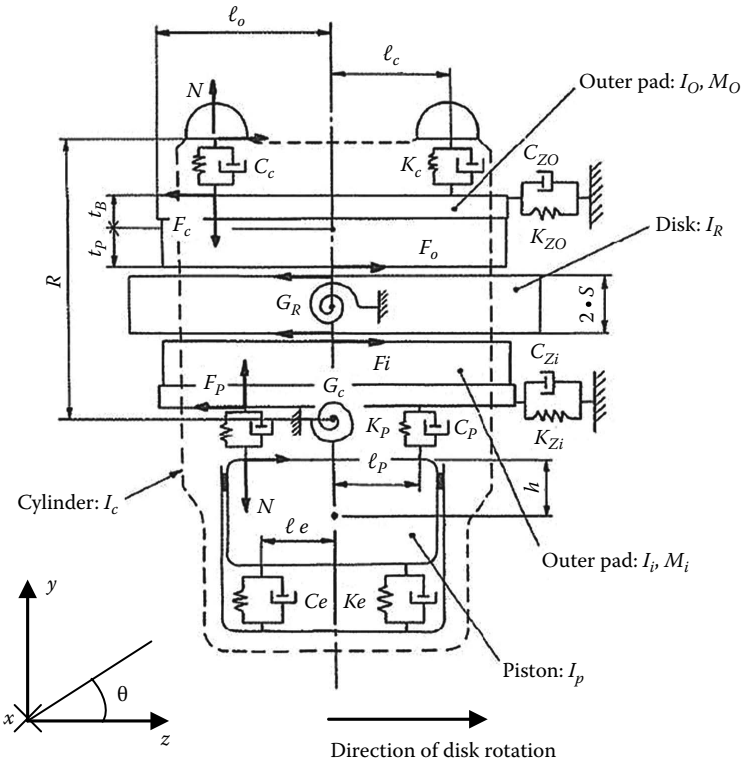

FIGURE 24.42 Model by Murakami, Tsunada, and Kitamura. (Adapted from Murakami, H. et al., A study concerned with a mechanism of disc-brake squeal, Technical Report, SAE, Paper No. 841233, Warrendale, PA, 1984.)

θ_R, θ_p, and θ_c and the displacements in the rotational directions Z_o and Z_i. The authors tried to explain the brake squeal phenomenon both through experimental and numerical methods (FEM and analytical). The main squeal energy source (in relation to the experimental results) is to be identified in the μ–v characteristic of the pad (Figure 24.43a) and in the braking force (acting

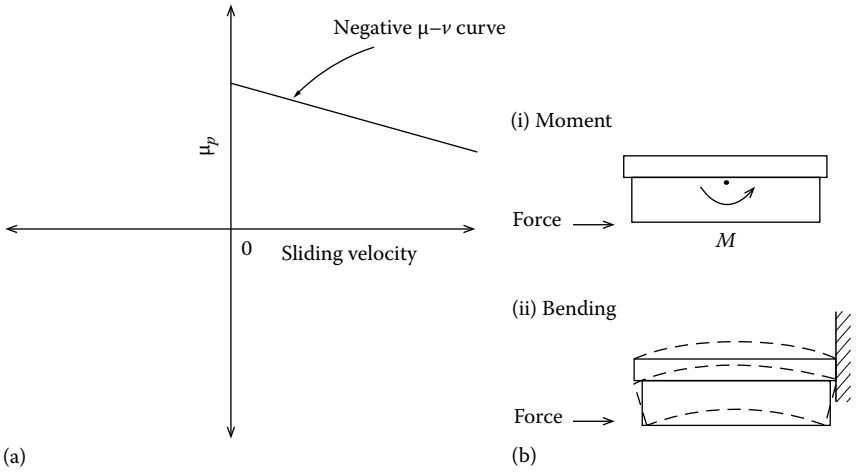

FIGURE 24.43 μ–v characteristic assumed in the model of Figure 24.15. (Adapted from Murakami, H. et al., A study concerned with a mechanism of disc-brake squeal, Technical Report, SAE, Paper No. 841233, Warrendale, PA, 1984.)

along the tangential direction to the disk rotation, see Figure 24.43b, (i) and (ii)) that causes a bending moment in the plane normal to the disk rotation. To confirm the reliability of the calculations, brake tests have been conducted in order to verify the lumped model experimentally and to understand the influence of each parameter on the rate of squeal occurrence. A good agreement was claimed. Given the following parameters:

- *TC*, *TP*, *TE*, *TCR*, *TPR*, *GRO*, and *GRI* (the moments due to the stiffness forces)
- *DC*, *DP*, *DE*, *DCR*, *DPR*, *DRO*, and *DRI* (the moments due to the damping forces)
- *KZO*, *KZI* (*CZO*, *CZI*) (the stiffness (damping) forces)
- *N* (the force along the axis *y*)
- F_o, F_i, F_c, and F_p (the friction forces)

the equations of motion are

$$\begin{aligned}
I_o\ddot{\theta}_o &= -TC - DC + F_o \cdot t_p + F_c \cdot t_B + N \cdot l_c - GRO - DRO \\
I_R\ddot{\theta}_R &= -G_R\theta_R - C_R\dot{\theta}_R + F_o \cdot S - F_i \cdot S - TCR - TPR - DCR - DPR \\
I_i\ddot{\theta}_i &= -TP - DP - F_i \cdot t_p - F_p \cdot t_B - N \cdot l_p - GRI - DRI \\
I_p\ddot{\theta}_p &= TP + DP - TE - DE + N \cdot l_p - F_p \cdot h \\
I_c\ddot{\theta}_c &= -G_c\theta_c + TC + DC + TE + DE - N \cdot l_c - F_c \cdot R \\
M_o\ddot{Z}_o &= -KZO - CZO + F_o - F_c \\
M_i\ddot{Z}_i &= -KZI - CZI + F_i - F_p
\end{aligned} \tag{24.71}$$

Another interesting mathematical model was developed by Nishiwaki to compare the equations of motion for a drum brake squeal, disk brake squeal, and disk brake groan noise [95]. Such brake noises are all generated by the dynamic instability in friction forces that act as nonconservative forces. Vibrations on the brake structures cause the displacements of the friction surfaces and, consequently, the friction forces work on the deformed surfaces of the brake system. The theoretical model for the disk brake squeal is shown in Figure 24.44. As in Murakami's model, the brake used in this study is a pin slider fist-type caliper. The disk is a circular plate with radius r_2, plate thickness t_d, and flexural rigidity D_d. The outer and the inner pads are installed at opposite locations and r_1 and r_2 represent, respectively, the radius of curvature of the inner and outer circumference of each brake pad (t_p is the thickness of the brake pads, D_p their flexural rigidity, and 2ϕ the center angle). The friction material is represented with a lining of thickness h adhered to each brake pad and modeled with a spring without mass (the spring coefficient E_1/h per unit area is distributed over the all friction surface).

In relation to the model's scheme (Figure 24.44), 4 DOFs are possible. Both the deflection of the disk within its plane, v_d, and the deflection of the brake disk and pads along the plane normal to previous one, w_{op}, w_{ip}, w_d, are modeled. The Lagrange equations of motion (expressed in a general form) are

$$M\ddot{X} + KX = \left(\frac{E_1}{h}\right)AX + \mu\left(\frac{E_1}{h}\right)BX \tag{24.72}$$

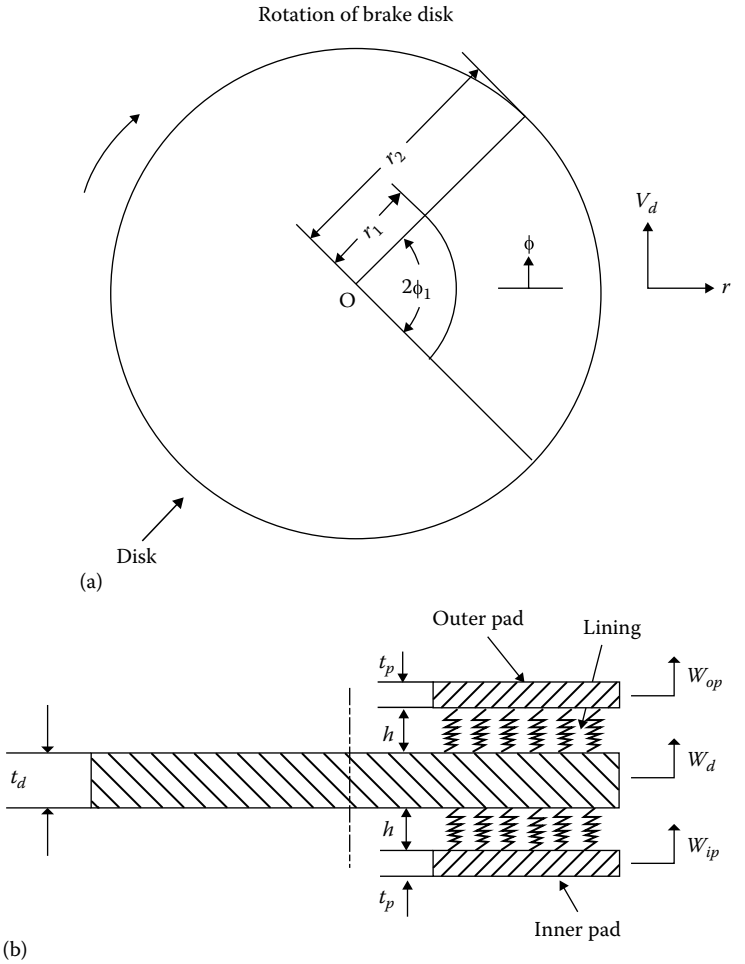

FIGURE 24.44 Model by Nishiwaki. (Adapted from Nishiwaki, M., *Proc. Inst. Mech. Eng.*, 207, 195, 1993.) (a) Plane view. (b) Section.

where, defining a_{ij} and b_{ij} as the constants depending on the vibration modes of the brake pad and disk, the brake pad shape, the lining position, and the brake pad, the terms M, K, A, B, and X assume the following form

$$X = \begin{bmatrix} q_{op}(t) \\ q_{ip}(t) \\ q_{d1}(t) \\ q_{d2}(t) \end{bmatrix}; \quad M = \begin{bmatrix} m_{op} & 0 & 0 & 0 \\ 0 & m_{ip} & 0 & 0 \\ 0 & 0 & m_{d1} & 0 \\ 0 & 0 & 0 & m_{d2} \end{bmatrix}; \quad K = \begin{bmatrix} k_{op} & 0 & 0 & 0 \\ 0 & k_{ip} & 0 & 0 \\ 0 & 0 & k_{d1} & 0 \\ 0 & 0 & 0 & k_{d2} \end{bmatrix}$$

$$A = \begin{bmatrix} a_{11} & 0 & a_{13} & a_{14} \\ & a_{22} & a_{23} & a_{24} \\ & & a_{33} & a_{34} \\ & & & a_{44} \end{bmatrix}; \quad B = \begin{bmatrix} 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ b_{31} & b_{32} & 0 & 0 \\ b_{41} & b_{42} & 0 & 0 \end{bmatrix} \tag{24.73}$$

Nishiwaki's models are limited to a pure mathematical study of the brake noise phenomena so that an experimental validation has not been conducted.

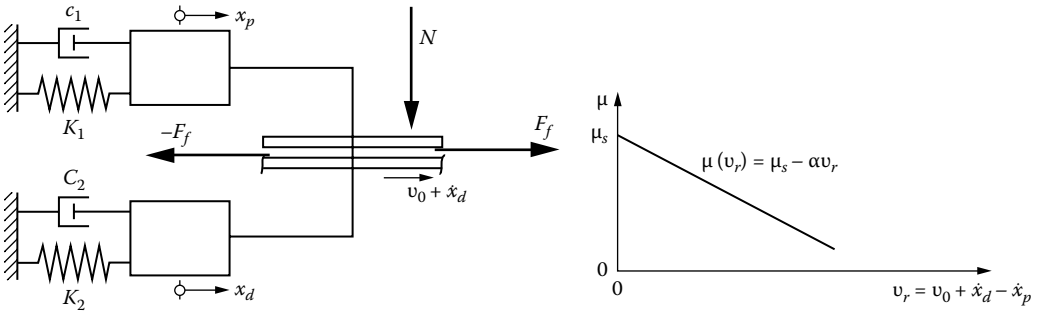

FIGURE 24.45 Model by Shin. (Adapted from Shin, K. et al., *JSME Int. J. C*, 45(2), 426, 2002.)

Brooks et al. developed a lumped-parameter model of brake squeal (with 12 DOFs). Such as in Murakami's model, Brooks considered the vibration in a disk brake as a friction-induced instability caused by a friction force that is a follower force. In addition, the authors used an eigenvalue sensitivity analysis to analyze the effects of small variations in the model parameters on the occurrence of squeal.

Shin's model [116] try to explain self-excited vibrations by a falling friction characteristic and stick-slip theory. The model has the advantage of being very simple, as well as the friction law that is linear, but it is difficult to link it to a real brake system. In fact, an experimental validation of the analytical results has not been made. μ*(v)* law and not linear motion equations are depicted in the succeeding text (Figure 24.45).

$$\begin{aligned} m_1\ddot{x}_p + c_1\dot{x}_p - N\alpha(\dot{x}_p - \dot{x}_d) + k_1 x_p &= N(\mu_S - \alpha v_0) \\ m_2\ddot{x}_d + c_1\dot{x}_d - N\alpha(\dot{x}_d - \dot{x}_p) + k_2 x_d &= -N(\mu_S - \alpha v_0) \end{aligned} \tag{24.74}$$

The linearized equations of motion are

$$\underline{z} = \begin{bmatrix} x_p \\ x_d \end{bmatrix}; \quad [M] = \begin{bmatrix} m_1 & 0 \\ 0 & m_2 \end{bmatrix}; \quad [C] = \begin{bmatrix} c_1 - N\alpha & N\alpha \\ N\alpha & c_2 - N\alpha \end{bmatrix}; \quad [K] = \begin{bmatrix} k_1 & 0 \\ 0 & k_2 \end{bmatrix} \tag{24.75a}$$

The addition of damping to either the disk or the pad alone may make the system more noisy.

A very interesting model from a scientific perspective is the one produced by Hoffmann and Gaul [104], which gathers all of the feature presented in previously presented minimal models. Such a model has the disadvantage to be rather different from an actual brake system, but apparently, the authors wanted to explore and explain the mode-coupling instability as a cause of self-excited friction-induced oscillations. The model in Figure 24.46 consists of a conveyor belt and a massive block with 2 DOFs.

Considering small perturbations around the steady sliding state and approximating the friction force by $F_F = \mu k_3 y$, the authors obtained the following linearized equations of motion

$$\underline{z} = \begin{bmatrix} x \\ y \end{bmatrix}; \quad [M] = \begin{bmatrix} m & 0 \\ 0 & m \end{bmatrix}; \quad [K] = \begin{bmatrix} k_{11} & k_{12} - \mu k_3 \\ k_{21} & k_{22} \end{bmatrix} \tag{24.75b}$$

where

$$k_{11} = k_1 \cos^2 \alpha_1 + k_2 \cos^2 \alpha_2$$

$$k_{12} = k_{21} = k_1 \sin \alpha_1 \cos \alpha_1 + k_2 \sin \alpha_2 \cos \alpha_2$$

$$k_{22} = k_1 \sin^2 \alpha_1 + k_2 \sin^2 \alpha_2 + k_3$$

The friction force acts like a cross-coupling force and flutter instability is possible. The model is not correlated to a specific brake system but, as the authors support in [104], it could "be of considerable help for practical design purpose."

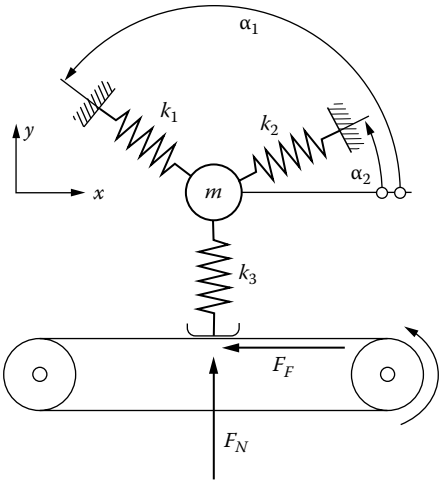

FIGURE 24.46 Model by Hoffmann and Gaul. (Adapted from Hoffmann, N. et al., *Mech. Res. Commun.*, 29, 197, 2002.)

Popp's model [99–101] can be considered a good development of the one by North. Like its inspiring model, it has only 2 DOFs and constant coefficient μ but has been enriched with two springs that simulate the contact pads of the disk and the damping effect on the 2 DOFs of the disk (Figure 24.47).

The linearized equations of motion (see Equation 24.76) may consider a preload N_0 on the two pads to ensure contact:

$$\underline{z} = \begin{bmatrix} x \\ \varphi \end{bmatrix}; \quad [M] = \begin{bmatrix} m & 0 \\ 0 & J \end{bmatrix}; \quad [C] = \begin{bmatrix} d_1 & 0 \\ 0 & d_2 \end{bmatrix}$$

$$[K] = \begin{bmatrix} c_1 + c_3 & -c_3 s \\ -c_3(s - \mu h) & c_2 + c_3(s^2 + \mu h s) \end{bmatrix} \tag{24.76}$$

$$[K] = \begin{bmatrix} c_1 + c_3 & -c_3 \\ -c_3(s - \mu h) & c_2 + c_3(s^2 + \mu h s) + 2N_0\left(h(1+\mu^2) + \mu s\right) \end{bmatrix}$$

Flint and Hultén [117] developed a model of a disk brake based on an eigenvalue analysis. In [117], they wrote "implement the disk and the pads as flexible components and incorporate the caliper as a rigid body but not weightless member" in order to investigate the tendency of small vibrations to grow.

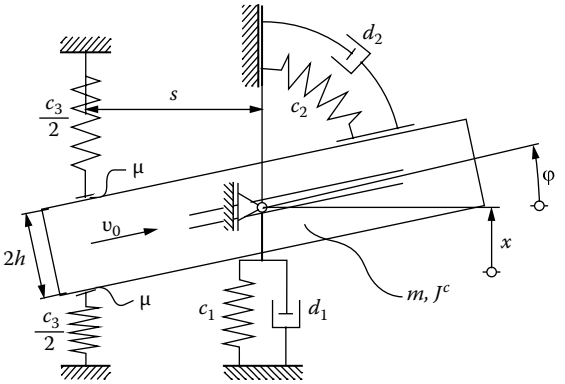

FIGURE 24.47 Model by Popp. (Adapted from Popp, K. et al., *VDI-Bericht*, 1736, 1, 2002.)

The disk is modeled as a flexible beam with cyclo-symmetric boundary conditions and is connected to two pads by the friction material (modeled as "an infinite number of springs"). The model is able to consider the moment created by the unequal friction forces on each side of the disk due to the different compression of the two friction materials. In this way, the rotation of the disk due to the moment can generate a traveling wave as the transverse vibration occurs. The backplates of the pad are represented by beams and they present a flexible contact with ground. The pistons are modeled as rigid bodies (with 1 DOF in the lateral direction), and they are in contact with the backplates by means of seven springs representing in this way a distributed contact (see Figure 24.48).

The equations for a linear and continuous system with external excitation are

$$M[\ddot{w}] + L[w] = 0$$

$$k_{ij} = \int_D \phi_i L[\phi_j] dD \quad m_{ij} = \int_D \phi_i M[\phi_j] dD \tag{24.77}$$

where L and M are linear differential operators; the partial differential equation can be discretized to a system of ordinary equations so that

$$k_{ij} = \int_D \phi_i L[\phi_j] dD \quad m_{ij} = \int_D \phi_i M[\phi_j] dD \tag{24.78}$$

where

D is the domain of integration
ϕ are the test functions ($i, j = 1, 2, \ldots, N$)
N the number of terms included in the analysis (for more details see [117])

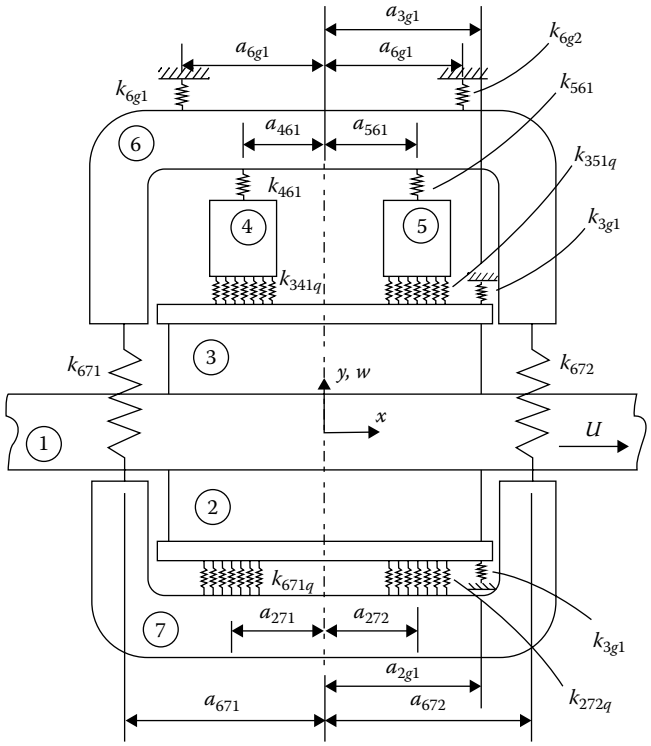

FIGURE 24.48 Model by Flint and Hultén. The model presents a disk (1) and the two pads (2 and 3) as continuous elements, while piston (4 and 5) and the caliper parts (6 and 7) are discrete elements. (From Flint, J. and Hultén, J., *J. Sound Vib.*, 254(1), 1, 2002.)

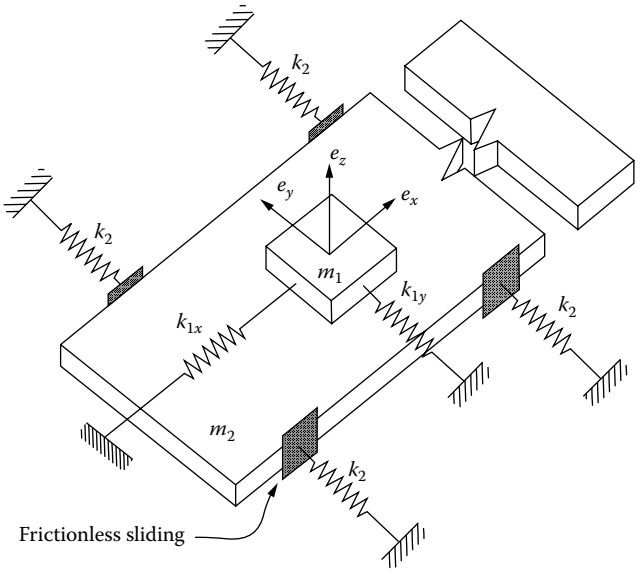

FIGURE 24.49 Model by Kinkaid, O'Reilly, and Papadopoulos. (Adapted from Kinkaid, N.M. et al., *J. Sound Vib.*, 287, 901, 2005.)

The model is able to reproduce the measured squeal frequencies fairly well for a certain real disk brake. The authors supported that "the good agreement between measured squeal and calculated instability is probably due to the fact that these particular squeals are close to disc resonance."

Kinkaid et al. model [24] is a simple model with four translational DOFs that reproduce the sliding of the pad of a disk brake. This model is able to capture the motion of the system in transverse (radial) direction and its main purpose is to simulate the transient phenomena during squealing (Figure 24.49).

In this model, the Amontons–Coulomb frictional law is used and the frictional behavior differs depending on whether the pad is sticking or slipping on the disk. The equations of motion of the system are

$$\begin{aligned} m_1\ddot{x}_1 + c_{1x}\dot{x}_1 + k_{1x}x_1 &= F_{fx} \\ m_1\ddot{y}_1 + c_{1y}\dot{y}_1 + k_{1y}y_1 &= F_{fy} \\ m_2\ddot{x}_2 &= -F_{fx} \\ m_2\ddot{y}_2 + c_{2y}\dot{y}_2 + k_{2y}y_2 &= -F_{fy} \end{aligned} \tag{24.79}$$

where

F_{fx} and F_{fy} represent the x and y components of the friction force
c_{1x}, c_{1y}, and c_{2y} represent the linear viscous damping coefficients

The model conceived by von Wagner et al. [118] has 3 DOFs that are reduced, by means of constraint equations, to two degrees and it reproduces the disk and both of the pads. One of the major advantages of this model is that it can be easily associated with a real disk brake (as one can see in Figure 24.50) but a comparison between the analytical results and a real brake system has not been done.

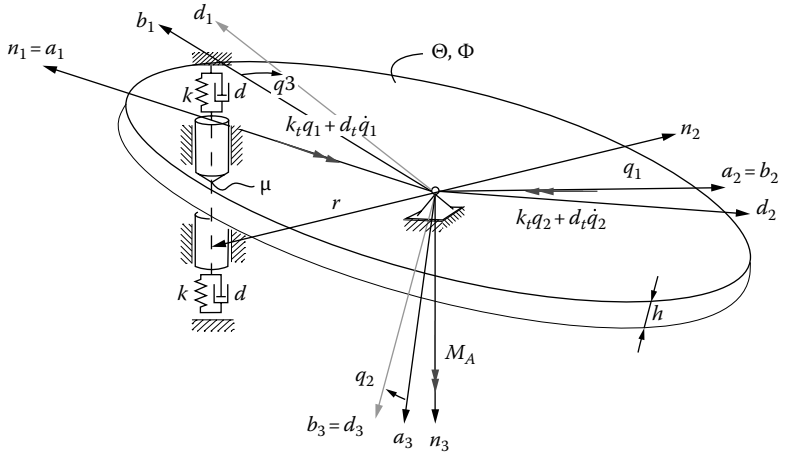

FIGURE 24.50 Model by von Wagner, Hochlenert, and Hagedorn. (Adapted from von Wagner, U. et al., *J. Sound Vib.*, 302, 527, 2007.)

Gyroscopic effects are introduced and the linearized equations of motion are reported in Equation 24.80, μ being the coefficient of friction, r the radius where the pressure is applied, and N_0 the preload:

$$\underline{z} = \begin{bmatrix} q_1 \\ q_2 \end{bmatrix}; \quad [M] = \begin{bmatrix} \Theta & 0 \\ 0 & \Theta \end{bmatrix}; \quad [C] = \begin{bmatrix} \frac{1}{2}\mu N_0 \frac{h^2}{r\Omega} + 2dr^2 + d_t & \Phi\Omega \\ -\Phi\Omega - \mu dhr & d_t \end{bmatrix}$$
$$[K] = \begin{bmatrix} k_t + 2kr^2 + N_0 h & \frac{1}{2}\mu N_0 \frac{h^2}{r} \\ -\mu(khr + 2N_0 r) & k_t + (1+\mu^2)N_0 h \end{bmatrix} \tag{24.80}$$

North's 8-DOF model [112] is one of the first analytical model well correlated with experimental results and its success was due to the correlation of increased damping and friction coefficient μ to decreasing squeal (see also [36]).

24.6.4.3 Models Derived from a Modal Approach

The main contributions appear to be given by Chan and Mottershead [119–122], Ouyang [72,123], and Giannini and Sestieri [124]. Here, following [36], a summary of the dynamic properties of vibrating disks is briefly reported.

Figure 24.51 represents a vibrating disk, the displacement of a generic point is $\boldsymbol{u} = \boldsymbol{u}(R, \phi, z, t)$; $\boldsymbol{u} = u_x \boldsymbol{e}_r + u_y \boldsymbol{e}_\phi + u_z \boldsymbol{E}_z$. The partial differential equation that governs the motion in the z-direction is

$$\rho h \frac{\partial^2 u_z}{\partial t^2} = \frac{h}{R}\frac{\partial}{\partial R}\left(\sigma_{RR} R \frac{\partial u_z}{\partial R}\right) + \frac{h\sigma_{\phi\phi}}{R^2}\frac{\partial^2 u_z}{\partial \phi^2} - \frac{Eh^3}{12(1-\nu^2)}\nabla^4 \boldsymbol{u}_z + q \tag{24.81}$$

where

h is the thickness of the brake rotor R with ϕ and z are a cylindrical polar coordinate system
u_z is the displacement in z-direction
E is Young's modulus
ρ is the mass density
ν is the Poisson ratio
σ_{RR} and $\sigma_{\phi\phi}$ are the stresses induced in the circular plate by the rotation Ω

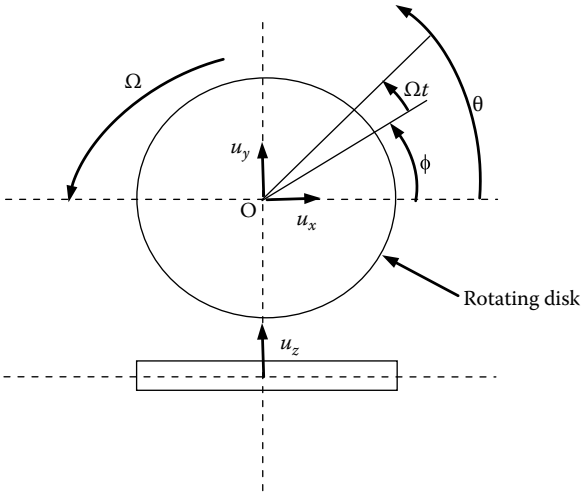

FIGURE 24.51 Reference system for a vibrating disk.

$q = q(R, \phi, t)$ represents the contribution of the external forces and moments and can be expressed as

$$q = -\left(\frac{\delta(R-R^*)\delta(\phi-\phi^*)}{R^*}\right)\frac{F_\phi}{R^*}\frac{\partial u_z}{\partial \phi} \tag{24.82}$$

where

δ is the Dirac delta function

R^* and ϕ^* are the positions where the external force is applied on the disk

Futhermore, ∇^2 is equal to

$$\nabla^2 = \frac{\partial^2}{\partial R^2} + \frac{1}{R}\frac{\partial}{\partial R} + \frac{1}{R^2}\frac{\partial^2}{\partial \phi^2} \tag{24.83}$$

If the external loading is absent and the disk does not rotate around its axis,

$$\rho h \frac{\partial^2 u_z}{\partial t^2} + \frac{Eh^3}{12(1-\nu^2)}\nabla^4 u_z = 0 \tag{24.84}$$

The solution of the above partial differential equation is

$$u_z(R, \phi, t) = \sum_{n=0}^{\infty}\sum_{m=0}^{\infty} F_{mn}(R)\sin(\omega_{mn}t)\left(A_{mn}\sin(n\phi + \psi_n)\right) =$$

$$= \sum_{n=0}^{\infty}\sum_{m=0}^{\infty} F_{mn}(R)\sin(\omega_{mn}t)\left(B_{mn}\sin(n\phi) + C_{mn}\cos(n\phi)\right) \tag{24.85}$$

ψ_n depends on where the excitation is given. The mth modes refer to circumferential nodal lines and are called singlet modes. Diametric nodal lines refer to nth modes and are related to *doublet* modes. Such modes are identical, have the same frequency (ω_{mn}), but their spatial phase is $\pi/2$.

The doublet modes can be interpreted as two waves traveling in opposite direction, actually

$$2\sin(\omega_{mn}t)\sin(n\theta+\psi_n)=\sin(n\theta-\omega_{mn}t+\psi_n)+\sin(n\theta+\omega_{mn}t+\psi_n) \tag{24.86}$$

If the disk is rotating but the centrifugal forces can be neglected, then the asymmetry caused by the disk rotation can be argued

$$2\sin(\omega_{mn}t)\sin(n\theta-n\Omega t+\psi_n)=\sin\left(n\theta-(\omega_{mn}+n\Omega)t+\psi_n\right)+$$
$$+\sin\left(n\theta+(\omega_{mn}-n\Omega)t+\psi_n\right) \tag{24.87}$$

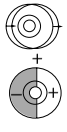
The nodal diameters may rotate at either uniform or nonuniform speed [36,125]. In Figure 24.51, the out-of-plane modes are shown.

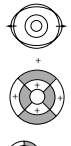
By inspection of Tables 24.5 and 24.6 it is clear how an ideal disk can vibrate. The actual disk of a car brake is quite different, due to the so-called hat and bolts acting as constraints. Additionally, the excitation comes from the vibration of the pad(s), which are in contact with the disk destroying the axial symmetry of the mechanical model. The vibration amplitudes are of the same order of magnitude of the disk irregularities (disk thickness variation (DTV), see Section 24.6.3), that is, some micrometer. The role of the excitation of DTV seems often underestimated.

Sestieri in 2006 [124] (and his coworkers) developed a modal model able to predict the squeal frequencies that occur during experiments performed on a laboratory brake setup. The proposed model accounts for the out-of-plane dynamics of the disk (see Figure 24.52). The small brake pad was modeled and its eigenfrequency proved to be crucial for squeal. They reported (see Figure 24.53) that when the eigenfrequency of the pad was nearly equal to the one of a doublet mode, the frequency of the doublet split and instability occurred.

In Table 24.6 the in-plane and combined (out-of-plane and in-plane) modes are shown.

In [37], a section is dedicated to the many contributions that appeared in the literature based on the modal approach.

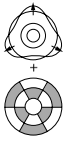




24.6.4.4 FEM Models

Again in [37], a section is dedicated to the many contributions that appeared in the literature based on the FEM approach.

In [126,127], Nack pioneered the derivation of nonlinear FEM analysis of brake vibration and/or noise. FEM modeling was used to describe the nonlinear effects and related transient analysis, but few details were given on how the contact between the pad and the disk was implemented. Actually, the crucial problem is how to connect the element of the disk with the ones of the pad. In [121], apparently, only a point was the location where forces were exchanged between pad and disk. This approach is common to most researches carried out until the beginning of 2000. Additionally, many papers did not account for the rotating disk [37]. Nonetheless, some hints were given on the instability, for example, in [128–130], the role of in-plane vibration of the disk was recognized, thanks to FEM analysis. In the importance of moving, load was pointed out. In [72], the caliper, the carrier, and the pad are modeled by FEM; the disk vibration is modeled analytically. The vibration modes when the disk is still are computed and agree well with experiments. There is a reasonable agreement between computed and measured results, even if, as usual for brake vibration and/or noise investigation, the predicted and experienced squeal frequencies do not always coincide.



In [131], a full FEM model of a disk brake was presented. At first (Figure 24.54a), a simple pad pressed against a hard body was studied. By exploiting the LS-DYNA code and letting the hard body slide under the contact, setting a constant friction coefficient ($\mu=0.4$), a limit cycle of the center of the contacting surface is computed (Figure 24.54b). Such an analysis leads directly to the computation of an "apparent" friction coefficient that diminishes as the sliding velocity increases justifying the Stribeck effect (see Section 24.6.4.1).

TABLE 24.6
The Main Positive and Negative Aspects of the Two Squeal Noise Analysis Approach

	Tires (Imbalance or Nonuniformities)	
Squeal Noise Analysis Approach	**Advantages and Detections**	**Disadvantages and Inaccuracies**
Complex eigenvalue analysis	• All unstable eigenvalues are found in one run (low computational time with respect to transient analysis). • All unstable vibration modes of the brake system can be predicted (modes with a real part), but in the actual case, not all diverge versus a squeal tendency.	• Limited accuracy in transient states (the method linearizes the nonlinearities) • Nonstationary features, such as material properties (time-dependent), cannot be included. • The real magnitude of a motion cannot be known.
Transient analysis	• The finite amplitude of a limit-cycle motion is known. • Time-varying properties of the brake system (introduced by moving loads) can be taken account.	• Runs occur to find a limit-cycle motion. • Time-domain solutions require a lot of memory storage. • Design changes are hard to perform on the basis of the big quantity of data.

24.6.5 Brake Vibration and/or Noise: Causes and Mechanisms

Referring to Figure 24.28, we will focus on the mechanisms that cause brake vibration and/or noise.

24.6.5.1 Judder

Two main groups of judder are identified according to traditional classification [45,46]:

- *Hot judder* caused by thermal deformation (e.g., coning and waving of the disk), uneven thermal expansion, and phase transformation of the disk material
- *Cold judder* caused by geometrical irregularities due to machining and mounting operations, uneven wear, deformation of the bearing system (hub and suspension included), uneven corrosion, or uneven friction film generation

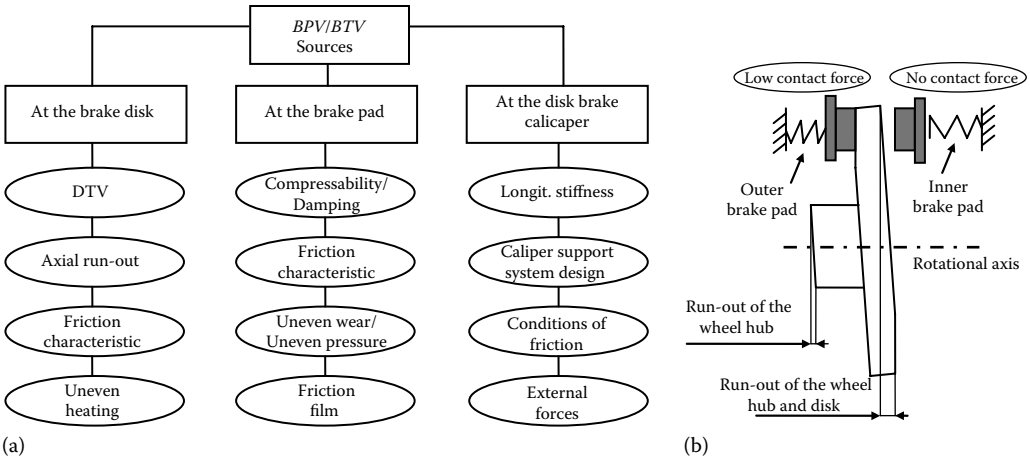

FIGURE 24.55 (a) Causes of brake pressure and brake torque variation (on the left). (Adapted from Jacobsson, H., *Proc. Inst. Mech. Eng., Part D*, 217, 419, 2003.) (b) Erosion on the disk brake surface due to disk run-out during off-brake driving ("cold wear" on the right). (From Grochowicz, J., Experimentelle und theoretische Untersuchungen zu Bremsdruck-und Bremsmomentenschwankungen an Pkw-Scheibenbremsen, Dissertation, Dresden Technical University, Dresden, Germany, 1996.)

Judder can also be classified as a function of its vibration order (many works, such as [45,47], referred to a *low-order geometrical deviations* and a *high-order geometrical deviations*).

The most important factors influencing brake pressure variation (BPV) and brake torque variation (BTV) are summarized in Figure 24.55a [47]. Brake judder is essentially due to geometrical deviations of the brake disk from the ideal shape and spatial variation (along the brake disk) of the coefficient of friction. In particular, the most important geometrical properties are DTV and run-out of the disk (see Figure 24.55b).

The magnitude of the run-out is determined by disk machining and mounting tolerances, bearing clearances and disk distortion during braking. In addition, external forces, such as tire forces and unbalances, affect the run-out. It should be noted that a DTV of 15 μm (measured in cold conditions) is observable as brake judder under hard braking conditions. Therefore, the initial DTV level varies between 6 and 10 μm for most manufacturers in order to guarantee a certain safety margin [132].

Another important effect of judder causing BTV/BPV is the uneven wear of the disk brake. It is caused both during off-brake conditions by geometrical irregularities of the disk brake ("cold erosion") and during braking conditions due to uneven thermal effects [133] (such as uneven contact area and pressure that generate uneven heating distribution on the sliding surface [134,135], uneven friction film thickness that contributes to several micrometer to the thermal growth of the DTV, and uneven corrosion and deposition of heated pad material on the disk).

BTP/BPV generates brake vibrations that are transmitted and amplified to different vehicle components (see Table 24.2). The wheel suspension amplifies the vibrations, especially the frequencies near its eigenfrequencies (for more details, see [136]). The second amplification of the vibration is associated to the steering system. The main ways to reduce judder is to reduce BTV and BPV acting on

- *Pad*: Depending on its tribological properties (density, melting point, flexural and shear strength, compressive stiffness, coefficient of friction and thermal expansion, thermal conductivity, corrosion, and porosity), BTV level can vary by a factor of 2–3 due to the pad composition (with the same DTV). In particular, the pad compressive stiffness should be as low as possible to promote uniform contact pressure and to avoid a thermoelastic instability (hot spots, thermal DTV, etc.), but, at the same time, to achieve a "good pedal feeling,"

the stiffness should be reasonably high and progressive [137,138]. In other words, linear pads are likely to accept higher disk thickness tolerances than 10 μm DTV (brake-by-wire technique offers other ways to achieving a "good pedal feeling") [46,139].

- *Disk*: In addition to the quality of the material (whose main properties are the thermal capacitance, heat dissipation, thermal conductivity, and thermal expansion coefficient), the basic design of the disk rotor is important. Ventilated brake disks are widely used for their weight savings and additional convective heat transfer. However, this type of brake may increase judder problems by inducing an uneven temperature filed around the disk [140]. Nevertheless, the use of composite materials that have particular thermal properties (thermal capacity, thermal expansion, and so on) may be useful to reduce judder and promote uniform contact reducing thermal DTV and hot spots [43–45].

24.6.5.2 Groan, Moan, and Howl

Groan and moan (100–500 Hz) are caused by the vibrations due to the dynamic instability of the wheel–brake system; the same happens for the source of the howl but at higher frequencies (500–1000 Hz).

Groan and moan are caused by stick-slip motion between the friction material and the disk surface. The superposition of several quasi-harmonic vibrations or unsteady vibration impulse sequences of different intensities are its main features. Therefore, this phenomenon is characterized by nonlinear excitation and nonlinear transfer mechanisms.

A very recent and significant model, conceived by von Wagner et al. [118], explains self-excited friction-induced vibrations as a phenomenon caused by the mode-coupling instability and based itself on North's instability criterion.

24.6.5.3 Squeal Noise

In Table 24.7, the many mechanisms for squeal noise generation are summarized.

Stick-Slip: A variable friction coefficient with respect to sliding velocity between pads and rotor is the origin for the brake squeal. When the static friction coefficient is higher than the dynamic coefficient ($\mu_s > \mu_d$), a mass sliding on a moving belt as shown in Figure 24.35 may become unstable. During the starting phase, the sliding force increases until it exceeds the static friction force. Consequently, the mass starts to slide. If the speed drops to zero, the sticking takes place. Then, sliding and sticking occur in succession. Mills in 1938 [141] argued that brake squeal was associated with a decrease in friction coefficient with rubbing speed as shown in Figure 24.35. Nowadays, this mechanism is still thought of as the cause of some low-frequency brake vibration problems.

Sprag-Slip: Spurr [113] introduced the term sprag-slip to name his theory of brake squeal. He actually did not write nor solved a set of differential equations to show instability. His reasoning is sharp but limited to qualitative sentences. The system in Figure 24.55 shows a relatively stiff, massless rod, able to rotate around O. An external force L acts at its free end. Spurr, assuming a friction force at the point contact between the plane and the rod ($F_f = T = \mu_d N$), showed that the system equilibrium implies

$$N = \frac{L}{1 - \mu_d \tan(\theta)}; \quad F_f = \frac{\mu_d L}{1 + \mu_d \tan(\theta)} \tag{24.88}$$

If $\theta \to \tan^{-1}(1/\mu_d)$, then $F_f \to \infty$. The flexibility of the rod let it load and unload, sustaining a *sprag-slip limit cycle* (Figure 24.56).

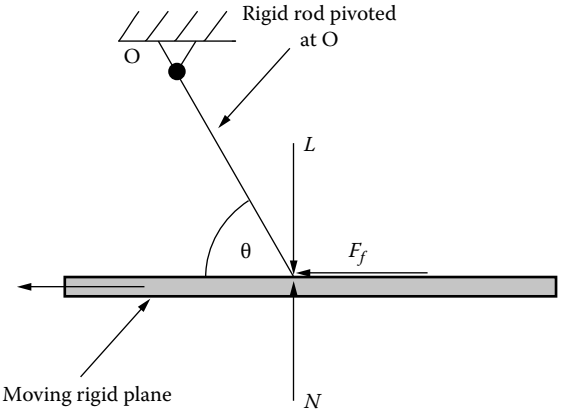

FIGURE 24.56 A stiff, massless rod loaded by an external force L, contacted with a rigid moving plane and pivoted at O. (Adapted from Kinkaid, N.M. et al., *J. Sound Vibration*, 267, 105, 2003.)

Later, researchers included sprag-slip into more complicated (multi-DOFs) models, defining a *geometrically induced* or *kinematic constraint instability*. The variation of the coefficient of friction with sliding speed was not necessary to cause the friction-induced vibrations.

Stick-Slip Combined with Sprag-Slip: Obviously, two mechanisms of instability may be present in the same mechanical model and cause instability. This may happen in models featuring refined and close to reality characteristics.

Mode Coupling: When two modes coalesce (mode locking) instability occurs. Following [78], we report

> The instability mechanism that develops in the laboratory brake can be summarized as follows: the friction force couples the bending vibrations of the laboratory brake and the in-plane vibration of the pad; the friction force is in-phase with the relative displacement between the disc and the pad. If the system vibrates with a frequency close to a natural frequency of the pad, i.e. if a natural frequency of the system falls close to an in-plane eigenfrequency of the pad, the pad vibrates with a 90 deg phase difference with respect to the bending vibration of the disc and the beams. This implies an elliptic trajectory of the contact point on the pad that can transfer energy from the continuous rotation of the disc to the vibrational motion of the pad.

Bifurcation: In nonlinear dynamical systems, the equilibria vary as system parameter varies. When a couple of complex eigenvalues have a positive real part, a Hopf instability occurs. Other saddle-node bifurcation may occur that is still to be assessed as a well-defined squeal mechanism.

Hammering: Rhee et al. proposed [146] a simple mechanical impact model (*hammering*) to explain the excitation mechanism of brake noise. Studies, reported in [146], showed that thermal deformations of the disk brake, as a result of the frictional heat during braking, could cause the formation of localized hot spots on the rotor surface.

Coupling of Horizontal Motions: Such a new mechanism [24] depends crucially on 2-D contact and does not require a friction coefficient that depends on the sliding velocity.

Others: Stick-slip may be correlated to chaos and thus instability. Parametric resonances due to disk vibration can be a source of instability (similar to hammering). The backward waves can be destabilized due to the interaction of the disk and the pad. In [148], thermo elastic dynamic instability (TEDI) is theoretically investigated and foreseen as a cause of brake vibration and/or noise.

24.7 CONCLUSION

In this chapter, the brake system of a vehicle has been described. The most important components of the brake system have been introduced taking into account both their function and the related construction issues.

At first, the functions of a braking system have been introduced, along with some important considerations on basic brake dynamics and energy involved. Then, the brake balance has been considered in-depth.

The hydraulic brake system has been described in detail. The most important construction issues have been briefly addressed. The problem of continuous braking has been considered and the different types of retarders have been described.

In the last section, the fundamental problem of NVH has been deeply investigated by considering all the most important published works. Brake vibration and/or noise has been studied since almost 80 years with minor practical results. This fact suggests that the proper mathematical models have not been identified or employed correctly. Possibly, the available computational power is still reduced to solve the "easy" problem of a pad sliding on a disk. As technology evolved, deeper insight was gained in understanding how pad and disk deform dynamically, which are the actual mechanisms that might be related to vibration and/or noise, which is the role of friction (and what actually friction is), and what are the thermal effects.

For sure, the mechanical/mathematical model of a brake has to be thought of as a complex system, in which many parameters play a crucial role. Such parameters belong either to the meso- or microscale. Some parameters are certain, and some parameters are uncertain. Nonlinearities seems to have a crucial role; actually, common practice suggests the presence of stable and unstable limit cycles.

In a near future, time-domain models will be increasingly used for a priori simulations. The elusive nature of friction will be further investigated. Possibly, the actual irregularities of the disk will have to be taken into account together with the careful mechanical characterization of *all* of the components of a vehicle suspension. The theory of nonlinear systems excited by stochastic processes could prove to be beneficial to assess the probability of occurrence of brake vibration and/or noise.

25.1 INTRODUCTION

Steering equipment is configured to enable a person to control the direction of a vehicle. The centripetal force when a vehicle turns is due to friction between the tires and the road and is configured to control the yawing moment applied to the vehicle by controlling the direction of the friction force. To control this yawing moment, methods using both lateral and longitudinal forces need to be considered. The former is called the steering method and is adopted by vehicles mainly using tires. The latter is called the brake control method and is mainly used by crawler-type vehicles. Further, in recent years, some of the vehicles that use tires have adopted the use of traction and braking force systems called the yaw moment control method, but currently, in this chapter, it has been decided to limit descriptions to control methods using steering, with the objective of supplementary stability control. (For more details on yaw moment control, see Chapters 30, 32, and 39.)

25.2 BASIC CONFIGURATION OF STEERING EQUIPMENT

Control methods are methods of controlling the size and direction of the lateral force by controlling the tire direction and can be divided into types that control the front wheels (FWS, front-wheel steering) and types whose control also include the rear wheels (4WS, four-wheel steering or AWS, all-wheel steering). Usually, analysis of the 4WS system is carried out in the field of vehicle

handling and control. Moreover, in recent years, the steer-by-wire system controlled by computers is one of the new topics in the field of steering systems. For example, by adding the factor of steering angular velocity to the output of steer angle, the delay in the driver's steer can be compensated. The analysis of such systems is also carried out in the field of vehicle handling and control. This chapter, therefore, mainly describes the configuration of the front-wheel steering system, types of power-assisted steering systems, and equations of motion for steering systems and power-assist systems.

25.2.1 Basic Configuration

Steering equipment can generally be thought of as comprising three parts: the control mechanism, the gear mechanism, and the link mechanism. The control mechanism is mainly the part that enables the driver to steer directly and comprises the steering wheel, steering shaft, and column. The steering force created by the driver is transmitted to the gear and link mechanisms and also plays the role of transmitting to the driver the aligning moments created by the tires and the kick-back from the road surface.

The gear mechanism decelerates the steering shaft rotations and is also responsible for changing the direction of operations of the steering mechanism, as well as increasing the steering moment. Vehicles in recent years have used a configuration that changes the gear ratio according to the rotation angle. Further, the nomenclature of the steering system changes depending on the type and configuration of the gears used. In addition, the history of steering systems greatly depends on changes to the gear configuration.

The link mechanism is the part that transmits the movements of the gear mechanism to the front wheels, and its configuration elements depend on the type of gear mechanism, but the configuration elements include a pitman arm, relay rod, tie rod, and knuckle arm as shown in Figure 25.1.

Further, in recent years, rack-and-pinion-type gear mechanisms have been widely adopted, and the gear mechanism has been combined with some link mechanisms. Generally, when turning a vehicle at extremely low speeds, it is necessary to change the steering angle due to the difference between the turning radius of the right and left wheels, and this is achieved by the design of the link mechanism.

These steering elements—the steering shaft, the link mechanism, and the bush for the joints, in particular—have elasticity so that these allow a deformation angle between the steering wheel and the steering tires. By this steering elasticity, the impact received from the road through the tire, especially for longitudinal and rotational direction such as kickback, is eased. On the one hand, it also greatly affects the steering stability by trying to return the steering angle to the central position due to the aligning moment (self-aligning torque) created by the front wheels during turning. It is necessary to decrease the value of cornering stiffness for the steered tire at low degrees of freedom without considering the steering system. In addition, hysteresis is described in the steering system between the steering wheel and the steering angle of the front wheels due to backlash and friction between the gear parts and the joints, and, further, nonlinearity also occurs depending on the link configuration and variable gear ratios (VGRs); therefore, it is necessary to consider these according to the modeling objectives. A typical steering characteristic between the steering torque and steering angle is described Figure 25.2.

25.3 HISTORY OF STEERING EQUIPMENT

25.3.1 History of Steering System Mechanisms

In the early days of car building, which developed from horse-drawn carriages, there were mainly two configurations of steering systems. One was to adopt the steering mechanism of the horse-drawn carriage, which rigidly fused the left and right wheels, and the other was a three-wheeled vehicle that combined the steered wheels into one. The gun carriage invented by Nicolas-Joseph Cugnot

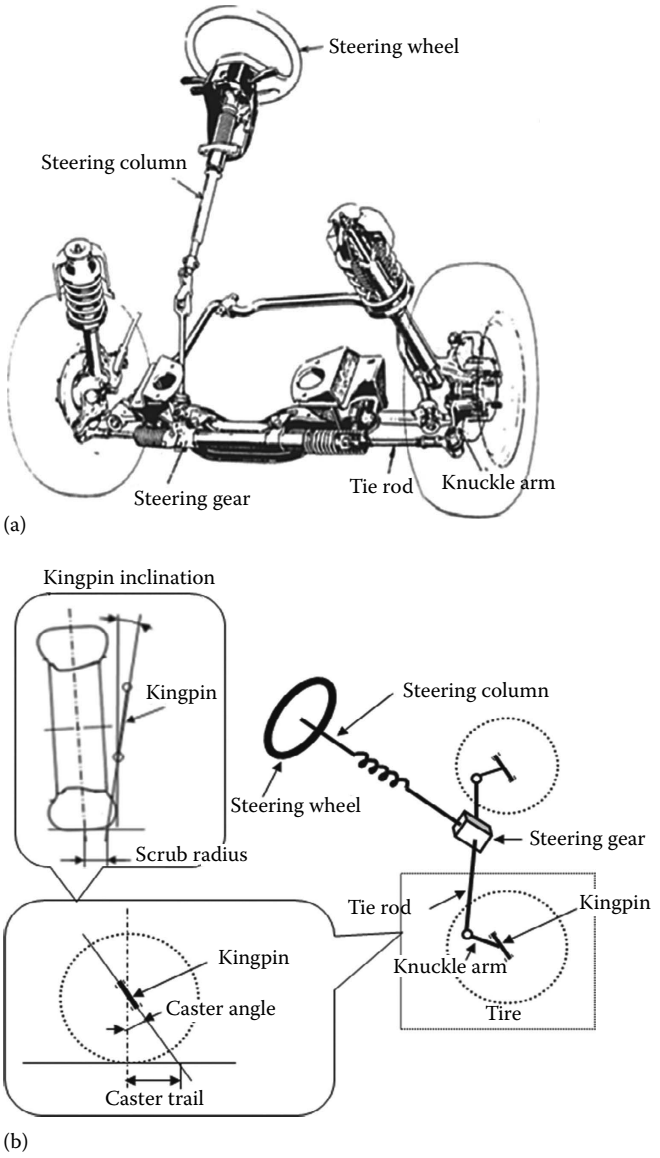

FIGURE 25.1 Outline of steering system. (From Komamura, S. et al., *Steering and Dynamics*, Sankai-do Press, Tokyo, Japan, 1996.)

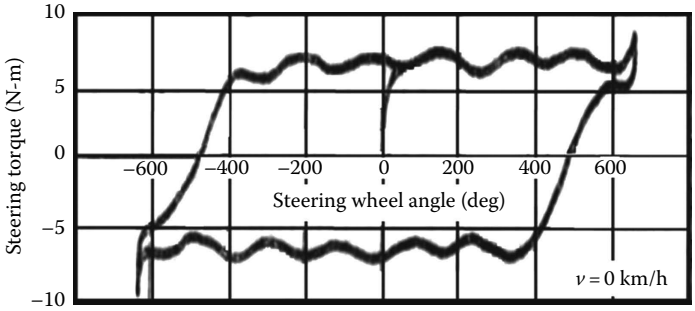
from France in 1769 [1,2], which can be considered to be the first motor vehicle, was a three-wheeler and the front wheel could be steered. And, in particular, the steering system was configured to rotate a part of the ring gear mounted directly on to the steering wheel by performing through two-step gears from the steering shaft as shown in Figure 25.3.

Further, 250 years earlier, in 1480, diagrams of automobiles drawn by Leonardo da Vinci [1], while not describing these steering mechanisms in detail, handled the steering wheels as a single wheel as shown in Figure 25.4.

When the geometry of turning is considered, these have the advantages that the wheels do not slide sideways, steering torque can be minimized, and the mechanism is comparatively simple. This three-wheel mechanism was also adopted by Karl Benz for his automobiles, which are one of the oldest gasoline-powered automobiles. When stability during turning is considered, however,



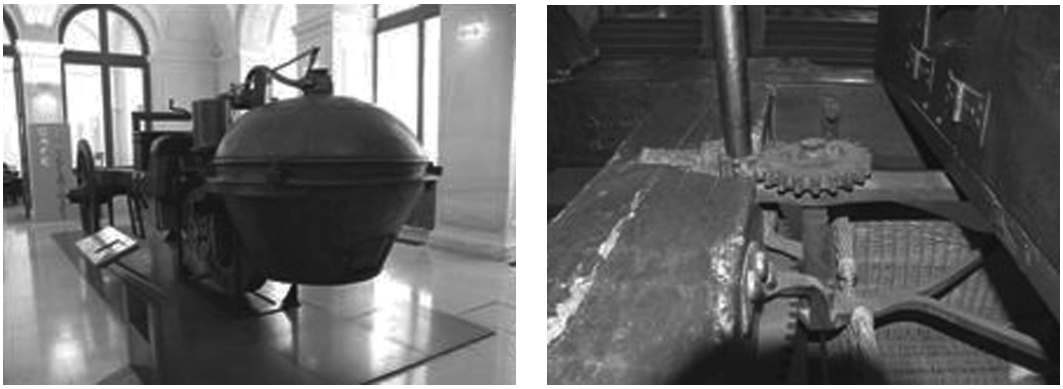


FIGURE 25.2 Relationship between steering torque and steering wheel angle (with power steering system). (From Kageyama, K. et.al., *Vehicle Dynamics*, Riko Press, Tokyo, Japan, 1984.)

(a) (b)

FIGURE 25.3 Gun carriage constructed by Nicolas–Joseph Cugnot. (Courtesy of National Technical Museum, Paris, France.) (a) The gun carriage. (b) Steering system.

four-wheeled vehicles are more effective, and Daimler cars, which were invented the same year, were four wheeled, and adopted the horse-drawn carriage steering mechanism described earlier, which minimizes sideways sliding during geometric turning.

When automobile stability at high speeds is considered, however, these two devices are unsuitable. With horse-drawn-carriage-type steering systems, a moment acts on the side to which the steering is applied. The moment occurs on the steering system shaft rotation and is

due to changes in the lateral force caused by the load transfer between the left and right wheels during turning. Consequently, the link-type steering mechanism, which was invented and patented by Rudolph Ackerman in 1817, came to be adopted. This mechanism performs steering using these links by mounting a rotating shaft to independent left and right wheels (see Chapter 21) and steers the inside wheel much more than the outside one due to the trapezoid links. This mechanism had already been mounted to carriages by Maybach, who invented it in 1889. This mechanism steered the tires using direct links from the steering wheel shaft, but later various steering gears such as the worm gear, planetary gear, screw nut gear, spur gear, and cam lever gear were invented from around 1900 with the objective of reducing the steering force and making steering easier.

Thereafter, the worm roller (cam roller) gear, which reduced friction due to rolling contact by using a single cam roller, was invented, and went on sale commercially in 1926. Almost immediately thereafter, the two-cam roller and three-cam roller were developed and widely adopted.

In 1939, the ball screw gear, with numerous balls inserted between the worm and nut to reduce friction, was invented. Due to problems of machining accuracy, however, this did not become widespread immediately. In 1967, the VGR, which aimed to improve high-speed linearity and reduce steering torque at low speeds by reducing the gear ratio appended to in-line steering wheels and increasing the gear ratio around large corners, was adopted for vehicles, and spread throughout the 1970s.

Further, in 1975, steering systems such as the worm pin type and worm roller type disappeared, and the ball screw type became mainstream in America, Japan, and other countries.

In addition, rack-and-pinion-type steering systems, which have simple link mechanisms, have excellent mountability, and can obtain highly rigid and guarded steering, started to be used in Europe from around 1905 and thereafter became widely adopted from around 1955–1975, such that this format was used overwhelmingly and became mainstream. Due to increasing miniaturization and compaction, and the take-up of four-wheel drive in particular, there was a move from ball screw gears to rack-and-pinion gears. Further, this mechanism, with its rack-and-pinion gear ratio, came to be adopted from around 1981 with the objective of reducing driving torque, leading to the present day.

25.3.2 History of Power Steering

Steering torque increased with the adoption of low-pressure tires, increased weight, and vehicle miniaturization. It was planned to increase gear ratios as a result of this, but power assistance came to be demanded, by heavy vehicles in particular, due to the relationship between the suitability of the steering gear ratio and the steering torque from the aspect of steerability.

In America, in 1926, the hydraulic power steering (PS) was created and was displayed mounted to the Pierce-Arrow Car. Thereafter, various types of power steering, such as the vacuum type, compressed-air type, and electrical type, etc., were tried. From around 1940, hydraulic power steering was mounted to heavy trucks and buses, becoming actualized. Further, due to power steering miniaturization, integral power steering (IPS), which combined the power cylinder and control valve on the steering gearwheel as one unit, was developed in 1962, and went into mass production in 1965.

Meanwhile, hydraulic power steering started to be mounted to ball screw steering systems in passenger vehicles in America from 1951. This ball screw IPS spread, and in America, in 1965, approximately 60% of vehicles had power steering mounted. In Europe, on the other hand, the rack-and-pinion type spread, and in 1955, this type of power steering went into mass production.

After the start of the 1980s, together with the increase in front-wheel load four-wheel drive, the mounting of power steering to ordinary people carriers increased rapidly. Concomitant with the spread of four-wheel drive vehicles, there was a shift from the existing ball screw IPS to rack-and-pinion power steering, and thereafter this type of power steering became mainstream.

In vehicles with a fixed amount of power assistance, there is a tendency for the steering torque to be reduced too much when driving at high speeds. Consequently, steering torque variable power steering soon became necessary in consideration of the balance between steerability and stability.

Around 1966, the amount of output from oil pumps was reduced in response to the number of engine rotations using flow control valves, and variable steering torque power steering that was made sensitive to the number of engine rotations and could suppress the amount of power assistance during high-speed driving. In Europe, in 1970, a system that varied the steering torque according to the vehicle speed and steering angle was mounted to Citroen SM vehicles.

Along with the progress made in electronics technology, during the 1980s, several types of electronically controlled variable torque power steering were developed and adopted one after the other. In 1981, the controllable flow-type electronically controlled variable power steering was adopted, and the controllable reaction force-type electronically controlled variable power steering was adopted in 1983, and then in 1989, the valve-sensitive adjustable control type was also adopted.

In 1988, power steering became electrically powered (EPS). A DC motor, as its power source, was successfully applied to compact vehicles. Compared to the hydraulic type, this EPS, with its simple and lightweight configuration, was an effective system with extremely small engine power loss. Thus, it gradually started to be used in big vehicles as well.

25.4 BASIC THEORY OF STEERING SYSTEMS

25.4.1 Ackerman Steering

The ratio between the steering wheel angle and the front tire steering angle (the mean between the steering angle of the inner wheel and that of the outer wheel) is called the overall steering gear ratio. The size of this value is related to the steerability and stability. As described earlier, and as shown in Figure 25.5, the actual steering angle between the inner and outer wheels is different as shown in Figure 25.6 [3].

The basic ideas for this occurrence are as follows:

With turning at extremely low driving speeds, the centripetal acceleration is almost zero, so there is no need for force on any of the tires. With turning at nonvanishing speed, the forces at the tires are nonvanishing due to the centrifugal force. If such force is applied, slip will occur on the tires. To prevent such tire force being applied improperly to the tires, that is, to prevent friction wear, a common method to set the tires is depicted in Figure 25.5. It should be noticed

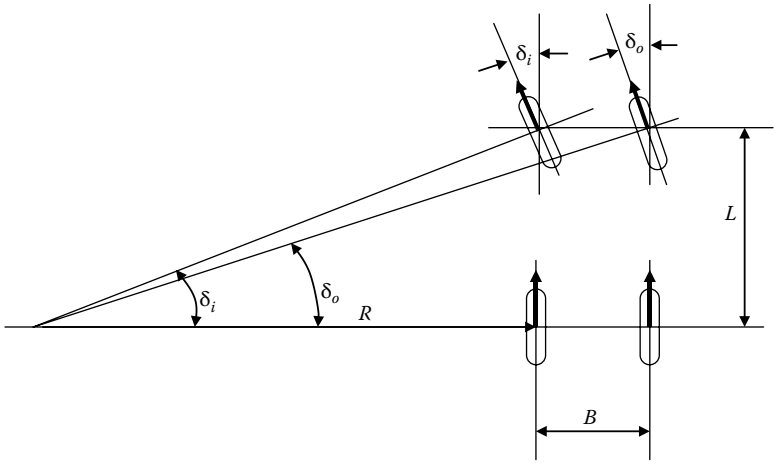

FIGURE 25.5 Geometrical relation between turning radius and steer angle. (From Kondo, M., *Basic Automotive Engineering*, Vol. I, Yokenndo, Tokyo, Japan, 1965; Kageyama, K. et.al., *Vehicle Dynamics*, Riko Press, Tokyo, Japan, 1984; Genta, G., *Motor Vehicle Dynamics*, World Scientific, Singapore, 1997.)

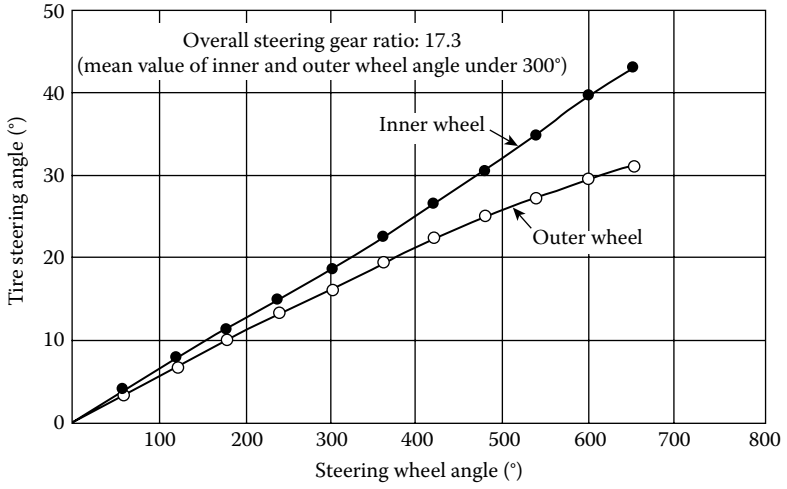

FIGURE 25.6 Example of the relationship between steering wheel angle and tire steering angle. (From Kageyama, K. et.al., *Vehicle Dynamics*, Riko Press, Tokyo, Japan, 1984.)

that this setting (Ackermann) is correct only when the speed is vanishing. When the speed is not vanishing, the setting in Figure 25.5 usually implies almost the same lateral slip at the two wheels of the same axle, which implies that, due to load transfer, the lateral forces are not equal between the two wheels of the same axle (the lateral force of the outer wheel is higher). This occurrence can be overcome by setting different steering angles at each wheel. It is necessary to set the tires so that side slip angle occurs. The position of the rotation center for the vehicle is located on the right-angled direction to each wheel center velocity. The geometrical rotation center at zero speed is on a line extending from each wheel axle. As shown in Figure 25.5, the inside steering angle is called δi, and the outside steering angle is called δo. It is assumed here that the wheel base (L) is the same for both left and right and that the tread (B) is also the same for both front and rear axles. The distance from the rotation center to the inside of the rear wheels is taken to be the turning radius (R). These relationships can be collated and expressed using the following equation:

$$\cot \delta_o - \cot \delta_i = \frac{B}{L} \tag{25.1}$$

If the turning radius here is extremely large compared to the tread, gathering the right and left wheels in the chassis longitudinal axis and assuming the steering angle to be δ, δ can be expressed as described in the following:

$$\tan \delta = \frac{L}{R} \tag{25.2}$$

Next, the relationship between the coordinates fixed on the road surface can be expressed as described in Figure 25.6. The coordinates of the vehicle longitudinal axis fixed on the road surface can be expressed here using the following equation:

$$R = \frac{-\sqrt{\left\{1 + (dy/dx)^2\right\}^3}}{d^2y/dx^2} \tag{25.3}$$

25.4.2 Modeling of the Steering System

25.4.2.1 Equivalent Moment of Inertia in Steering Systems

Steering systems perform steering using steering gears, so it is necessary to examine the equivalent moment of inertia around the steering shaft. A model of the steering system is described in Figure 25.7. Assuming that screw displacement is small, the equation of equilibrium in this diagram can be determined using the following equations [3]:

$$\begin{aligned} T &= I_h\ddot{\theta}_h + r_1F_1 \\ r_2F_1 &= I_s\ddot{\theta}_s + r_3F_2 \\ F_2 &= m\ddot{x} \end{aligned} \tag{25.4}$$

Further, the following formula describes the relationship between the angles and the displacement:

$$\begin{aligned} r_1\theta_h &= r_2\theta_s \\ r_3\theta_s &= x \end{aligned} \tag{25.5}$$

Consequently, the following formula can be obtained from these relationships:

$$T = \left\{ I_h + \left(\frac{r_1}{r_2}\right)^2 \left(I_s + r_3{}^2 m\right) \right\} \ddot{\theta}_h \tag{25.6}$$

Consequently, the equivalent moment of inertia around the steering shaft of the steering system can be obtained using the following formula:

$$I_{eh} = I_h + \left(\frac{r_1}{r_2}\right)^2 \left(I_s + r_3{}^2 m\right) = I_h + \frac{\left(I_s + r_3{}^2 m\right)}{n^2} \tag{25.7}$$

Here, n describes the gear ratio ($n = r_2/r_1$).

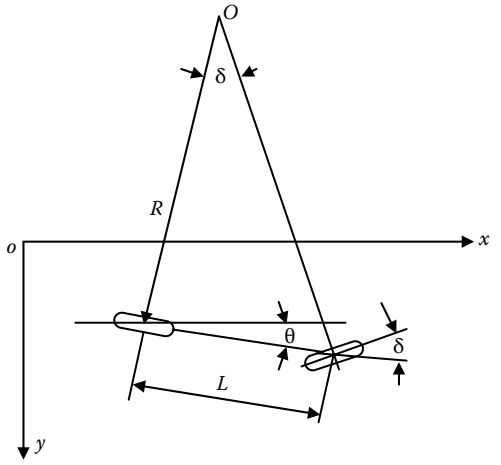

FIGURE 25.7 Geometrical relation between turning radius and steer angle. (From Kageyama, K. et.al., *Vehicle Dynamics*, Riko Press, Tokyo, Japan, 1984; Genta, G., *Motor Vehicle Dynamics*, World Scientific, Singapore, 1997.)

Conversely, the moment around the shaft behind the steering gear can be described similarly as shown by the following equation:

$$I_{es} = I_h n^2 + I_s + r_3^2 m \tag{25.8}$$

From the preceding equation, it can be seen that if passing through the steering gear (gear ratio n), the moment of inertia for the steering wheel are $x\,n^2$ over the circumference of the front-wheel steering shaft.

Simplifying this analysis means considering the rotation operation around the kingpin only. The equivalent moment of inertia for the steering system described in Figure 25.7 can be determined as described in the following equation:

$$I_{es} = I_h n^2 + I_s \tag{25.9}$$

25.4.2.2 Modeling for Simple Steering Systems

The steering system needs to be modeled by considering viscous friction and dry friction. The friction occurs in the shaft, and the elastic warping of the shaft is also important. The steering performed by the driver on the vehicle becomes angle inputs or torque inputs. The actual steering angle of the front tires here is not proportionally related to the steering wheel angle. To consider these effects, it is necessary to configure the equations of motion that describe the steering system, and to solve them simultaneously with the vehicle equations of motion. This section instructs on the equations of motion for the steering system only.

The steering system in Figure 25.8 has two degrees of freedom, and the equations of motion for the steering torque inputs can be solved simultaneously with the equation of equilibrium of the moments for the kingpin circumference and the balance for the moments of the steering shaft circumference. For simplification, try replacing the item on the steering shaft circumference with the kingpin shaft circumference.

Balance of steering shaft circumference:

$$I_h'\ddot{\theta}_h' + D_s\theta_h' + k\theta_h' - k\theta_s - D_s\theta_s = T_h' \tag{25.10}$$

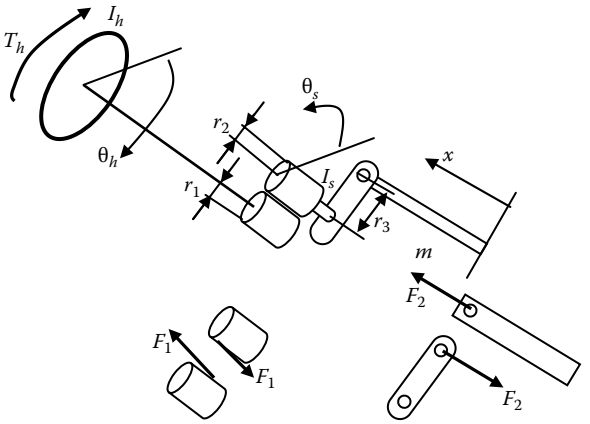

FIGURE 25.8 Element of steering system.

Balance of kingpin shaft circumference:

$$I_s\ddot{\theta}_s + D_s\dot{\theta}_s + k\theta_s - k\theta'_h - D_s\dot{\theta}'_h = -T_s \tag{25.11}$$

With these formulae, the parameters marked with an apostrophe (′) describe the values calculated for the kingpin shaft circumference and are expressed using the following formula:

$$I'_h = I_h n^2, \quad T'_h = T_h n, \quad \theta'_h = \frac{\theta_h}{n} \tag{25.12}$$

Further, the parameters are also described in Table 25.1.

With steering wheel angle inputs, it is not necessary to consider the effect of moment of inertia for the steering wheel. Therefore, the simple equation for the steering system is described as one degree of freedom around the kingpin shaft, and the total equations of motion are solved with the vehicle equations of motion simultaneously:

$$k\theta'_h - T_s = I_s\ddot{\theta}_s + D_s\dot{\theta}_s + k\theta_s \tag{25.13}$$

In this equation, T_S is the restoration moment of the tire and is the product of adding the self-aligning torque and the moment caused by front-wheel geometry (i.e., the effects of caster trail, kingpin inclination, roll center, kickback from road, and so on) (Table 25.2).

TABLE 25.1

Parameter	Explanation
T_h	Steering torque
I_h	Moment of inertia around steering axis
I_s	Moment of inertia around output steering gear
θ_h	Steering wheel angle
θ_s	Steer angle for output gear
F_1	Inner force of steering gear
F_2	Inner force of steering link
m	Mass for link
r_1	Radius for input steering gear
r_2	Radius for output steering gear
r_3	Radius for pitman arm

TABLE 25.2

Parameter	Explanation
T'_h	Equivalent steering torque
I'_h	Equivalent moment of inertia around
I_s	Moment of inertia around kingpin
θ'_h	Equivalent steering wheel angle around kingpin
Δ	Steer angle
K	Rotational spring constant around steering shaft
T_s	Restoration moment
D_s	Viscous resistance coefficient
K_s	Cornering stiffness
B	Slip angle
V	Vehicle speed

25.4.2.3 Detailed Model of the Steering System

The preceding section examined a simple model of the steering system. Here, the steering system described is a more advanced model [4].

As described in Figure 25.9, the steering shaft has an inclination of Φ over the vertical shaft. Consequently, the vehicle rotation operation is affected. Here, the yawing velocity must be considered. Further, the moments and torque due to viscous resistance and dry resistance in the bearings are used. In addition, it is also necessary to consider the elastic warping of the parts that maintain the steering system. Moreover, when the front wheels rotate, and the camber angle changes in the steering wheels due to the roll operation, the gyro moment affects the steering shaft circumference. This section describes the operational formulas for steering systems that consider these points.

In Figures 25.9 and 25.10, the steering system can be divided into two parts, above and below the steering gear. The operational formula from the steering wheel to the steering gear can be described using the following equation:

$$T_h = I_h(\ddot{\theta}_h + \dot{r}\cos\phi) + k_h\left(1 - \frac{n^2 k_h}{n^2 k_h + k_s + k_1}\right)\theta_h - \frac{nk_h k_s}{n^2 k_h + k_s + k_1}\theta_s \pm \frac{n^2 k_h}{n^2 k_h + k_s k_1} R_h \tag{25.14}$$

The parameters used here are described in Table 25.1. Further, in this formula, the viscous resistance of the shaft is not considered. Next, the operational formula from the steering gear to the front wheels can be described using the following equation:

$$I_s(\ddot{\theta}_s + \dot{r}) - \frac{nk_h k_s}{n^2 k_h + k_s + k_1}\theta_h - \left(\frac{{k_s}^2}{n^2 k_h + k_s + k_1} - k_s - k_2 - 2K_s\right)\theta_s + D_s\dot{\theta}_s + 2K_s\beta$$
$$+ 2I_w\frac{v}{R}\dot{\gamma} \pm \left(\frac{n^2 k_h}{n^2 k_h + k_s k_1} R_h - R_s\right) = 0 \tag{25.15}$$

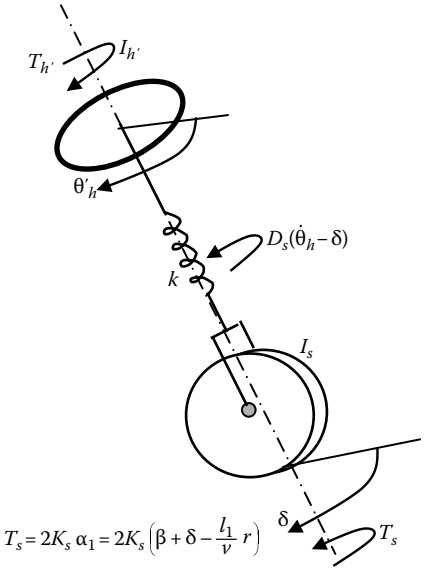

FIGURE 25.9 Simple steering model.

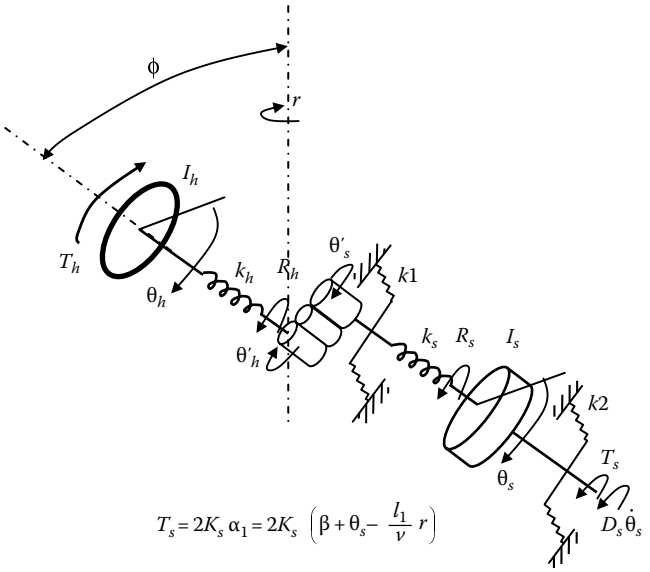

FIGURE 25.10 Detailed model of the steering system. (From Kondo, M., *Basic Automotive Engineering*, Vol. II, Yokenndo, Tokyo, Japan, 1967.)

TABLE 25.3

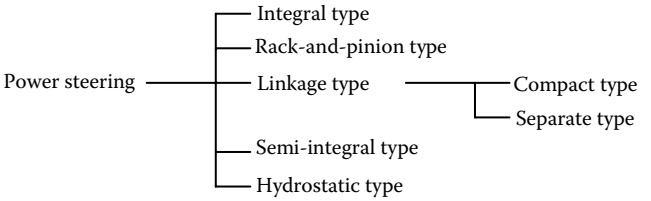
Parameter	Explanation
Φ	Inclination of steering shaft
R	Yawing velocity
K_h	Rotational spring constant around steering shaft
K_s	Rotational spring constant around kingpin
k_1	Spring constant at installation part 1
k_2	Spring constant at installation part 2
D_s	Viscous resistance coefficient around kingpin
R_h	Dry friction around steering shaft
R_s	Dry friction around kingpin

In this formula, the gyro moments due to the rotation of the steering wheels are considered. The section on viscous resistance considers the kingpin shaft circumference only. Further, the ± in the formulas is the section on dry friction, and tends to reverse rotation according to the direction of operation and rotation of each part (Table 25.3).

25.5 POWER STEERING

To lighten the steering torque in manual steering, it is necessary to increase the steering gear ratio and reduce the friction in all parts. By increasing the gear ratio, however, the steering angle is also increased at the same time. Power steering devices are steering systems that are equipped with motive power assistance devices to assist the steering torque, with the aim of reducing the steering torque.

By using this power assistance, the gear ratio can be selected freely, and the amount of design freedom can also be increased. Steering is a bilateral system, and as it is not the driver who inputs the steering torque but that the torque is input to the steering system from the tires, for the driver,



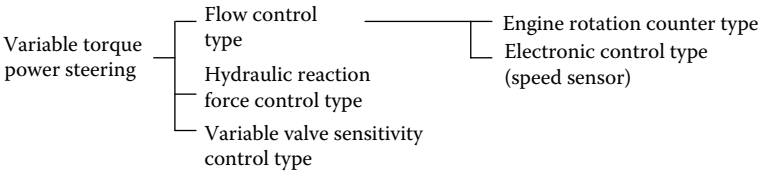
this also becomes a type of information while driving. With this in mind, it is necessary to consider power assistance that satisfies the following requirements [5]:

- Steering torque is suitable.
- Both steering torque and maintained steering force enable the close relationship with the road surface reaction force to be felt.
- There is no impediment to recovery from turning the vehicle's steering wheel.
- This enables suitable absorption of shock from the road surface.

25.5.1 Types of Power Steering

Hydraulics, air pressure, and electric motor are all sources of motive power in the power assistance devices of power steering, but the hydraulic type is the mainstream power steering due to its compactness, high output, responsiveness, and reliability. Further, in recent years, due to its excellent ease of mounting, attributed to its lightweight compactness and simple configuration, the electric type power steering has started to be adopted, mainly for compact vehicles [5].

There are various types of hydraulic power steering, depending on the control valve; power cylinder; and steering gear box configuration, arrangement, and assembly. These can be classified as follows:



Classifications are shown in the preceding diagram.

The integral type combines the control valve and power cylinder inside a ball-screw-type steering gear box and is used in some passenger vehicles, trucks, and buses. The rack-and-pinion type combines the control valve and power cylinder inside this type of gear box, and the main unit is combined with part of the link mechanism. This type is widely used in passenger vehicles. The linkage type arranges the control valve and power cylinder in the link part, which is behind the steering gears. This is either all-in-one or separate, and can be classified either as combined or separate type. This type of power steering is historically old and is currently used only in some large trucks. The semi-integral type combines the control valves in the gear box, and the power cylinder is mounted to the link part. This type is used in industrial vehicles and construction vehicles. The hydrostatic type operates the power cylinders for the car wheels using hydraulics from the control valve, which is mounted to the operation part, with no mechanical link connections between the operation part and the wheels. This type is used in agricultural tractors, fork lift trucks, and construction vehicles.

With power steering, it is necessary to control the amount of power assistance according to the conditions. Essentially, steering torque becomes excessive and power assistance is necessary when accelerating at extremely low speeds from a standstill. Further, conversely, if excessive assistance is performed during high-speed driving, the vehicle operations will become oversensitive, and there is a tendency for the steering wheel system stability to be lost. Here, it is necessary to perform major power assistance at extremely low speeds in garages and during major steering maneuvers and to perform controls to reduce assistance at high speeds. Normally, control by

speed sensors and by engine rotation counters is performed. These can be collated as shown in the following diagram.

25.5.2 Modeling for Power Steering Systems

As shown in the aforementioned diagram, with hydraulic power steering, which is the current mainstream and which performs power assistance using controlled operating oil, the power cylinders can be divided into three parts: control valves, which control the direction of the hydraulic flow, and oil pumps, which are powered by the engine. A torsion bar is mounted to the steering shaft, and turn torque is created in the steering shaft by steering, and the direction of the operating oil is controlled by operating the control valve (e.g., spool valve) according to the turn angle of this torsion bar. This operating oil that is being controlled is fed into the power cylinder to enable power assistance to be performed.

The parameters are described in Table 25.4.

The formula for balancing the circumference of the steering wheel is described as follows:

$$I_h\ddot{\theta}_h + C_h\dot{\theta}_h + K_t(\theta_h - \theta_w) = T_h \tag{25.16}$$

TABLE 25.4

Parameter	Explanation
T_h	Steer torque around steering wheel
T_w	Warm shaft torque
T_c	Sector torque
F_p	Force between warm shaft and ball-nut
I_h	Moment of inertia around steering wheel
I_w	Moment of inertia around warm shaft
I_c	Moment of inertia around sector shaft
M_p	Mass for ball-nut
Θ_h	Rotational angle around steering shaft
Θ_w	Rotational angle around warm shaft
Θ_c	Rotational angle around sector shaft
X_p	Lateral deviation of ball-nut
K_t	Equivalent rotational spring constant for spool
K_c	Equivalent rotational spring constant for output shaft
C_h	Viscous resistance coefficient around steering shaft
C_w	Viscous resistance coefficient around warm shaft
C_p	Viscous resistance coefficient of ball-nut
C_c	Viscous resistance coefficient around output shaft
R_c	Radius of pitch circle of sector gear
E_w	Lead of warm gear
A_p	Effective area for ball-nut
P_a	Pressure of ball-nut vessel *a*
P_b	Pressure of ball-nut vessel *b*

The formula for balancing the sector circumference is as follows:

$$I_w\ddot{\theta}_w + C_w\dot{\theta}_w + K_t(\theta_w - \theta_h) = -\left(\frac{e_w}{2\pi}\right)F_p \tag{25.17}$$

The formula for balancing the ball-nut circumference is as follows:

$$m_p\ddot{x}_p + C_p\dot{x}_p = F_p + A_p(p_a - p_b) - \frac{T_c}{r_c} \tag{25.18}$$

The following formula can be obtained using the balance with the external force around the output shaft (sector shaft):

$$I_c\ddot{\theta}_c + C_p\dot{\theta}_c - K_c\theta_c = T_c \tag{25.19}$$

Here

$$\begin{aligned} x_p &= \frac{e_w}{2\pi}\theta_w \\ \theta_c &= \frac{x_p}{r_c} = \frac{\theta_w}{n} \\ n &= \frac{2\pi r_c}{e_w} \end{aligned} \tag{25.20}$$

From the preceding relationships, the equations of motion for the power steering system can be written as follows:

$$I_h\ddot{\theta}_h + C_h\dot{\theta}_h + K_t(\theta_h - \theta_w) = T_h \tag{25.21}$$

$$I_{wt}\ddot{\theta}_w + C_{wt}\dot{\theta}_w + K_{ct}\theta_w + K_t(\theta_w - \theta_h) = A_{pt}(p_a - p_b) \tag{25.22}$$

Here

$$\begin{aligned} I_{wt} &= I_w + \left(\frac{r_c}{n}\right)^2 m_p + \left(\frac{1}{n}\right)^2 I_c \\ C_{wt} &= C_w + \left(\frac{r_c}{n}\right)^2 C_p + \left(\frac{1}{n}\right)^2 C_c \end{aligned} \tag{25.23}$$

$$K_{ct} = \left(\frac{1}{n}\right)^2 K_c$$

$$A_{pt} = \frac{r_c}{n}A_p$$

25.5.3 Example Analysis Including Power Steering System

An analysis using the power steering system model described in the preceding paragraph is shown. The block diagram of the power steering system is shown in Figure 25.11.

Figure 25.12 shows an analytical result of frequency response of the vehicle using the model in Figure 25.11. The parameter of this calculation is rigidity of the power steering system, and the vehicle used in the calculation is a light truck.

From this figure, it is found that the rigidity of the PS has a big influence on the vehicle behavior [5]. And, the influence of sensitivity of the valve and the viscous resistance inside the PS to vehicle behavior has been examined [5–7].

In addition, it is important that the evaluation method of the PS has been investigated from the viewpoint of human engineering [8–12]

25.5.4 Electric Power Steering

The electric power steering (EPS) system has high potential because various characteristics can be reproduced by using its control algorithm [11,13–17]. Furthermore, various driver support systems are constructed by using the EPS, for example, parking assistance, lane keeping, and so on [18–21].

Moreover, this system can attempt the improvement of fuel consumption compared with the hydraulic-type power steering system. Therefore, many compact cars have mainly adopted the EPS

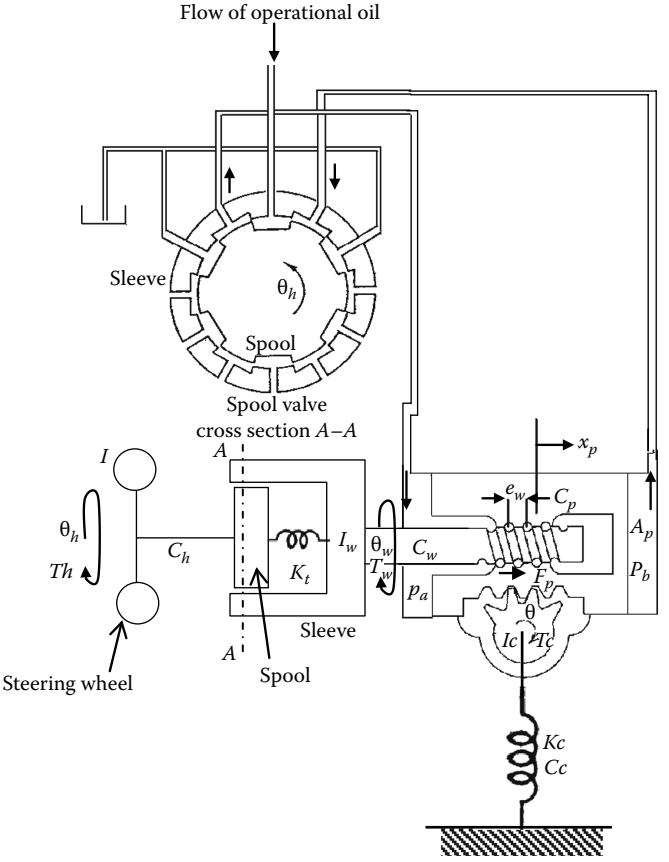


FIGURE 25.11 Modeling of power steering system. (From Komamura, S. et al., *Steering and Dynamics*, Sankai-do Press, Tokyo, Japan, 1996.)

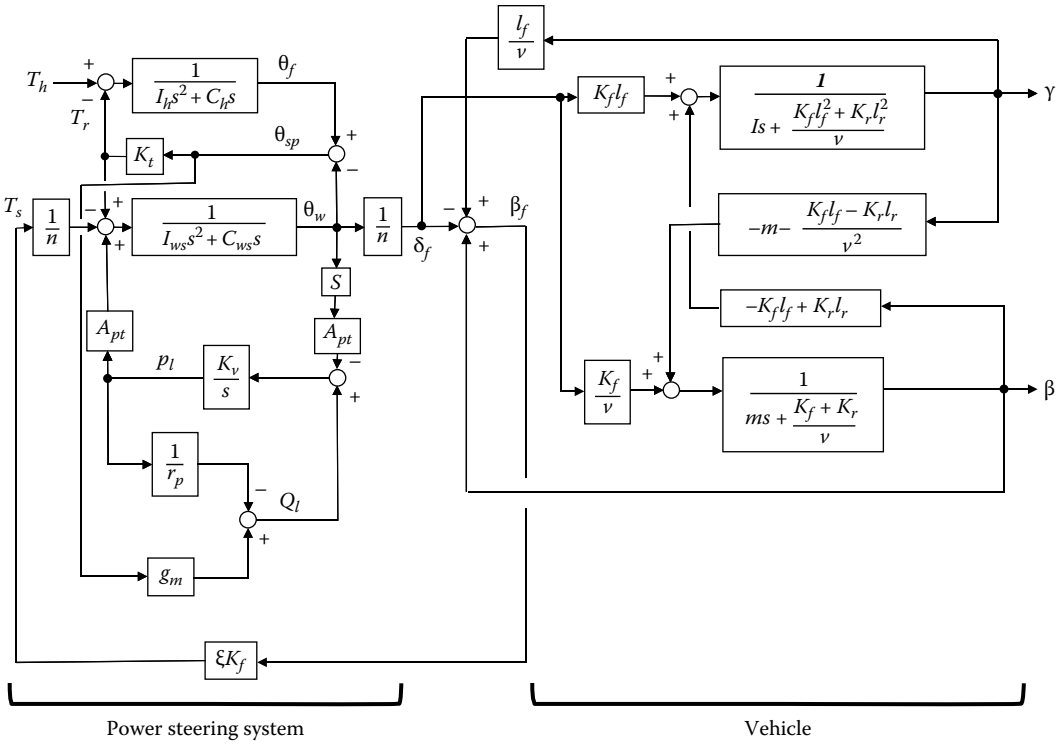

FIGURE 25.12 Block diagram for power steering system. (From Komamura, S. et al., *Steering and Dynamics*, Sankai-do Press, Tokyo, Japan, 1996.)

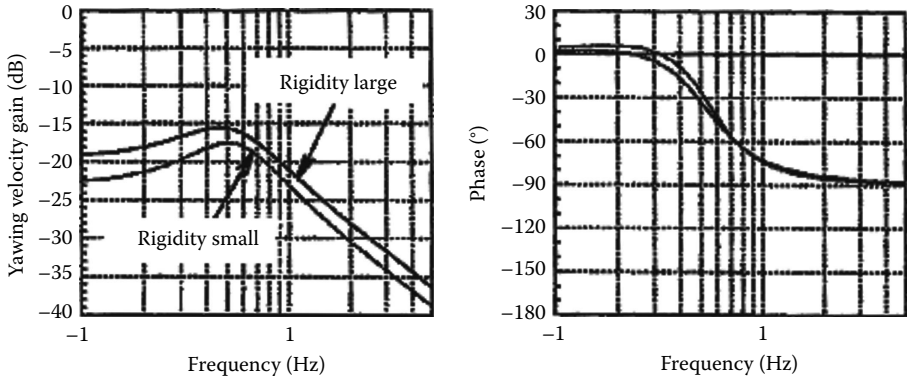

FIGURE 25.13 Analytical result of the vehicle including power steering (Influence of rigidity of PS). (From Komamura, S. et al., *Steering and Dynamics*, Sankai-do Press, Tokyo, Japan, 1996.)

in recent years [5]. The EPS is divided roughly into the following three types by the assist position of a motor: the column-assisted type, the pinion-assisted type, and the rack-assisted type as shown in Figure 25.13.

25.5.4.1 Modeling for EPS

Recently, many EPSs in the market adopt the pinion-assist type. Therefore, the pinion-assist-type EPS is described as the analytical model (see Figure 25.14) [16].

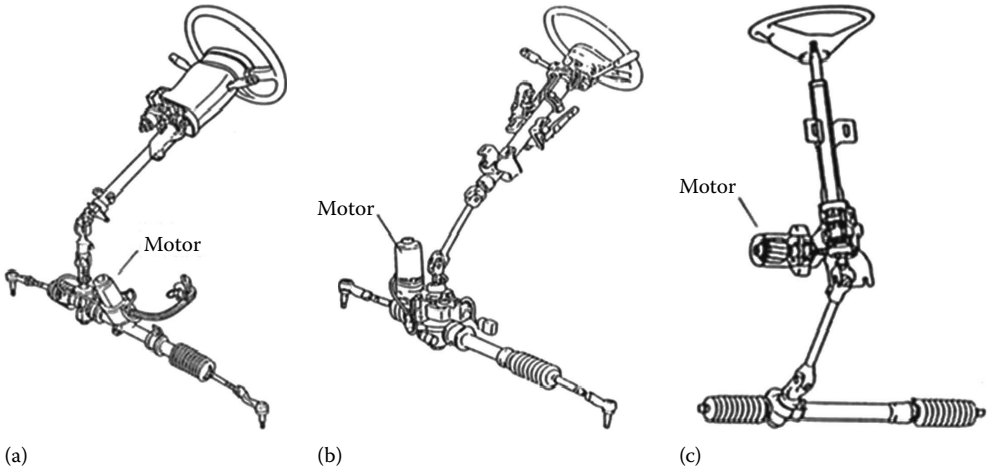

FIGURE 25.14 EPS types. (a) Rack-assist type, (b) Pinion-assist type, (c) Column-assist type. (From Komamura, S. et al., *Steering and Dynamics*, Sankai-do Press, Tokyo, Japan, 1996.)

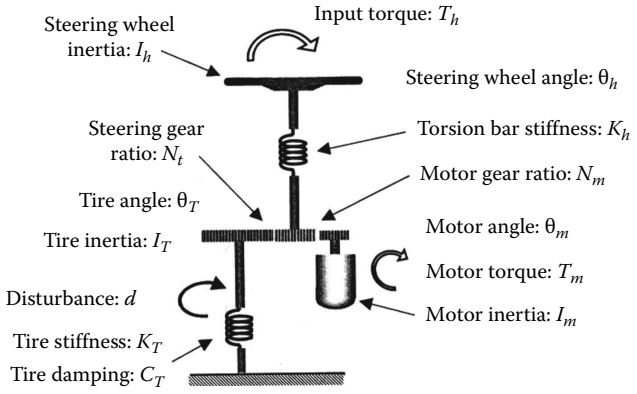

FIGURE 25.15 Model of electric power steering. (From Takehara, S., Control of electric power steering, Preprint of intensive seminar for vehicle dynamics, *JSME*, 08–44, 45, 2008.)

The parameters used here are described in Figure 25.14. Further, in this model, the viscous resistance of the model is considered in the part of tire. Next, this model is simplified as shown in Figure 25.15. In this model, the equivalent parameters are used as shown in Figure 25.15.

Using this model, the equations of motion for the EPS are described as follows:

$$I_H\ddot{\theta}_H + K_H(\theta_H - \theta_M) = T_H$$
$$I_M\ddot{\theta}_M + C_T\dot{\theta}_M + K_T\theta_M + K_H(\theta_M - \theta_H) = T_M + d \tag{25.24}$$

25.5.4.2 Block Diagram of Control System

An analysis using the electric power steering model described in the preceding paragraph is shown. Therefore, the block diagram of the control system for the EPS is as shown in Figure 25.16. In this figure, K_1 and K_2 are the control gains: K_1 is the assist gain and K_2 is the damping gain for the total system [16].

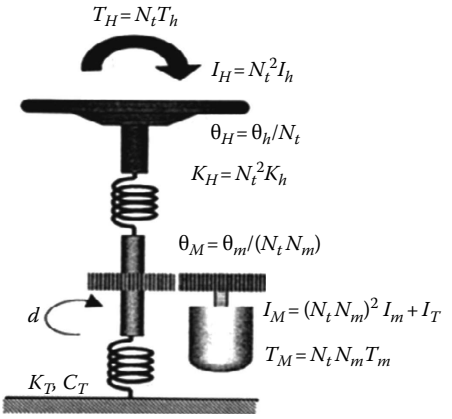

FIGURE 25.16 Simplified electric power steering model. (From Takehara, S., Control of electric power steering, Preprint of intensive seminar for vehicle dynamics, *JSME*, 08–44, 45, 2008.)

25.5.4.3 Vehicle Model Including EPS

An analytical vehicle model with the simplified EPS is described as shown in Figure 25.17. Here, the caster trail, which is the length between kingpin axis at the road and the center of a tire contact point, is described by ξ as shown in Figure 25.1. The parameters of the vehicle are shown in Figures 25.17 and 25.18 [16].

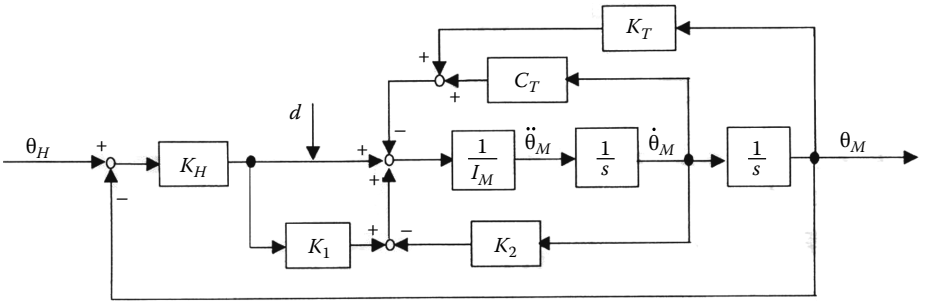

FIGURE 25.17 Block diagram of control system with EPS. (From Takehara, S., Control of electric power steering, Preprint of intensive seminar for vehicle dynamics, *JSME*, 08–44, 45, 2008.)

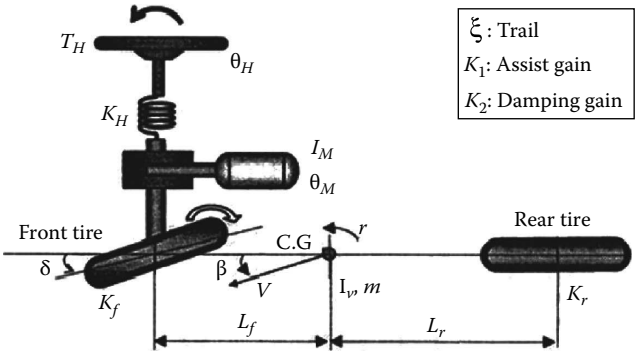

FIGURE 25.18 Vehicle model with EPS. (From Andonian, B. et al., Driver steering performance using joystick vs steering wheel controls, SAE Paper No. 2003-01-0118, 2003.)

The formulas for balancing the circumference of the vehicle are described as follows:

$$\left\{mv + \frac{2(l_f K_f - l_r K_r)}{v}\right\} r + mv\dot{\beta} + 2(K_f + K_r)\beta = 2K_f\delta$$

$$I_v\dot{r} + \frac{2\left(l_f{}^2 K_f + l_r{}^2 K_r\right)}{v} r + 2(l_f K_f - l_r K_r)\beta = 2l_f K_f\delta \tag{25.25}$$

The equations of the EPS part are described as follows:

$$I_H\ddot{\theta}_H + K_H(\delta - \theta_H) = T_H$$

$$I_M\ddot{\delta} + C_T\dot{\delta} + 2\xi K_f\delta + K_H(\delta - \theta_H) - 2\xi K_f\left(\beta + \frac{l_f r}{v}\right) = T_M \tag{25.26}$$

$$T_M = K_1 K_H(\theta_H - \theta_M) - K_2\dot{\theta}_M$$

Using these equations, the relationship between vehicle behavior and design parameter of the EPS is derived [5,21,16]. In addition, it is important that the evaluation method of the EPS is investigated from the viewpoint of human engineering, and also the examination of robustness for the control system becomes important [16,17].

26.1 INTRODUCTION

The body of a vehicle is a very complex structure. Usually, it consists of thin-walled beams, characterized by an appropriate section shape, and thin shells properly drawn in order to obtain the selected body shape. Figure 26.1 shows an example of a recent car body: body frame structure, panels, lateral doors, back door, and motor compartment hood are clearly visible. Steel in sheets, with a relatively large, and further increasing, variety of steel types available today, is a much utilized material for car body construction. Recently, other materials, both metallic and plastic, are also widely used, with an increasing percentage, mainly due to the lightweight requirements for new vehicles.

The body structure is designed to play a number of different functions, of great relevance for the product quality, that is, for those vehicle characteristics that a customer will consider carefully when he/she decides to buy a vehicle.

In particular, one has to consider the following:

- The room, the exterior look, and the passenger compartment style.
- The aerodynamic shape and performance have a large influence on the fuel consumption (and therefore on the operation costs).
- The bending and torsion stiffness of the vehicle structure have a large influence on handling, on the riding comfort, on the fatigue strength, and even on the entity of squeaks and rattles.
- The anchoring structure for mounting and/or connecting all the vehicle mechanical subassemblies and devices: the internal combustion engine, the gear box, and the motion transmission line, the vehicle suspensions and the steering system, the brake system and the driver pedals, the exhaust pipe, and so on.
- The reliability, with particular reference not only to the fatigue endurance but also to ageing phenomena, that is, the progressive decrease in other quality characteristics with time and use.
- The acoustic and vibration comfort (commonly called NVH or noise, vibration, and harshness) with particular reference to the passenger compartment and with respect to the main noise sources related to the internal combustion engine, the gear box, and the tire rolling.

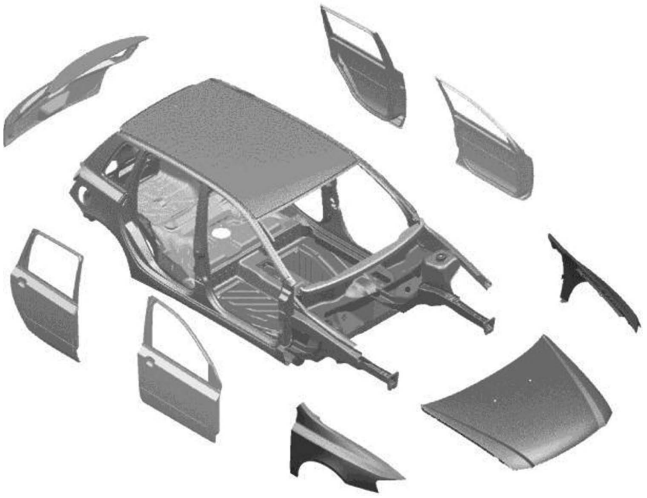

FIGURE 26.1 Body of a recent car with five doors.

- The thermal/climatic comfort inside the passenger compartment.
- The comfort for the vehicle driver and the passengers, in terms of both accessibility and seating position during the ride; for the vehicle driver position, there are some other additional requirements related to the easy accessibility and maneuverability of the commands.
- The passenger safety in case of accident.

These points will be briefly examined in the following paragraphs with particular attention to the more recent solutions and design approaches.

26.2 EXTERIOR LOOK AND PASSENGER COMPARTMENT STYLE

Vehicle style is the capital, although not unique, factor for the sell success of a vehicle. Vehicle style has, on one side, details distinctive of the car manufacturer that are maintained over the years and, on the other side, specific characteristics linked to the customer preference evolution, taking into account the differences encountered in the different markets. Nowadays, it is evident that there is a tendency toward vehicle personalization as a distinctive mark of its owner. Personalization is obtained through the careful choice of a number of aesthetic details that differentiate the available versions of the same vehicle. Moreover, there are the so-called niche models, that is, vehicles produced in small/medium series with an exterior look remarkably differentiated with respect to the mass production vehicles (e.g., the mono-volume vehicles that, starting with the Renault Espace, have progressively gained relevant market portions, in comparison with the more traditional sedans of the two- or three-volume types).

Nowadays, the passenger compartment has also definitely gained importance in vehicle aesthetic characterization and increasing attention is paid to the style of the seats, dashboard, instrument set, steering wheel, door inward panels, and other interior dressing panels. Finally, it is worth noting that a little attention is also paid to the engine compartment dressing; even in this compartment, nowadays, an orderly and pleasant disposition of different devices, electric cables, and tubes is expected.

26.3 AERODYNAMICS

The dramatic energy crisis of the 1970s contributed to point out the role of the aerodynamic performance of the exterior shape of the vehicle with respect to the fuel consumption while riding [1,2]. Since that date, systematic studies about the aerodynamic profile of the external shape of the

body have been developed, particularly aimed to reduce the longitudinal aerodynamic coefficient C_x. Refinement of the analysis techniques allowed to study in detail the dependence of all the six aerodynamic coefficients on the vehicle characteristic motion angles with respect to the air flow direction. From this point of view, particular attention has been paid to the effect of the lateral aerodynamic flow on the driving stability through specific studies on the sensibility of the vehicle trajectory to the lateral wind.

The external shape has been progressively modified over the years, and optimal parameters have been identified, such as, for example, the windscreen angle and the rear truncation shape, both for two-volume and the three-volume vehicles. Optimized shape and position for aerodynamic profiles have been researched: Front aerodynamic dam has been added to improve the air flow through the water cooler of the internal combustion engine, appropriate position has been determined for the intake vent to improve the passenger compartment air flow, and rear spoilers have been added [3]. Moreover, the external shape of the vehicle deck has been specifically studied in order to have appropriate air flow under the vehicle with a little lift aerodynamic effect. The type and shapes of the external joints of the body structure parts have been deeply modified: The drop channels, which were typical of the automobiles up to the 1970s, progressively disappeared and the modern roof is smooth; the window sealant contours, especially in the case of the front windscreen, have been redesigned in order to avoid the detachment of the air flow and the formation of vortexes; and the external shape of the lateral mirrors and door handles have been modified with the same scope for aerodynamic performance optimization [3,4].

Furthermore, the aerodynamic design of the vehicle body has led to important improvement in the air flow inside the passenger compartment. The inlet and outlet vents have been properly positioned in order to obtain more favorable air mass flow. Careful studies of air flow inside the passenger compartment have been conducted in order to improve both the internal climatization, toward a good uniformity of the temperature, and the windscreen wipe, against mist.

Research in the field of aerodynamics has developed in two main directions: On one side, the experimental test through the design and development of aerodynamic wind tunnels equipped with specific instruments and sophisticated measurement devices for the analysis of aerodynamic flow; on the other hand, the numerical simulation through the development of computational codes, based on the fluid domain discretization by a specialized finite element approach, that permits a detailed analysis of the aerodynamic behavior of the vehicle profile. The use of the numerical approach requires very large computing machines because it is necessary to discretize, with good quality mesh, details of a vehicle's external shape, with good refinement in the air volume in the neighborhood of the body, and with sufficient detail of other air mass inside the wind tunnel.

The persevering comparison of the measured experimental results, not only the global values expressed by the six aerodynamic coefficients characteristic of the vehicle body but also the values of the specific localized phenomena, with the numerical simulation results, has permitted the development of a good mathematical model. Furthermore, through this analysis, the profile designer has gained better knowledge of the influence of each shape detail on the vehicle global behaviour.

26.4 BENDING AND TORSION STIFFNESS

The vehicle structure has its own values of the bending and torsion stiffness, and both are calculated on the basis of the displacements, measured at one of the axles with respect to the other one that is completely clamped, due to vertical forces applied at the wheel centers. These stiffness values are the consequence of the structure configuration that has been chosen for the base frame and for the deck. These values increase when the windshield and the window glasses are applied, due to their effect as shear panels, and when the whole vehicle is considered. Data on the body stiffnesses are reported in Table 26.1.

TABLE 26.1
Comparison of Torsion Stiffness K_t and Bending Stiffness K_f Values for European Vehicles of the Same Market Segment

	Torsion Stiffness, K_t (kN-m/rad)			Bending Stiffness, K_f (kN/m)			Glass Contribution to Stiffness (%)		Torsion Stiffness to Weight Ratio
Vehicle Model	Body-in-White	Body w. Glasses	Complete Body	Body-in-White	Body w. Glasses	Complete Body	K_t	K_f	Body-in-White (m/rad)
Fiat Punto MY94 5 doors	573	701	796	6.3	6.4	6.7	22	2	302
Renault Clio MY90 5 doors	540	740	770				37		355
Fiat Uno MY90 5 doors	342	404	478	4.3	4.4	4.8	18	3	225
Ford Fiesta MY89 5 doors	420	515	665	3.5	3.6	3.8	23	1	258
Lancia Y MY85	445	556	678	6.4	6.8	7.6	25	6	295
Citroën AX MY87	455	635	690	4.6	5.0	5.7	40	10	358
Peugeot 205 3 doors	390	500	588	3.2	3.6	3.8	28	11	275
Fiat Punto MY94 3 doors	578	728	834	6.0	6.2	6.3	26	4	312
Fiat Uno MY90 3 doors	336	423	486	4.4	4.6	4.8	26	3	224
Peugeot 106 3 doors	567	730	820	5.7	5.9	6.4	29	4	
Opel Corsa 3 doors	410	540	690	4.9	5.0	5.1	32	2	
Nissan Micra 5 doors	300	370	510	4.8	4.9		23	2	
VW Polo MY94	550	660	790	4.1	4.2		20	2	
VW Polo MY82 3 doors	360	380	435	4.9	5.0	5.2	6	2	242
Renault 5 5 doors	340	480	530	4.2	4.5	4.8	41	6	243
Fiat Palio 2V 5 doors	428	579	683	5.8	6.0	6.2	35	3	222
Lancia Y10	583	735	835	6.8	8.9	7.2	26	31	

In order to obtain the highest values of both stiffnesses, the following aspects are very important:

- The layout of the longitudinal and transverse beams (see Figure 26.2a)
- The wall thickness
- The shape of the beam section (that very often has an internal wall in order to increase the section moment of inertia and to oppose the wall buckling)
- The design of the structural multiple joints (they are put in evidence in Figure 26.2b; this last aspect is of great importance)

Furthermore, it is well known that the stiffness improvement is given by the panels that are joined to the beam skeleton by welding. Commonly, electric spot welding is used; recently, laser welding has also been employed, both continuous and dash, with a slight although appreciable increment in the structure stiffness [5–12]. More recently, there are also some adhesive joint applications; this type of joint requires proper design of the joint itself to take full advantage of technology [13–20].

The panels (see Figure 26.3), according to the structural scheme originally proposed by Pawlowski [21] and still in use to develop basic structural considerations, are submitted to tensile, compression, and shear loads. Their relevant shear properties contribute in a decisive manner to increase the structure stiffness, substantially locking the deformation modes with rigid rotation around the hinges, typical of the articulated parallelograms that could take place in the body frame structure due to the finite compliance of the joints [22–24].

The care in the design of structural details, together with a refined analysis by the finite element technique, led to a relevant increase in the body stiffness performance even without an increase in the structure weight.

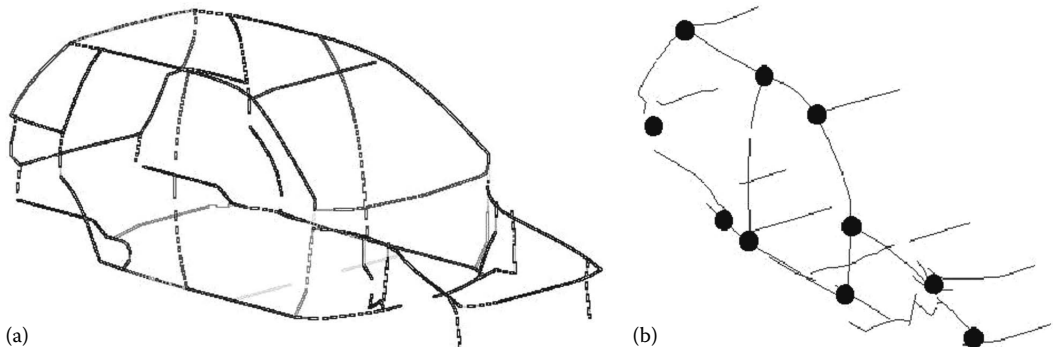

FIGURE 26.2 Layout of the beams in the body structure (a) and structural nodes (b).

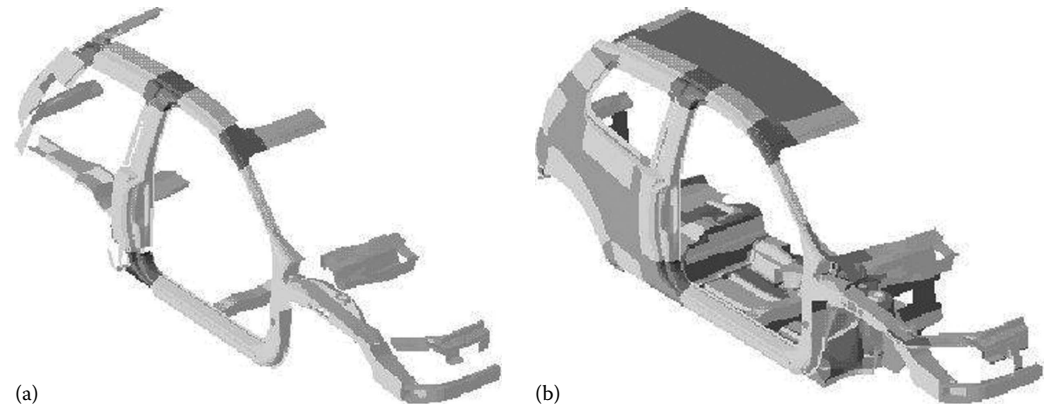

FIGURE 26.3 Structural model of the vehicle body beams (a) and model with fixed panels (b).

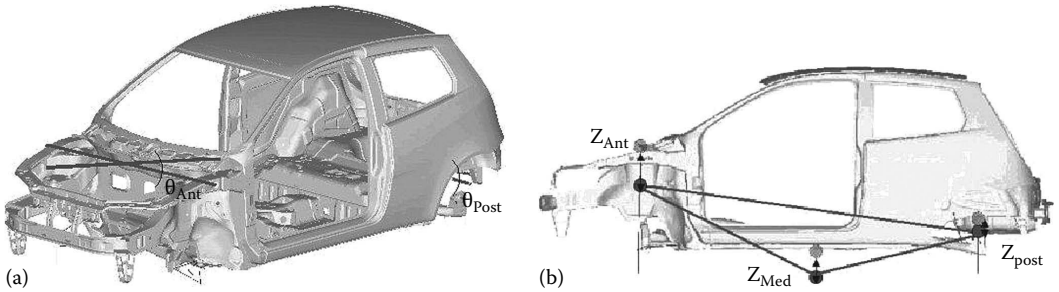

FIGURE 26.4 Evaluation of the torsion (a) and bending (b) stiffness of a car body.

Figure 26.4 shows the scheme of loads and constraints used for the evaluation of the torsion stiffness (Figure 26.4a) and bending stiffness (Figure 26.4b) of a car body. Table 26.1 collects data of stiffness for a number of vehicles of the same market segment. The vehicle list is enriched by two relevant information: the model year and the number of doors. By comparison of the values of the new model with respect to the previous one (see, e.g., Fiat Punto versus Fiat Uno), it is possible to have an appraisal of the evolution of these indexes with time toward higher values, as a consequence of appropriate design choices. By comparison of the values of the five-door version with the three-door version of the same model (see, e.g., Fiat Punto), it is possible to have an appraisal of the effect of this architectural difference.

In Table 26.1, stiffness values are reported specifying the contribution of the body in white, the body with glasses, and of the complete vehicle. The contribution of the glasses (and in particular of the windscreen) is very important for torsion stiffness; in most cases, it ranges between 20% and 40%.

High-performance vehicle and sports cars, due to major requirements in drive precision, are characterized by higher values of their torsion stiffness; typical values for the body in white structure are in the range of 850–1700 kN-m/rad. Lamborghini, for the Gallardo coupé model, gives the torsion stiffness value of 1600 kN-m/rad.

In many cases, these high-performance cars are in the coupé version architecture. This architecture reduces and very often eliminates the contribution of the upper part of the body structure to the vehicle torsion stiffness. Therefore, the lower part of the body structure has longitudinal and transverse beams of larger sections, in order to recover the desired value of the stiffness.

In recent years, a tendency toward the use of frame structure can be noticed [7–11,25–28]. The frame structure is substantially based on the use of prismatic beams of the desired cross section, connected by three-dimensional joints, often made by casting. Prismatic beams are generally made by extrusion of aluminum alloys and the desired curved axis line is obtained by cold stamping or hydroforming [28–36]. By using beams of different lengths but of the same cross section and with the same three-dimensional joints, it is possible to make car bodies of different dimensions, even with small production quantity (the niche vehicles); thus, vehicle personalization is feasible not only with respect to the appearance of the vehicle but also with respect to the vehicle dimensions.

Three other points are to be noted in the recent evolution of the car body construction [37,38]:

- The use of steel types different from the traditional low-carbon mild steel that is preferred by manufacturing people because of its particular suitability for deep drawing
- The use of material types in sheet different from steel to make structural parts
- The use of joining technologies different from the usual electric spot welding for the assemblage

The traditional steel types have had a significant evolution [37] in order to obtain more ductility, aimed to increase deep drawing formability, and oxidation resistance by definition of specific surface passivating treatments and painting technology.

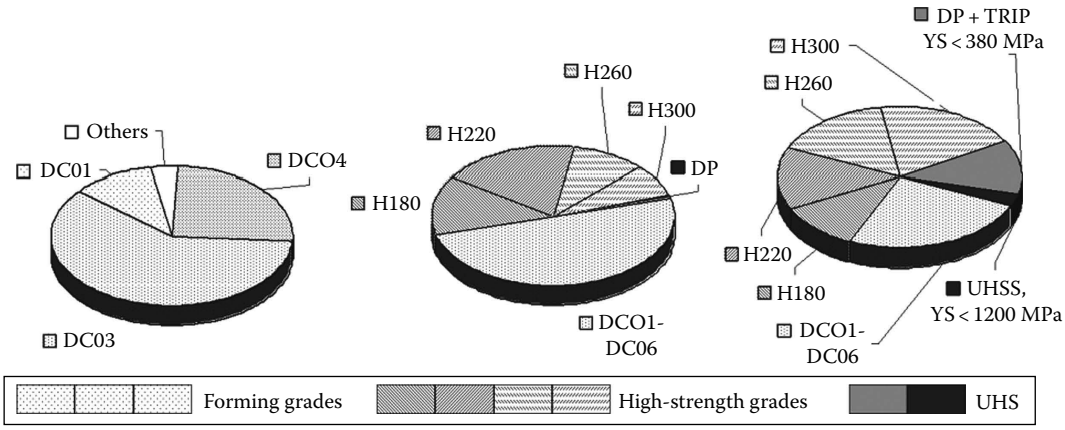

FIGURE 26.5 Past and present situation and future trends in the steel grades' utilization for car body construction (DC01-DC06, EN 10030; H130-H300, high-strength steels, yield strength 130–300 MPa; UHSS, ultrahigh strength steel; DP, double phase steel; TRIP, transformation-induced plasticity steel; YS, yield strength).

New steel families of very high performance have been developed, besides the so-called HS (high-strength) steels; nowadays, UHS (ultra high strength) steel and dual phase steel with bake hardening characteristics are also available [29,37–43]. Figure 26.5 illustrates the use of different grades of steel in car body construction 25 years ago, at present, and in the near future [29,37].

The steel types characterized by high-strength grades exhibit higher values of the yield and ultimate strengths but smaller ductility and fracture strain with respect to the traditional low carbon steel. The use of this type of high-strength steel allows for reduction in the wall thickness of the structural members formed from sheets and thus for relevant reduction in the weight of the car body structure. Of course, the reduction in the wall thickness has a negative influence both on the global torsion and bending stiffness and on the local buckling values; the desired values must be recovered by an appropriate design of the beam section shapes.

Once again, in order to obtain lightweight car body structures, aluminum solutions have been developed; in this perspective, the Ferrari Modena solution and the solution, known as the ASF or Audi Space Frame, developed by Audi in cooperation with Alcan and adopted for the Audi 8 and then for the Audi 2 models, and the Jaguar XJ8 have to be mentioned. Table 26.2 lists the most notable space-frame-based vehicles, together with information on materials and assembly methods.

Aluminum types for car body are in the 5xxx and 6xxx range [34,44–50].

The Audi 8 first generation was the first model produced; it had a relatively small quantity of production per year. Audi 2 followed: it had a relatively large quantity of vehicle production. Therefore, it was decided that Audi 2 had a completely new design solution that took advantage of the experience gained from the previous model but also introduced deep design and manufacturing changes in the perspective of production of a larger quantity.

The ASF of Audi A8 was revolutionary, but many improvements came with the A2 frame [37]. The original A8 space frame made extensive use of simple, cold-extruded aluminum tubes connected to each other with complex rigid cast joints by MIG welding and other mechanical joining methods, such as punch riveting.

The A2 space frame is made with rolled aluminum profiles and simpler cast joints, assembled by laser welds and adhesives. Cost savings has been obtained through a drastic reduction in the number of parts (from 334 to 225) and with extensive use of automation for assembly operations.

Some particular parts, at the moment mainly lateral doors [51] and seat structures, made of magnesium are also to be mentioned as interesting experiences of using light metal other than aluminum for structural parts.

TABLE 26.2
Main Up-to-Date Marketed Space-Frame-Based Vehicles

Brand/Model	Year	Structure Type	Materials	Assembling Methods
Ford AIV	1998	AVT[a], stamped sheet	AA5754-0	Weld bonded
Audi A8	1994	ASF[b], cold extruded aluminum tubing	Aluminum alloys	Rigid cast joints, MIG welding, punch riveting
Audi A2	1999	ASF[b], aluminum profiles	Aluminum alloys	Simpler cast joints, laser welds, and adhesives
Ferrari 360 Modena	1999	Aluminum ALCOA space frame (153 kg)	6008-series Al alloy (mainly 6008)	Sand cast structural joints, MIG welding
Volvo XC90	2002	High-strength steel frame	HSS, EHSS, UHSS	Welding (various) and brazing, adhesives, fasteners
Jaguar XJ8	2004	Ultrastiff stamped aluminum monocoque	Aluminum alloys	Bonded and riveted
Chevrolet Corvette Z06	2006	DANA space frame (129 kg)	Aluminum alloys	Self-piercing rivets (236), laser welding (14 m)

[a] Aluminum vehicle technology (ALCAN).

[b] Audi space frame.

Finally, some experience in the making of relevant parts of the car body structure, such as the deck, with fiber-reinforced plastic material has to be mentioned [52]. Composite materials are of great interest as they have very high strength to density ratio and therefore allow for very light structures [53–56]. Due to cost reasons, which is still rather high for composite materials in comparison with steel, glass fibers have been mainly used, although carbon fibers have been also considered. The possibility of sandwich structures made by thin skins of plastic matrix composite material and polymeric foam or honeycomb core can be the desired compromise [25,53,57–60].

The adoption of materials other than metals requires careful consideration and satisfying solutions for dismounting and material recycling at the end of the vehicle's life.

In the field of the part-joining technologies, beside the classical spot welding and, in some cases, the bolting of metal sheets, applications of great relevance have been developed by laser welding and structural adhesives [5–7,12,18–20,61–64]. While solutions with classical riveting, self-perforating riveting [64–68], and clinching have also been experimented with, it is clear that joining technology other than welding, and in particular the solution with structural adhesive, is needed when materials other than metals are used.

Great advantages come, not only for each structural component but even for the whole car body, from the extensive use of adhesives [64,69,70]. Adhesive joining solutions have already been developed for some high-class European cars (BMW, Mercedes, and Jaguar [67,68]). Adhesives offer many improvement possibilities to the car body construction. Since the adhesive joint is continuous instead of a series of spots, stiffness characteristics of bonded components are higher. Furthermore, adhesives act as a sealant, providing the advantage of good protection against seepage and corrosion.

The adhesive solution offers potential for great improvement in the overall bending and torsion stiffness of the car body [71–74]. It has been shown that bonded crash columns can absorb and dissipate much more energy than an equivalent spot-welded column [75], provided there is a suitable design for the bonded column: For example, the usual half-shell with flanges [13,20] to be spot welded should be substituted with pieces without flanges. Furthermore, adhesives have high damping properties and help in improving the NVH characteristics of the car [76,77].

One of the drawbacks of the use of adhesives is the long manufacture cycle time required to obtain a sufficient level of polymerization of the adhesive [78]. For that reason, it is necessary to

use additional joining devices to hold the sheet in place until the adhesive is able to develop its full strength. Another possible concern is the difficulty in preparing and putting in place the sheets for adhesive joining, because this asks for higher precision with respect to spot-welding technology. However, this problem can be solved in the concurrent design process of the body shell.

Since it is not ideal to keep together the sheets to be bonded with spot welds, alternative joining methods have to be found. Mechanical fastening can be used. Traditional riveting is not likely to be used for several different reasons (including aesthetic appearance) but punch riveting [79,80] or clinching [81] is effective for solving this problem. Both methods can be easily automated and are also cost-effective solutions [56,82].

26.5 DYNAMIC BEHAVIOR AND MODAL ANALYSIS OF CAR BODY

The car body is characterized by its static torsion and bending stiffness. These values are important indexes of the car ride comfort and handling because the car body as a whole can be considered as one torsion and one bending spring placed in series with respect to the front and rear suspensions.

Beside these static characteristics, the vibration and acoustic characteristics are also of relevance for a car body. Figure 26.6 shows a schematic subdivision of the frequency range of interest for car body comfort, distinguishing ride vibrations from harshness and noise.

The dynamic behavior of a vehicle is strongly influenced by the global and local dynamic stiffness, structural damping, and vehicle mass [83–85]. For the acoustic performance of the passenger compartment, the quantity and layout of the phono-absorbing and phono-isolating materials are also of importance.

Vibration and acoustic phenomena are determined by the dynamic excitations that come from different sources (see Figure 26.7) such as the motor engine, the gear box and the drive line, the tire rolling, and the aerodynamic air flow. Each of these sources is dominant in a certain range of frequency. In order to study the noise level inside the passenger compartment, it is important to consider and identify two different transmission paths: the structure path and the air path.

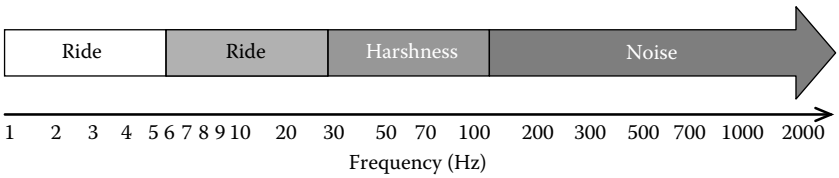

FIGURE 26.6 Characteristic frequency ranges for vehicle comfort.

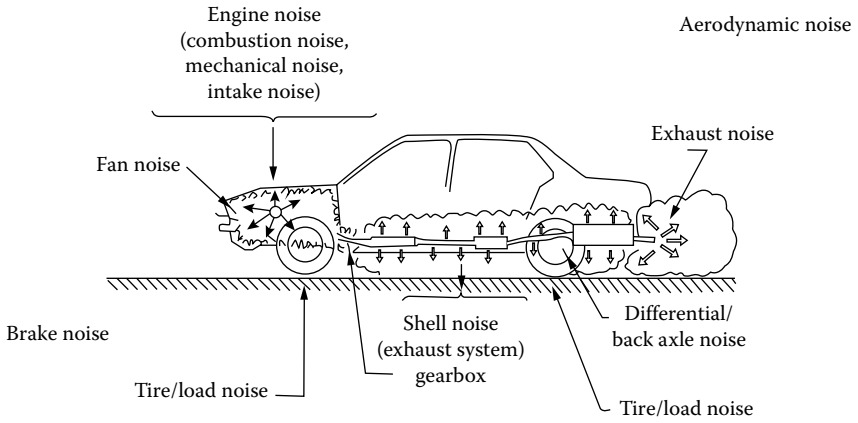

FIGURE 26.7 Noise and vibration sources.

Let us consider as an example the vibration of a motor engine [84–89]. When the engine is running, it vibrates at frequencies that are multiples of the rotational speed of the engine itself. The noise of the engine is heard directly from its walls; this noise has a particular intensity level when the excitation frequency is equal to one of the engine structure eigenfrequency. The acoustic waves that are present in the engine compartment pass through the body structure and enter the passenger compartment (the so-called acoustic "transparency" is a measure of this phenomena). This type of noise is usually called "air-borne" noise (as it is transmitted through the air path) and is generally predominant at the higher frequencies (>500 Hz).

The car body vibration is excited also by the cyclic forces that are applied at the engine mechanical links. Vibration energy is thus transmitted through the solid structure to the human–machine interface points (such as the steering wheel, the seats, the pedals, the feet places on the deck, etc.). Vibration energy is also transmitted to the passenger compartment panels that begin to vibrate themselves, producing further internal noise. This type of noise is usually called "structure-borne" noise (as it is transmitted through the structure path) and is generally predominant at lower frequencies (<200 Hz).

The performance of the car body in the noise transmission perspective is quantified through the acoustic transfer function *P/F*, where *P* is the noise at one point inside the passenger compartment—usually, microphones are placed corresponding to one of the ears of the driver or to that of one of the passengers—while *F* is the exciting force applied to one point of the body structure. This transfer function is clearly a frequency function (Figure 26.8).

The overall value of the noise heard by the ear, caused by the motor engine, can be calculated by the summation of the contribution of all the engine mechanical link points using the following equation:

$$P = \sum_{n=1}^{m} F_n \times \left(\frac{P}{F}\right)_n \cong \sum_{n=1}^{m} (K_n \times X_{mtp,n}) \times \left(\frac{P}{F}\right)_n \tag{26.1}$$

where *m* is the number (one for each loading direction) of these engine link points to the car body.

By means of this equation, it is possible, once the objective for the overall internal noise *P* has been fixed, to get partial objectives for the subsystems, in particular for the elastic characteristic curve *K* of the engine mounts, for the displacements X_{mtp} of the motor engine group, and for the *P/F* acoustic

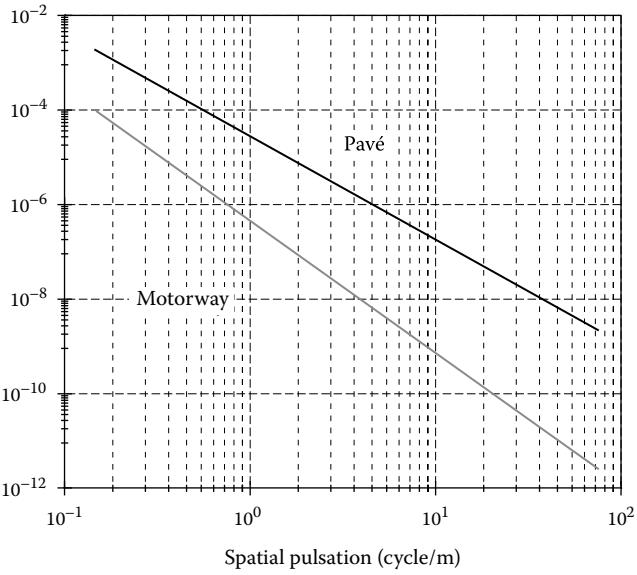

FIGURE 26.8 Excitation from the road surface irregularities: comparison of the power spectra characteristic of a motorway and a pavé.

transfer function of the body. Obviously, the displacement X_{body} of the link point of the engine mount to the body must be negligible in comparison with the displacement X_{mtp} of the motor engine such that it can be neglected in Equation 26.1. A sample *P/F* transfer function is shown in Figure 26.12.

With the scope of quantifying the dynamic response of a structure, the acceleration over force transfer function that is easily obtained from experimental tests is generally used. When the input (excitation) point and direction coincide with the output (acceleration) point and direction, this transfer function is called inertance function:

$$I_k = \frac{\ddot{u}_k(\omega)}{f_k} = \frac{-\omega^2 u_k(\omega)}{f_k} = \sum_{i=1}^{n} \frac{\omega^2 \varphi_{ki}^2}{-\omega^2 m_i + i\omega b_i + k_i} \tag{26.2}$$

$$K_{dyn,k} = \frac{f_k}{u} \rightarrow K_{dyn,k} = -\frac{\omega^2}{I_k} \tag{26.3}$$

where

I_k is the inertance function

$K_{dyn,k}$ is the dynamic stiffness function for the load application point k

In Equations 26.2 and 26.3, according to the usual modal analysis symbols,

ω is the angular pulsation considered

i is the eigenmode index

m_i, b_i, and k_i are the modal mass, the modal damping, and the modal stiffness, respectively, associated to the i eigenmode

φ_k is the k component of the i eigenmode

Equation 26.3 puts in evidence that the higher the inertance value, the lower the structure dynamic stiffness. In Figure 26.9, some examples of the inertance curve are shown and, for the sake of comparison, three curves for the constant stiffness case are also drawn.

The dynamic stiffness of a car body is the result of a number of structural vibration modes that are present all together. These structural modes can be subdivided in two groups: the global modes

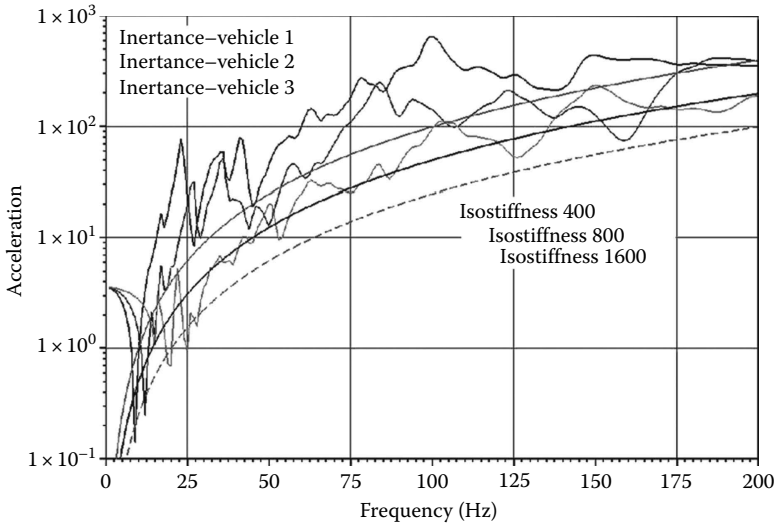

FIGURE 26.9 Inertance curves and constant stiffness curves versus frequency.

and the local modes. The first group includes the modes that involve the whole structure with vibration of some amplitude; the second group includes the modes that involve only one substructure, more or less localized; while the rest of the structure is nearly not vibrating.

The global modes are at the lower frequencies, generally lower than 50 Hz. They are easily detected and classified as torsion modes, bending modes, and waving modes.

For each of these modes, it is further possible to distinguish if the modal shape has its larger displacement at the front part or at the rear part of the car body structure. It is well known that the modal shapes are independent from the entity of the applied loads; therefore, the dynamic deformed shape of the car body, as a consequence of the superposition of its global modes and of a mass distributed in a more or less uniform way, could be quite different from the static deformed shape.

In Figure 26.10, modal deformation shapes of a body structure for some global modes are shown; the corresponding eigenfrequencies are also reported. The car body exhibits two torsion modes: one is of the global type and the other one has larger deformation motion at the front part of the structure.

As already mentioned, the mass distribution is relevant for the eigenfrequencies of the global modes. Therefore, one has to consider that when all the other devices, covers, and internal dressing elements are applied to the car body, the mass values are increased, and somehow its distribution modified, without relevant modification in the structure stiffness and, therefore, without changes in the static stiffness values. In contrast, the dynamic response changes and the eigenfrequencies of the global modes become lower [86].

Global modes are very important from several points of view: first of all, the coupling of the global modes with the vehicle suspension modes and, eventually, with the other supporting frames that are connected to the car body through more or less rigid links. It is clear that it is of primary importance that these link points move as little as possible during the dynamic vibration of the structure. Thus, the dynamic vibration of the car body can influence the drive quality of the vehicle itself in a remarkable manner, in terms of both handling precision and comfort.

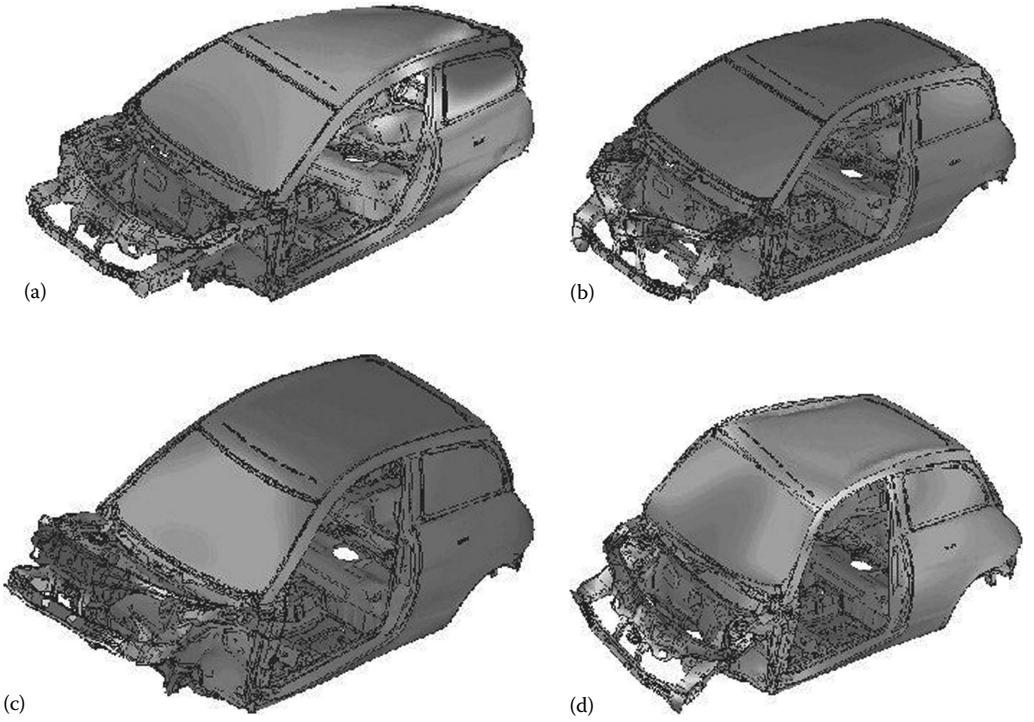

FIGURE 26.10 First four modal shapes of a car body with glasses but without movable parts: (a) global torsion mode, (b) front structure waving mode, (c) front bending mode, and (d) second front torsion mode.

Another relevant point is the possibility that the structure global eigenfrequencies are in resonance with other vibration frequencies, such as the excitation frequency of the motor engine at idle or the eigenfrequencies of the steering wheel–steering column–steering mechanism. In both cases, the frequency coupling results in a remarkable amplification of vibration and noise in the passenger compartment. In these cases, it is possible to obtain a solution to the problem by the so-called structural modification procedure [90]. This procedure is based on the modal model obtained by the experimental modal analysis. A proper modification of the system modal mass and/or the system modal stiffness is "virtually" made in order to move the eigenfrequency and to decouple the resonant modes. From the modified modal model, it is then necessary to go back to the real model and to determine the consequent modifications of the system parameters. It is not easy to give an indication of the distance between frequencies to guarantee their decoupling, as it is influenced also by the value of the modal damping.

Let us move to the vibro-acoustic phenomena. Besides the body structure eigenmodes in this perspective, the volume of the air cavity inside the passenger compartment must be carefully considered. The air cavity has its own dynamic behavior characterized by eigenmodes and eigenfrequencies that are present and even coupled with those of the body structure. The cavity properties are very important to the evaluation of the noise level heard by the passengers.

The air volume has its own dynamic behavior that is obviously different from the structural behavior, as it is constituted by fluid. In the analysis phase, it is possible to use an approach that is similar to the modal analysis already addressed for the structure vibration analysis. As for the structure, it is possible to evaluate the overall response as summation of a number of contributes due to the different modal deformations; in a similar way, it is possible to evaluate the acoustic response of the passenger compartment cavity as the summation of its pressure eigenmodes.

Table 26.3 collects typical values of the three lower eigenfrequencies of the passenger compartment cavity modes, distinguishing between vehicles of different market segments.

For a cavity of simple regular geometry, it is possible to calculate the eigenfrequencies of the cavity modes easily through an analytic approach; they are inversely proportional to the time taken by an acoustic (pressure) wave to travel back and forth in the cavity in one considered direction. The pressure wave propagation velocity in air is the sound speed (344 m/s in normal conditions, i.e., 293 K, 101,325 Pa).

The cavity modes (see, e.g., Figure 26.11), similarly to the structural modes, have node points, where the pressure dynamic variation is null, just as in the vibration modes where displacements were null. If the driver or the passengers have their ears near these points, they will hear little noise component at the corresponding frequency, with a beneficial effect on the perceived noise level and consequently an increment in the internal comfort.

In the same manner, if a noise source (e.g., a vibrating panel) is placed near one of these acoustic nodes, it will not be able to excite the corresponding cavity mode and the internal noise will not suffer due to its contribution. On the contrary, if acoustic sources or the passengers' ears are close to the points of cavity mode maximum amplitude, internal noise results to be amplified with a detrimental effect on the perceived acoustic comfort.

TABLE 26.3
Typical Values of the Lower Cavity Eigenfrequencies for Different Vehicle Segments

	Typical Frequencies of Cavity Modes		
	Small Car Segments (Hz)	**Compact Car Segments (Hz)**	**High-Class Car Segments (Hz)**
First longitudinal mode	60–70	55–65	45–55
Longitudinal mode	115–130	100–115	85–100
First transverse mode	130–145	120–135	110–130

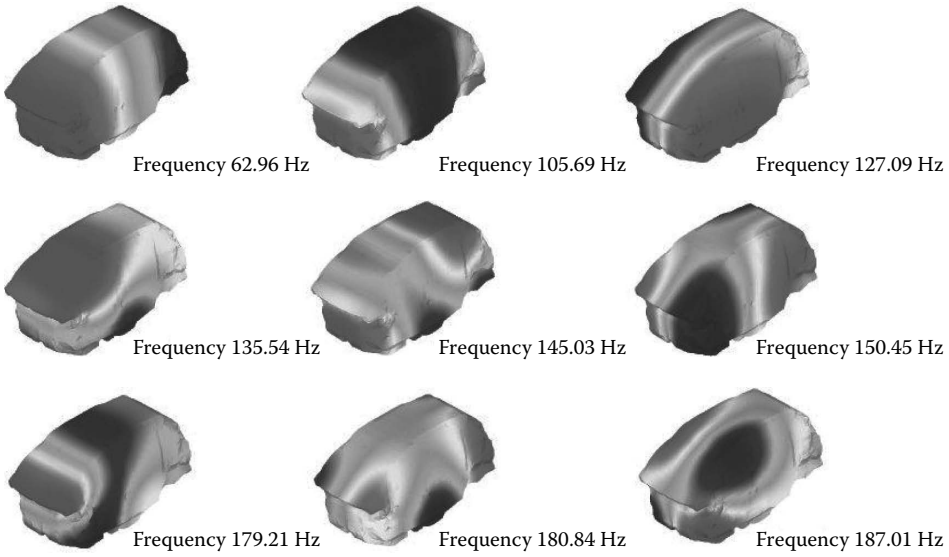

FIGURE 26.11 First nine cavity modal shapes and the related eigenfrequencies.

The air motion in the passenger compartment and structural vibrations are dynamically coupled. When the structure vibrates, the panels that contour the passenger compartment impose their kinematical movement as boundary conditions to the air. In contrast, the local air pressure imposes pressure values as boundary conditions to the dynamic deformation of the structure.

It is possible to apply the modal analysis methodology to the structure and to the cavity coupled [91,92]. Thus, the following equations system could be written as follows:

$$[-\omega^2[M]_s + i\omega[B]_s + [K]_s] \times u(\omega) = F(\omega, t) + [A]^T \times p(\omega) \tag{26.4}$$

$$[-\omega^2[M]_f + i\omega[B]_f + [K]_f] \times p(\omega) = -[A] \times \ddot{u}_n(\omega) \tag{26.5}$$

where

M, B, and K are the mass, damping, and stiffness matrices of the structure (subscript s), respectively, and of the fluid (subscript f)
A is the coupling surface
u is the displacements
p is the pressures
ω is the pulsation

The resulting coupled dynamic problem has the following formulation:

$$\begin{bmatrix} -\omega^2[M]_s + i\omega[B]_s + [K]_s & -[A]^T \\ -\omega^2[A] & -\omega^2[M]_f + i\omega[B]_f + [K]_f \end{bmatrix} \begin{pmatrix} u \\ p \end{pmatrix} = \begin{pmatrix} F \\ 0 \end{pmatrix} \tag{26.6}$$

From the solution to this system, both the structural displacement u, taking into account the air motion, and the air pressure p, taking into account the panel motion, can be evaluated. Figure 26.12 shows some results of a research study on the dynamic coupling of structural modes with cavity modes for a vehicle passenger compartment. Figure 26.12 shows a comparison between experimental test results and numerical simulation results.

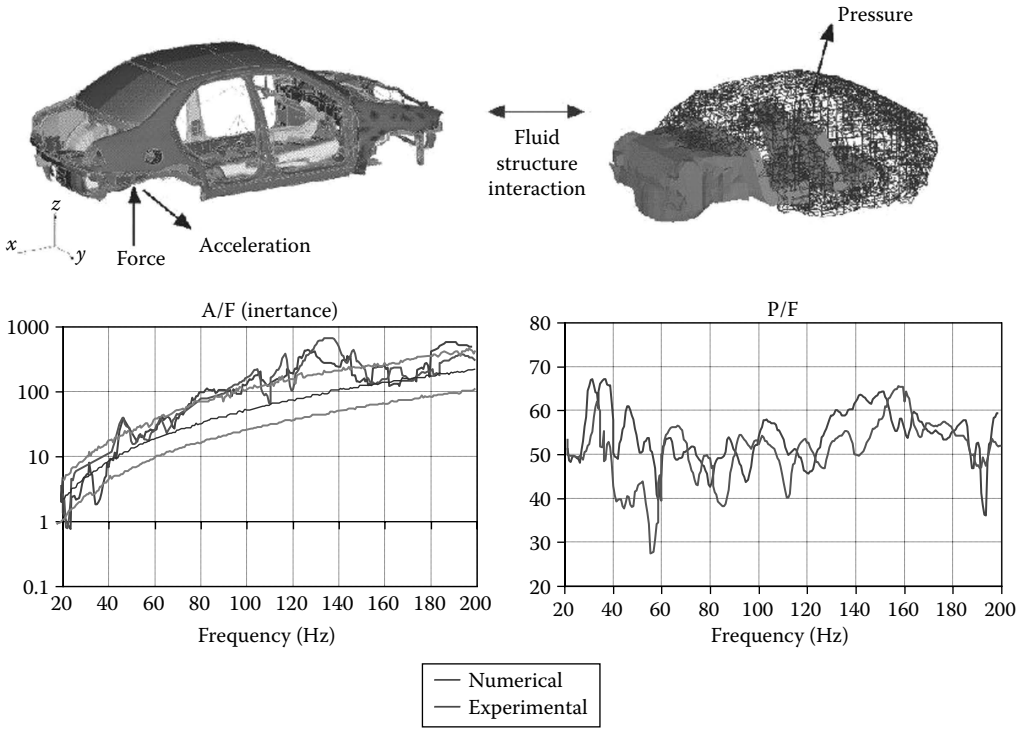

FIGURE 26.12 Structural modes and cavity modes coupling, with the qualitative inertance and pressure responses as a function of frequency.

26.6 PASSIVE SAFETY

Passive safety is the protection that the vehicle structure and the on-board devices (e.g., the safety belts and the air bags) give to the driver and to the passengers in case of an accident, their operation being automatic, that is, does not need commands by the driver for their activation [93,94].

In case of collision with another vehicle or with a fixed obstacle, the kinetic energy of the vehicle must be completely dissipated and the vehicle stopped in a time duration of the order of magnitude of one tenth of a second.

The kinetic energy is absorbed by the plastic deformation of the material of the body structure if it is a metallic material, or by fracture and fragmentation if it is a brittle plastic material such as composite materials with polymeric matrix.

In the perspective of passenger safety, the progressivity of the energy absorption phenomena is fundamental just as the accelerations and the forces to which the different parts of the human body are submitted to do not exceed the tolerability values that are typical of the human body, that is, those limit values over which permanent injuries or even the death of the person is caused.

With this scope, the vehicle body structure (see, e.g., Figure 26.13, where the characteristic components of the front structure of a recent vehicle is shown) is designed in order to get a vehicle deceleration history that is progressive. Figure 26.14 shows the typical history of the deceleration measured on the vehicle deck at the front seats' anchoring points during a frontal crash carried out according to the EuroNCAP testing procedure. In the graph, the different levels of the deceleration that are due to the different parts of the vehicle structure can easily be detected.

According to the EuroNCAP test procedure [95,96], the vehicle impact occurs against a deformable barrier that is intended to reproduce the impact deformation and energy absorption capability

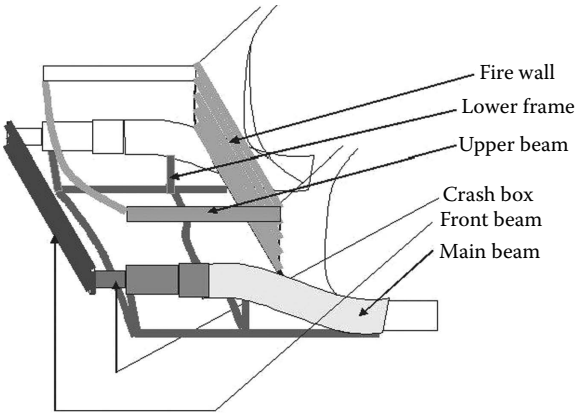

FIGURE 26.13 Characteristic components of the front structure of a recent vehicle.

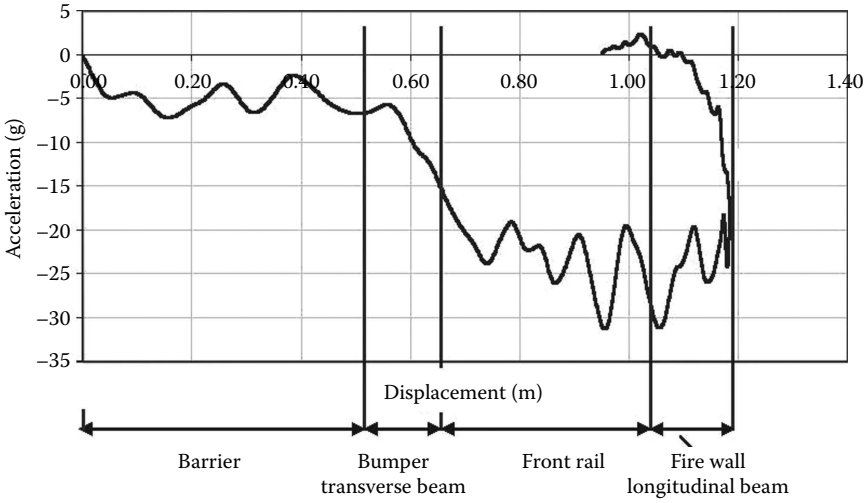

FIGURE 26.14 Typical course of the deceleration during a EuroNCAP crash test.

of the other vehicle when a "car-against-car" impact is considered [97,98]. The initial part of the curve shows the deceleration due to the compression failure of that deformable barrier; then, in the order, the deformation of the front transversal beam; that of the so-called crash boxes; and finally, that of the front structure longitudinal beams follow. Usually, these structure beams are thin-walled boxed beams made of drawn steel sheet and joined by spot welding.

The beam deformation mechanism of plastic axial collapse resulting in the formation of a sequence of folds is the most favorable mechanism that guarantees the absorption of the desired amount of energy and in the meantime satisfies the progressivity requirements [93,94].

The initialization of every new fold determines an increment of the beam axial antagonist force and, therefore, an increment in the vehicle deceleration. This increment is detectable in the deceleration history diagram as a peak. The plastic deformation evolves then through the development of localized plastic hinges in the beam walls. These localized plastic deformations of the metallic material give the desired energy absorption (see Figure 26.15 for typical specific absorbed energy for some structural car body materials).

It is thus evident that the structural behavior of the vehicle body during its collapse is the determinant factor for the entity of the deceleration to which the driver and the passengers are submitted.

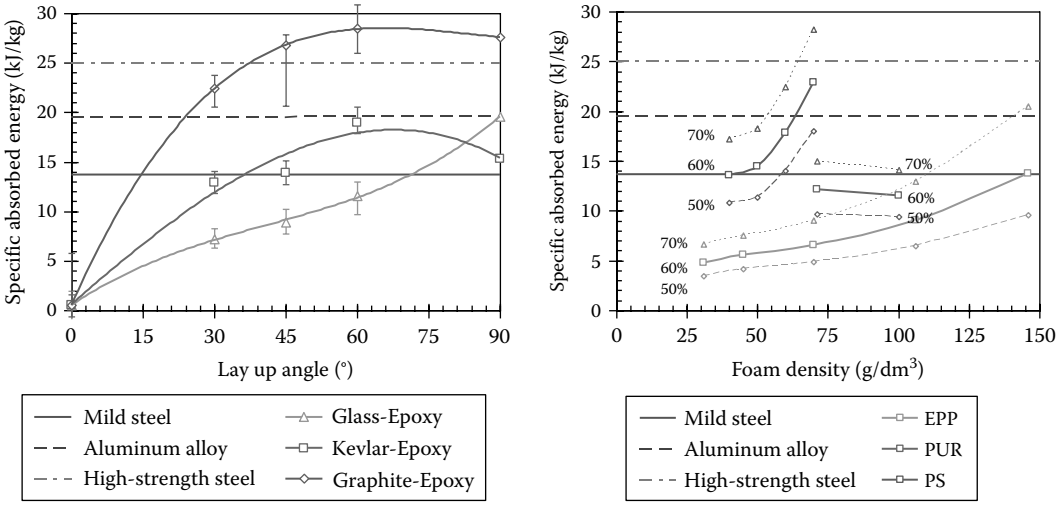

FIGURE 26.15 Typical specific absorbed energy for some structural car body materials.

As it is described in Chapter 43, in order to evaluate the safety level of the passengers, in a quantitative manner, biomechanical criteria are used. In particular, the actions on the head (through the *HIC*, Head Injury Criteria, index [99]), neck, and thorax, related to possible fatal consequences, and on the pelvis, legs, and femur and tibia bones, related to possible invalidating injuries, are considered [97]. The use of safety belts and air bags contributes to limit the motion of the passengers inside the passengers' compartment and, therefore, contributes to control the values reached by the biomechanical parameters, ensuring that they stay below the limit values indicated by the regulation [93].

Recently, a further regulation that accounts for possible impact of a vehicle against pedestrians has been developed [101]. Once again, some biomechanical parameters are used to verify that the level of possible injury suffered by the pedestrian is maintained below limit threshold [102]. The vehicle structure is involved with particular reference to the front bumper and the hood. For these two components, limits are prescribed relating to their aggressivity against the femur (front bumper) and the head (hood) [93].

26.7 FATIGUE ENDURANCE

Fatigue failures are determined by the application in service of loads of variable amplitude to the body structure [103,104].

The analysis of the fatigue strength of such a complex structure is quite difficult because it depends mainly on the following

- The real load history applied to the structure and its variability caused by the different driving conditions and styles
- The material fatigue strength and its natural dispersion
- The stress concentration effects that are induced by geometry details in the structure design and assembly joints
- The manufacturing process and the modification that it induces into the fatigue strength characteristics of the material, due, for example, to residual stresses

In order to have sufficient information about the real load histories that vehicles are submitted to during real-life riding, it is common to instrument some vehicle and to acquire signals of the applied loads and of the resulting strain fields when riding in typical riding conditions on typical roads. This procedure implies the determination of the vehicle's typical mission and utilization model [105]. Figure 26.16 shows an example of a resulting load spectrum that could be used for testing.

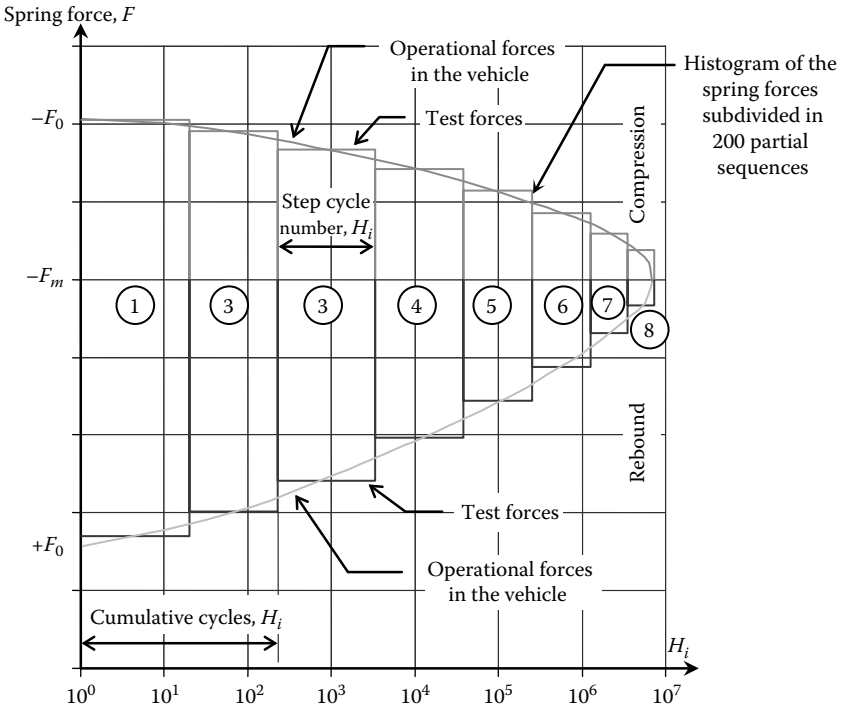

FIGURE 26.16 Load spectrum for fatigue test.

The acquired signals are processed in order to condense the information contained in the time histories and to get the so-called load cumulative, that is, the equivalent spectra of the stress mean and amplitude values. In the automotive industry, this signal processing is generally made by the rain flow algorithm [106–109], resulting in a three-dimensional matrix that accounts for stress mean values, stress oscillation amplitude values, and the number of times [106–110].

In recent years, the relevance of another factor on the fatigue behavior was pointed out: the loading frequency. It has become clear that load must be applied not simply to the "static" structure, as is traditionally done, but taking into account the vibration deformed shape that can be excited by the fatigue loads, due to their variability in time. Therefore, signal processing has been improved by the extraction of the coupled frequency information, resulting in a four-dimensional matrix [108].

This picture of real-life loading is used both for the design development through numerical simulations and for the laboratory experimental tests [104].

Road loading simulators [111] are nowadays in common use at the automotive industry testing laboratories due to the repeatability of the loading condition, ease of surveillance, and the rapidity with which the fatigue test can be completed, with respect to the tradition of road tests [111].

Fatigue performance of the materials has been analysed, with particular reference to the typical dispersion of the fatigue data, in order to have the so-called SNP (stress, number of cycles, probability) Wöhler curves [106–109]. In many cases, the companion curves, based on the strain (instead of stress) Wöhler-like curves, have been experimentally obtained, in order to take into account in a more appropriate way the plastic deformation content of each fatigue cycle [112,113].

Furthermore, the fatigue-testing procedure based on the thermoelastic and thermoplastic effects has been developed, as demonstrated by the correlation between the local temperature field and the fatigue failure localization [114].

As for all mechanical structures, the typical locations for fatigue failures in a car body are found where geometry determines stress concentration effect.

There are two structural details that are commonly of relevance in this perspective:

- The excessive sharpness of a sheet bent, where the geometry effect is generally coupled with material hardening due to the drawing plastic deformation
- The weld spot

In particular, this latter theme has been widely studied both from the theoretical and the experimental point of view.

The effect of stress concentration of the weld spot in the structure has been considered with the classical fatigue approach and with the fracture mechanic approach [115–120]. A good correlation between the experimental results and the finite element simulation results has been obtained by the application of the so-called hot-spot methodology [121], in order to identify a position for the evaluation of the actual stress entity, and the development of specialized finite elements [120].

The fatigue analysis has then been extended from the single weld spot to the behavior of the welded structural elements, where the interaction between the spot weld and the part geometry on one side and the entity of the weld pitch on the other side have relevant effects on the structure endurance.

In view of the adoption of the joining technique other than the spot welding, fatigue analysis has also been performed on adhesive joints [74,75] and on bolted joints [122]. These innovative joining methods have fatigue strength comparable to or better than spot welds, and, unexpectedly, adhesives show even better long-term behavior (Figure 26.17) [122,123].

The manufacturing process at least leaves the manufactured parts with important alteration with respect to the nominal conditions [124].

Deep drawing induces sheets reduction of the wall thickness of variable entity, somewhere very large, increment of the yielding strength and reduction of the metal ductility due to strain hardening, residual stresses of particular relevance when the elastic spring-back is constrained.

All these alterations of the real structure situation with respect to the nominal one lead to modification of the fatigue behavior of the considered structure that in a even more refined fatigue analysis should be accounted for [125].

Data on fatigue and fracture mechanics properties of the most commonly used materials for car body construction are listed in Table 26.4.

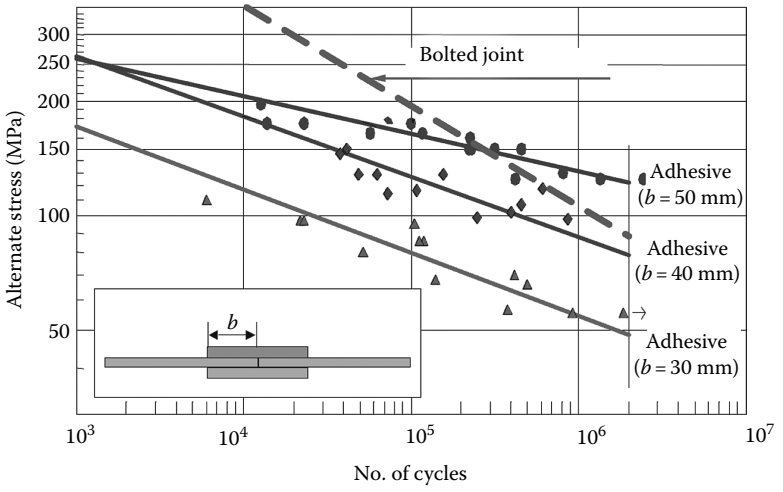

FIGURE 26.17 Comparison of the fatigue strength of some different joining techniques for car body structures. (From Lazzarin, P. et al., *Int. J. Fatigue*, 19, 401, 1997.)

TABLE 26.4
Fatigue and Fracture Mechanics Properties of the Most Commonly Used Materials for Car Body Construction

Reference	Material	E (GPa)	YS (MPa)	UTS (MPa)	A_f (%)	K_{1e} (MPa √m)	K_{1c} (MPa √m)	C	n	$\sigma_{D,-1}$ (MPa)
	DC01 EN10130		280	270–410	28			6.90E-12	3	
	DC03 EN10130		240	270–370	34			6.90E-12	3	
	DC04 EN10130		210	270–350	38			6.90E-12	3	
	DC05 EN10130		180	270–330	38			6.90E-12	3	
	DC06 EN10130		180	270–350	38			6.90E-12	3	
	S185 EN10027–1	207	185							
	S235 EN10027–1	207	235	325				2.43E-12	3.3	≥170
	S275 EN10027–1	207	275	360–510	24	110	77	1.91E-11	3	≥210
	S355 EN10027–1	207	355	450–610	22					≥280
[ULSAB-AVC]	DP500		300	500	30–34					
[ULSAB-AVC]	DP600		350	600	24–30					230–290
[ULSAB-AVC]	DP700		400	700	19–25					
[ULSAB-AVC]	DP800		500	800	14–20					310

27.1 INTRODUCTION

For a basic understanding of the low-frequency behavior of an automobile, it is essential to model its corresponding characteristics in a simplified, mainly linearized way. As a consequence, analytical solutions or easy to interpret results can be used to analyze the vehicle behavior for a large area of driving and testing conditions, for example [1–11].

With these simplified vehicle models, it is possible to consider the longitudinal and lateral behavior of the vehicle for a large range of problems separately. Then, characteristic phenomena, for example, the design of the braking system or under- and oversteer behavior, can be understood without much effort.

Another field of application for linearized models is the area of vehicle dynamics control systems, since with these models feedback control gains and state observers can be derived and designed rather easily; for example, they constitute the theoretical basis of the electronic stability program (ESP) or of similar control systems.

Establishing an adequate vehicle model is a compromise of what is to be investigated and what restrictions and/or simplifications should determine the details of the vehicle model. Consequently, at the beginning of the sections on modeling, a list of possible applications and model assumptions not only give an overview of the characteristics of the vehicle model but also define its range of applications.

As most handling features can be shown with a passenger car (more easily), this type of vehicle is presented in the following.

27.2 LONGITUDINAL VEHICLE BEHAVIOR

27.2.1 Application and Vehicle Model Features

The "longitudinal" behavior of the vehicle is characterized by equal tire loads (tire normal forces) at the left and right side of the car or small differences that can be neglected. So driving along a curved trajectory can be analyzed assuming that the lateral accelerations or other conditions causing changes in left to right load transfer are small.

Consequently, the following objectives can be investigated:

1. Driving, starting, and braking on a road of arbitrary grade
2. Effects of different drive train configurations like front-wheel drive, rear-wheel drive, four-wheel drive
3. Basic brake system design
4. Brake systems with control system, for example, antilock braking system (ABS)
5. Interaction of driver–vehicle–road (traffic)
6. Different road surface properties including μ-split conditions
7. Engine performance, effects of (automatic) transmission, clutch, converter, and other drive train components
8. Fuel consumption, efficient driving

Some of these tasks not only require a vehicle model but also completions by models of the drive train and its components, the engine characteristics, and the longitudinal force transfer behavior of the tires.

With restriction to a plane vehicle model and an overall description of the drive train (including a simple engine and tire behavior description), the main objectives of points 1–3 and 6 can be solved. For point 5, the application of a driver model is necessary, see Chapter 38, and for point 4, nonlinear tire characteristics need to be included. A detailed model of the engine characteristics and its fuel consumption is necessary for the investigation of 7 and 8. With a focus on the overall vehicle behavior, the aforementioned tasks 1–3 and 6 are addressed here, while point 4, in particular, is considered in Chapter 30 of this handbook. For points 7 and 8, please refer to [7] and [12], respectively.

27.2.2 Vehicle and Drive Train Model

The vehicle is assumed to be represented by a plane rigid body model, where the relative motions of the wheels with respect to the car body, except their spins, are neglected (see Figure 27.1, e.g., [2,5,6]). The tire–road contact is described either by pure rolling and/or by its limitation with a maximum longitudinal contact force coefficient $\mu_{max} = (F_x/F_z)_{max}$, which is (to simplify matters) the same as μ_s for the locked or sliding wheel. For most of the basic longitudinal investigations, this tire force transfer model assumption is an efficient and reasonable approximation, because the longitudinal tire slip is small, when the wheel does not slide.

For establishing the equations of motion, the vehicle running on a grade (angle ϑ) with velocity v_x and acceleration a_x is considered.

At the center of gravity *CG* of the whole vehicle (mass *m*), the aerodynamic lift W_Z, drag force W_L, and lift moments M_Y act (see Section 27.2.3.2) besides weight *mg*. The tire forces F_{xi} and F_{zi} (i=*F*, *R*)

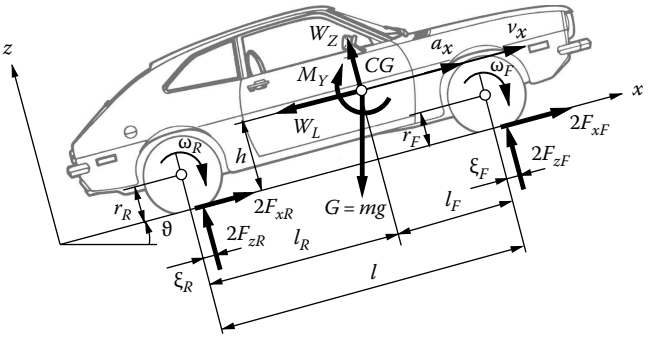

FIGURE 27.1 Plane longitudinal vehicle model.

corresponding to each wheel are assumed to be equal for the right- and left-hand side. The longitudinal shift ξ_i of F_{zi} (i=F, R) is the consequence of the rolling resistance of the tire resulting in the rolling resistance coefficient (see also Section 27.2.3.1)

$$f_{Ri} = \frac{\xi_i}{r_i} \tag{27.1}$$

which is assumed to be equal for all tires and named f_R.

Newton's law and Euler's equation with respect to CG constitute (for $G = mg$)

$$ma_x = 2F_{xF} + 2F_{xR} - W_L - G\sin\vartheta \tag{27.2}$$

$$0 = 2F_{zF} + 2F_{zR} + W_Z - G\cos\vartheta \tag{27.3}$$

$$2I_F\dot{\omega}_F + 2I_R\dot{\omega}_R = 2F_{zR}(l_R - \xi_R) - 2F_{zF}(l_F + \xi_F) - 2(F_{xF} + F_{xR})h + M_Y \tag{27.4}$$

with the moments of inertia I_F, I_R of the front and rear wheels, which rotate with the angular velocities ω_F, ω_R.

To get the drive-train and/or brake system involved, the corresponding drive and/or braking moments, MDi and/or MBi, are presented in Figure 27.2, acting at one rear wheel. The forces X_R, Z_R result from the force transfer between the car body and the center of the wheel. Aerodynamic effects on the wheels are not considered separately, but assumed to be taken into account by W_L, W_Z, M_Y in (27.2) through (27.4) (see Section 27.2.3.2). The corresponding Euler's equation w.r.t. CG_R is

$$I_R\dot{\omega}_R = M_{DR} - M_{BR} - M_{FR} - F_{zR}\xi_R - F_{xR}r_R \tag{27.5}$$

including the friction moments M_{FR} of the wheel bearing. To simplify the kinematics, as indicated before, and further assuming the same tires on the front and rear axle, a rolling condition of the wheel is established by

$$\begin{aligned} r\omega &= v_x \\ r\dot{\omega} &= a_x \end{aligned} \tag{27.6}$$

$$\begin{aligned} \text{with } r &= r_F = r_R \\ \omega &= \omega_F = \omega_R \end{aligned} \tag{27.7}$$

And the simplification that the effective rolling r is equal to the loaded radii $r_F = r_R$.

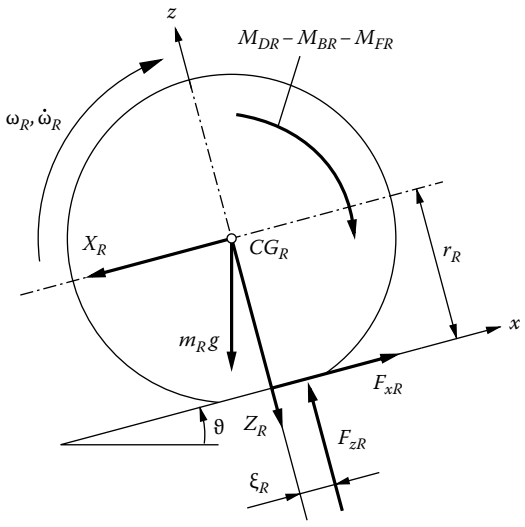

FIGURE 27.2 Forces and moments at the rear wheel.

Now, the longitudinal tire force F_{xR} in (27.5) can be expressed by using (27.1), and (27.7):

$$F_{xR} = \frac{1}{r}(M_{DR} - M_{BR} - M_{FR}) - \frac{I_R \dot{\omega}}{r} - f_R F_{zR} \tag{27.8}$$

With (27.8) and a corresponding equation for the front wheel, (27.2) reads

$$ma_x + 2I_R \frac{\dot{\omega}}{r} + 2I_F \frac{\dot{\omega}}{r} = \frac{1}{r}\left[(2M_{DR} + 2M_{DF}) - (2M_{BR} + 2M_{BF})\right]$$
$$-2\left[\left(\frac{M_{FR}}{r} + \frac{M_{FF}}{r}\right) + (f_R F_{zR} + f_R F_{zF})\right] - W_L - G\sin\vartheta$$

or by incorporation of (27.6) and (27.3)

$$\left(m + \frac{2I_R}{r^2} + \frac{2I_F}{r^2}\right) a_x = \frac{M_D}{r} - \frac{M_B}{r} - W_{total} \tag{27.9}$$

with the substitutes

$$W_{total} = \frac{M_F}{r} + W_R + W_L + W_G$$

$$W_R = f_R(2F_{zR} + 2F_{zF}) \overset{(27.3)}{=} f_R(G\cos\vartheta - W_Z)$$

$$W_G = G\sin\vartheta \tag{27.10}$$

$$M_F = 2(M_{FR} + M_{FF})$$

$$M_D = 2M_{DR} + 2M_{DF}$$

$$M_B = 2M_{BR} + 2M_{BF}$$

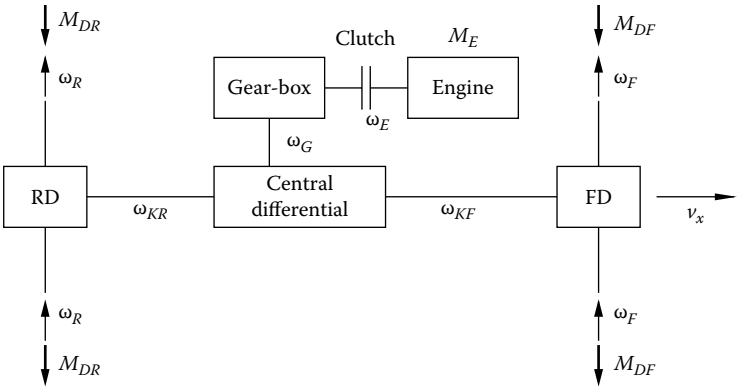

FIGURE 27.3 Schema of a four-wheel drive with manual transmission (RD, rear differential; FD, front differential).

Equation 27.9 reveals that the acceleration of the vehicle is determined by the sum of the driving torques M_D at the wheels, the braking torques M_B, and the whole driving resistance force W_{total} (see Section 27.2.3), comprising influences of the rolling resistance W_R, the grade by W_G, the aerodynamic drag W_L, and smaller effects by friction moments in the wheel bearings that are usually neglected.

The drive train is modeled in such a way that the different drive concepts—front-wheel drive, rear-wheel drive, and four-wheel drive—can be considered (Figure 27.3). In this figure, the wheels are omitted since the dynamics are already taken into account by (27.5). The same wheel-spin velocities ω_F, ω_R and driving torques M_{DF}, M_{DR} for both wheels of an axle hold for the presumed straight-line motion and symmetric conditions left–right. (For open differentials and, e.g., cornering the wheel spins, ω_i will be different for each wheel, while for locked differentials the drive moments will be different for each wheel.)

Considering the power–energy equation $\dot{E}_{kin} = \sum P$ and taking into account that the derivative of the translational kinetic energy is balanced by the corresponding power of the longitudinal external forces acting on the considered system, the derivative of the rotational kinetic energy

$$E_{rot} = \Theta_E \frac{\omega_E^2}{2} + I_C \frac{\omega_G^2}{2} + I_{DR} \frac{\omega_{KR}^2}{2} + I_{DF} \frac{\omega_{KF}^2}{2} \tag{27.11}$$

has to be only considered (Figure 27.3). Θ_E is the substitutive moments of inertia of the engine and all parts rotating with the angular velocity ω_E of the engine; I_C, the moments of inertia of parts of the transmission and central differential rotating with ω_G; and I_{DR}, I_{DF}, the moments of inertia of the rear and front differential and parts rotating with ω_{KR}, ω_{KF}, respectively. The moments of inertia of the drive shafts from differential to wheels are assumed to be included in I_R, I_F. Thereby, the power–energy equation results in

$$\frac{dE_{rot}}{dt} = \eta M_E(\omega_E)\omega_E - 2M_{DF}\omega_F - 2M_{DR}\omega_R \tag{27.12}$$

The input power $M_E\omega_E$ of the engine torques $M_E(\omega_E)$ is reduced by applying a coefficient of efficiency $\eta < 1$, presenting the transfer losses in the system.

By means of the central differential, a distribution of the driving torques M_D to the cardan shafts can be accomplished:

$$2M_{DF} = M_D \nu_F, \quad 2M_{DR} = M_D \nu_R$$
$$\nu_F + \nu_R = 1 \tag{27.13}$$

$$\begin{aligned} \text{for rear-wheel drive:} \quad & \nu_R = 1 \\ \text{for front-wheel drive:} \quad & \nu_F = 1 \\ \text{for 4-WD with equal distribution:} \quad & \nu_R = \nu_F = 0.5 \end{aligned} \tag{27.14}$$

By introducing transmission ratios N_{Gn} of the gears and N_D of the differentials, the following kinematic relations are obtained:

$$\begin{aligned} \omega_E &= \omega_G N_{Gn} \\ \omega_G &= \nu_R \omega_{KR} + \nu_F \omega_{KF} \\ \omega_{KR} &= N_D \omega_R, \quad \omega_{KF} = N_D \omega_F \end{aligned} \tag{27.15}$$

The transmission ratio N_{Gn} is determined by the chosen gear.

With the simplifications (27.6) and (27.7) and the relations in (27.13) and (27.15), Equation 27.12 provides the driving torques

$$\begin{aligned} M_D &= 2M_{DF} + 2M_{DR} \\ &= \eta M_E(\omega_E) \cdot N - r \left[\frac{\Theta_E N^2}{r^2} + \frac{(I_C + I_{DR} + I_{DF})}{r^2} N_{Gn}^2 \right] a_x \end{aligned} \tag{27.16}$$

with

$$N = N_{Gn} N_D$$

In (27.16), it is assumed that N_{Gn} is not a function of time (as it may happen with continuous gear transmissions), and that there is no instantaneous change due to an action of the clutch or a converter.

An essential assumption for this kind of drive train model is (27.6), (27.7), where no slip–force relation at the tire is considered. An extension of this drive train model, applicable also for cornering, is given in [9].

Finally, inserting (27.16) into (27.9) yields the relation between engine torques input and resulting acceleration of the vehicle

$$(m + m_r) a_x = \frac{\eta M_E \omega_E \cdot N}{r} - \frac{M_B}{r} - W_{total} \tag{27.17}$$

with the equivalent mass of the rotating components

$$m_r = \frac{1}{r^2} \left[\Theta_E N^2 + (I_C + I_{RD} + I_{FD}) N_{Gn}^2 + (2I_R + 2I_F) \right] \tag{27.18}$$

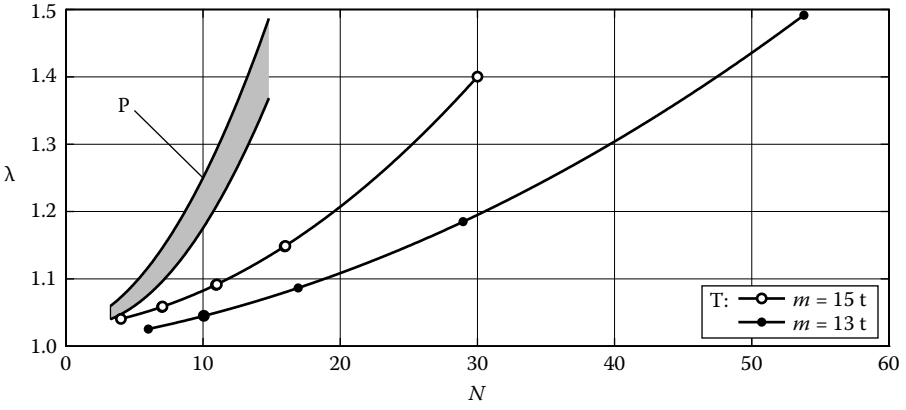

FIGURE 27.4 Typical mass factor λ as a function of the overall transmission ratio N for passenger cars (P) and trucks (T).

Due to the $N = N_{Gn}N_D$, the mass factor

$$\lambda = \frac{m + m_r}{m} \tag{27.19}$$

depends to a great extent on the applied gear ratio N_{Gn} (see Figure 27.4, [5]).

For the determination of the longitudinal force coefficient of wheel i,

$$\mu_i = \frac{F_{xi}}{F_{zi}} \tag{27.20}$$

the normal tire forces F_{zi} have to be derived from (27.3) and (27.4).

$$0 = 2F_{zF} + 2F_{zR} + W_Z - G\cos\vartheta$$

$$2I_F\dot{\omega}_F + 2I_R\dot{\omega}_R + ma_x h = -2F_{zF}l_F + 2F_{zR}l_R + (-W_L - G\sin\vartheta)h + M_Y - 2(\xi_F F_{zF} + \xi_R F_{zR})$$

by using $(2F_{xF} + 2F_{xR})$ from (27.2). With $\xi_F = \xi_R = \xi$ and (27.6), (27.7), the aforementioned two equations result in

$$2F_{zF} + 2F_{zR} = G\cos\vartheta - W_Z \tag{27.21}$$

$$-2l_F F_{zF} + 2l_R F_{zR} = \left[\left(\frac{2I_F}{r} + \frac{2I_R}{r}\right)a_x + (ma_x + W_L + G\sin\vartheta)h + M_Y + \xi(G\cos\vartheta - W_Z)\right] \tag{27.22}$$

and with a_x from (27.17), the normal tire forces can be determined explicitly. Often, only the main components of the right-hand sides are considered: $M_Y \approx 0$, $W_Z \approx 0$, and by neglecting

the small terms $(2I_F + 2I_R)/r \ll mh$ as well as $\xi(G\cos\vartheta) \ll (ma_x + W_L + G\sin\vartheta)h$, the normal tire forces follow from

$$\frac{F_{zF}}{G} = \frac{l_R}{l}\cos\vartheta - a^* \frac{h}{l} \tag{27.23}$$

$$\frac{F_{zR}}{G} = \frac{l_F}{l}\cos\vartheta + a^* \frac{h}{l} \tag{27.24}$$

$$\text{with } a^* = \left(\frac{a_x}{g} + \sin\vartheta + \frac{W_L}{G} \right) \tag{27.25}$$

where, moreover, for common grades $|q| \leq 20\%$ (respectively, $|\tan\vartheta| \leq 0.2$), the approximation $\cos\vartheta \approx 1$ is appropriate (error $\leq 2\%$). The tire load transfer front–rear, with respect to acceleration a_x and grade ϑ, can now be easily evaluated.

27.2.3 Driving Resistances

Sometimes expressions like "acceleration resistance" and "resistance due to a grade"—which can by definition be positive or negative—can be found in literature, but need not be considered separately, since these phenomena are already included in the formulations of Section 27.2.2, for example, by "ma_x" and "$G \sin\vartheta$." The friction moments M_F caused by the wheel bearing can generally be neglected compared, for example, to the rolling resistance [7].

27.2.3.1 Rolling Resistance

The rolling resistance originates from the energy dissipation of the deformation of the rolling tire [7]. Thereby, the pressure distribution in the tire contact patch has larger values in the direction of rolling (see Figure 27.5), which results in a normal tire force acting in the front of the virtual tire contact point A. This effect is already taken into account in Figures 27.1 and 27.2 by the introduction of ξ.

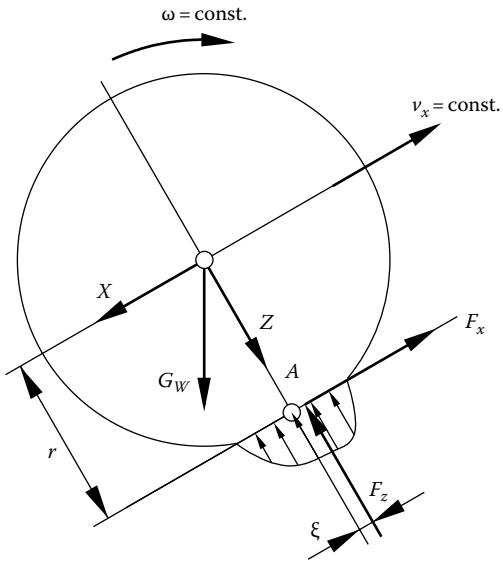

FIGURE 27.5 Tire moving with constant velocity without axle torques.

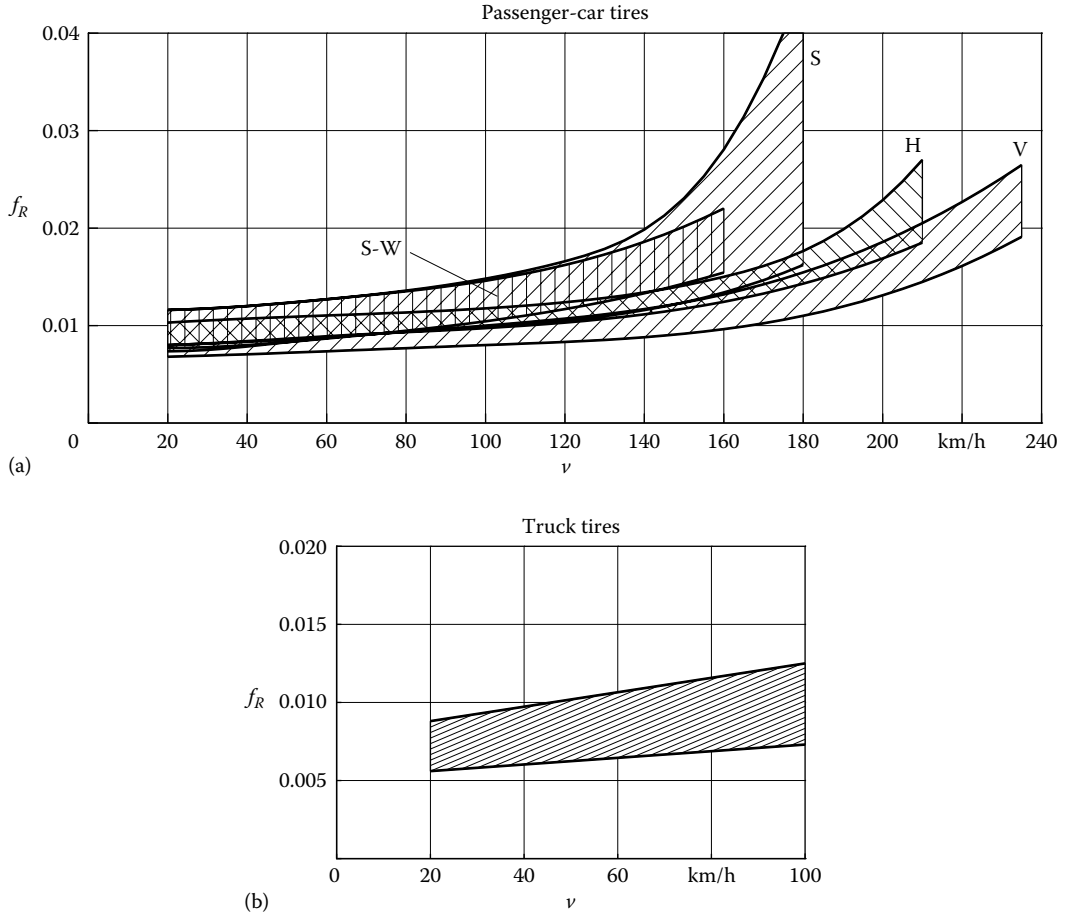

FIGURE 27.6 Rolling resistance coefficient for different types of (a) radial passenger-car tires (S-W: winter tires; permitted max. velocity for S: 180 km/h, H: 210 km/h, V: >210 km/h) and (b) truck tires (wheel loads between 20 and 30 kN). (From Mitschke, M. and Wallentowitz, H., *Dynamik der Kraftfahrzeuge*, Springer Verlag, Berlin, Germany, 2004.)

By stating the equation of equilibrium for the moments with respect to the wheel axle, the longitudinal tire force can be expressed by

$$F_x = -\frac{\xi}{r} F_z = -f_R F_z \tag{27.26}$$

The value of the rolling resistance coefficient f_R mainly depends not only on the type of tire and velocity (see Figure 27.6) but also on inflation pressure (see e.g., [7]) and tire temperature (see e.g., [6]). A water layer on the road surface also increases f_R (see e.g., [7]). Especially on soft soil, the rolling resistance will increase dramatically (see [14]).

27.2.3.2 Aerodynamic Phenomena and Drag

For many years, the aerodynamic flow around the moving vehicle has been intensively investigated; some essential findings and data can be found in Chapter 16 and [6,7,15,16].

The aerodynamic pressure distribution acting on the vehicle is represented by its reduction to a reference point and the corresponding forces and moments. Due to the complexity of this pressure system, mostly wind tunnel measurements are used to determine the aerodynamic coefficients used

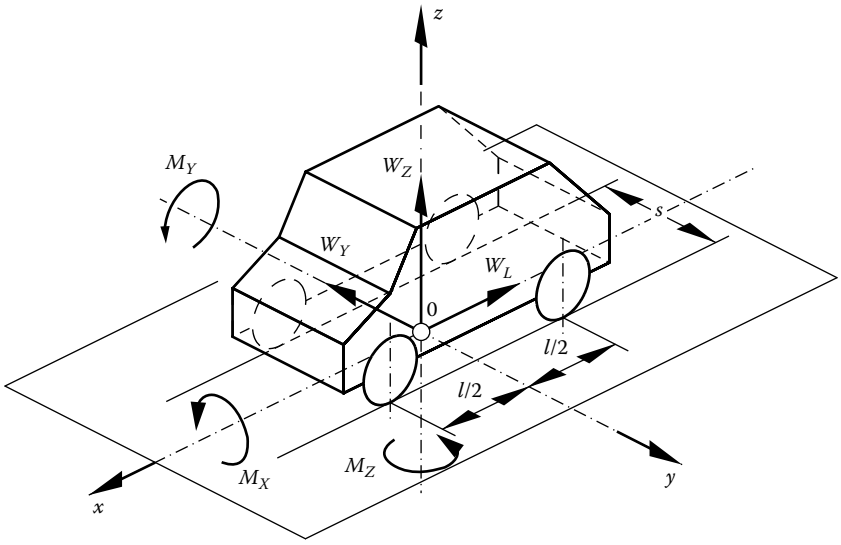

FIGURE 27.7 Aerodynamic forces and moments.

for the description of the reduction results for reference point 0 in the center of the rectangle made up by the contact points of the wheels (Figure 27.7 [7]).

Most relevant for the magnitude of forces and moments is the resultant air velocity vector $\vec{v}_R$, defined by its magnitude v_R and the aerodynamic side slip angle β_a (see Figure 27.8). The vector $\vec{v}_R$ results from the negative driving velocity of the vehicle $-\vec{v}$ and the velocity $\vec{v}_W$ of the ambient wind.

The dynamic pressure p_d for the vehicle is defined by (with air density ϱ)

$$p_d = \frac{\varrho v_R^2}{2} \tag{27.27}$$

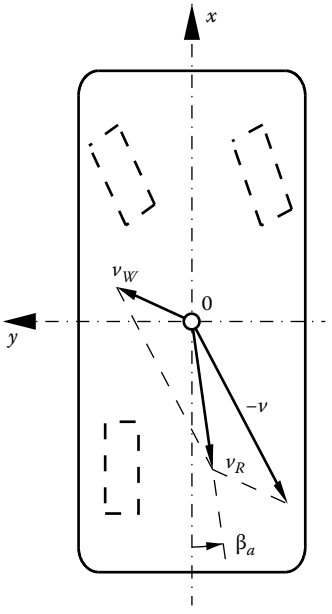

FIGURE 27.8 Resultant aerodynamic velocity $\vec{v}_R$ due to ambient wind $\vec{v}_W$ and vehicle velocity $\vec{v}$.

According to the *Vehicle Dynamics Terminology* (see [16,17]), the forces and moments acting on the vehicle at 0 (Figure 27.7) are described by applying force and moments coefficients $C_x \ldots C_{Mz}$

$$W_L = C_x A \cdot p_d, \quad W_Y = C_y A \cdot p_d, \quad W_Z = C_z A \cdot p_d$$
$$M_X = C_{Mx} A \cdot p_d l, \quad M_Y = C_{My} A \cdot p_d l, \quad M_Z = C_{Mz} A \cdot p_d l \tag{27.28}$$

with the vehicle area A (projected frontal area including tires and underbody parts). The coefficient C_x, responsible for the aerodynamic drag, is a specific value of the tangential aerodynamic coefficient $C_T(\beta_a)$, [15], $C_T(0) = C_x$. In general, for passenger cars, C_T is nearly constant for small aerodynamic side slip angles β_a, whereas a stronger influence can be seen for other vehicle body shapes (Figure 27.9).

C_x, $C_x A$ are often used to indirectly characterize the fuel consumption efficiency of cars and trucks. For today's passenger cars, values of $C_x = 0.3$ and $C_x A = 0.6$ m^2 are common, and for trucks, the values are about $C_x = 0.8$ and $C_x A = 5$–7 m^2 and even more, especially for trucks with trailers [4].

For small β_a, the coefficients C_Y, C_{Mx}, and C_{Mz} show a nearly linear increase with β_a. For example, there is a pronounced influence of the shape of the rear end (Figure 27.10); for more detailed characteristics, refer to [15]. Obviously, the box-type rear end of the station wagon has the advantage of a smaller aerodynamic yawing moments that can contribute to improved stability at higher velocities.

Nowadays, computational fluid dynamics (CFD) approaches are used to investigate aerodynamic details of the body shape as well [15], but generally the aerodynamic coefficients are still measured in wind tunnels.

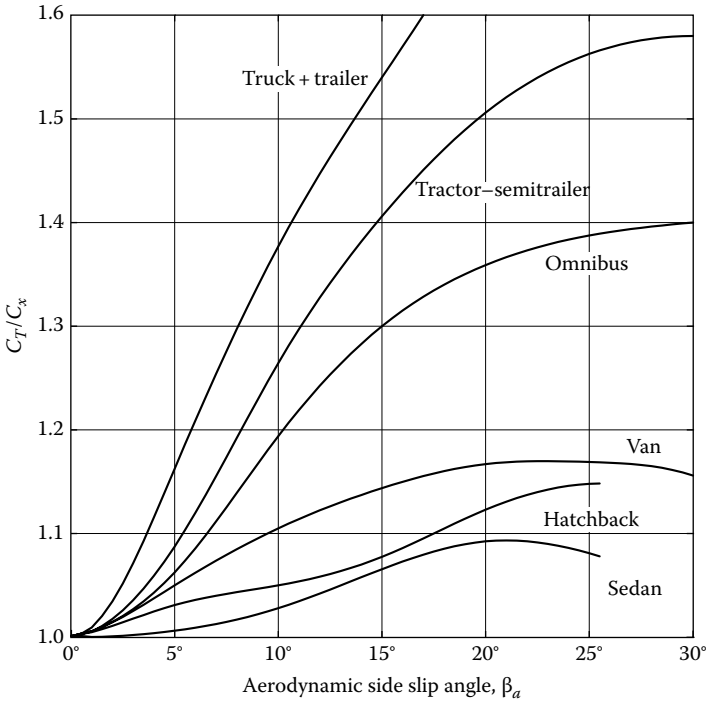

FIGURE 27.9 Influence of type of vehicle (vehicle body shape) on the normalized tangential aerodynamic coefficient $C_T(\beta_a)/C_x$.

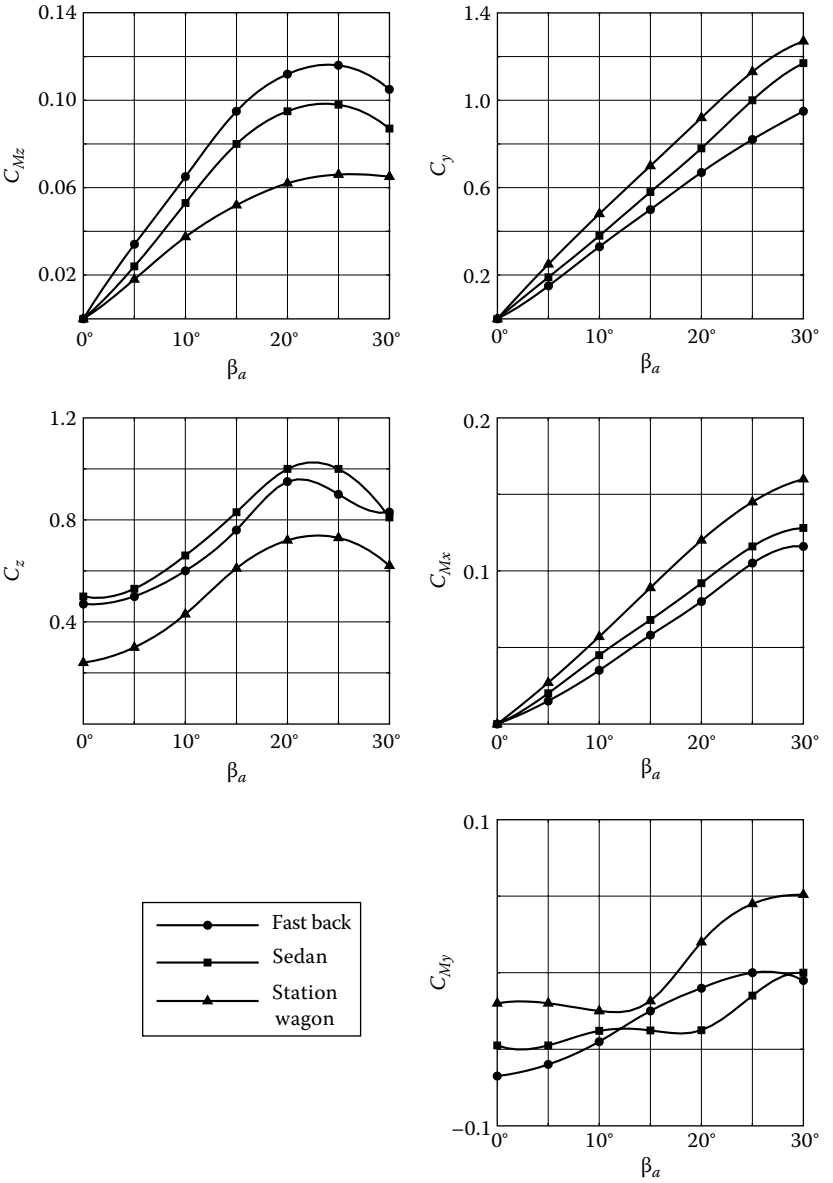

FIGURE 27.10 Aerodynamic coefficients as functions of aerodynamic side slip angle β_a for different rear-end shapes.

27.2.4 Vehicle Performance

Keeping in mind the description of the longitudinal dynamics in (27.17) and the driving resistances of W_{total} in (27.10), including rolling resistance and aerodynamic drag (Section 27.2.3), the engine torques $M_E(\omega_E)$, the overall gear ratio N, and the braking activities M_{Bi} will determine the performance of the vehicle.

27.2.4.1 Driving Performance

Here, no braking torques are applied and the engine torques is decisive for driving speed or acceleration performance (e.g., traction limit). The fuel consumption will not be considered in this context,

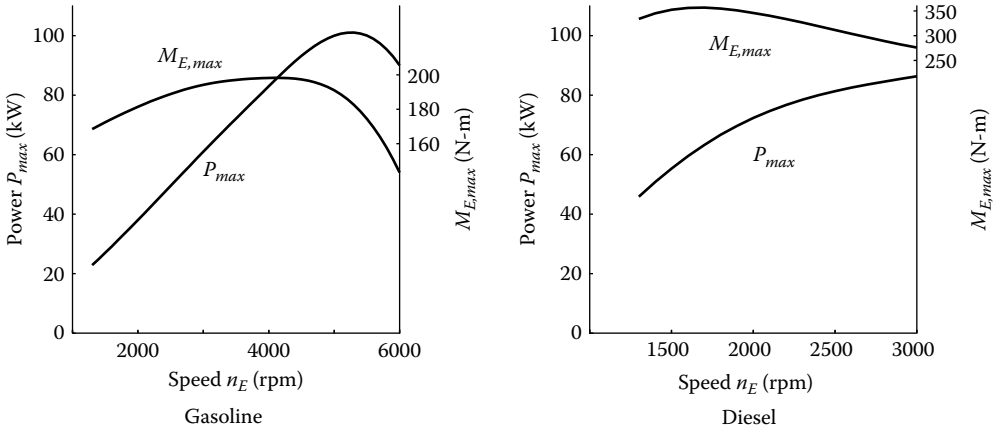

FIGURE 27.11 Examples for full-throttle engine characteristics, $M_{E,max}$, P_{max}.

but could be related to the engine characteristics [7,12]. Two typical full-throttle engine characteristics are shown in Figure 27.11 [6].

The power is defined by (engine speed n_E in r.p.m.)

$$P = M_E \cdot \omega_E = M_E \cdot \frac{n_E \pi}{30} \tag{27.29}$$

With throttle position $0 \le \lambda_T \le 1$, the applied torques M_E of the engine can be varied between engine drag $M_{E,d}$ and full-throttle engine torques $M_{E,max}$ in about a linear way:

$$M_E = (M_{E,max} - M_{E,d})\lambda_T + M_{E,d}$$

To obtain an overview of the vehicle performance for different speeds v_x and grades ϑ, the engine torques $M_E(\omega_E)$ is transformed to a net driving force $K_E = K_E(v_x, N_{Gn})$ as a function of v and different gear ratios N_{Gn}:

$$K_E = \frac{\eta M_E(\omega_E) \cdot N_{Gn} N_D}{r}, \quad \omega_E = v_x \cdot \frac{N_{Gn} N_D}{r}$$

With (27.17), (27.19), there follows

$$m\lambda a_x = K_E(v_x, N_{Gn}) - W_{total}(v_x, \vartheta) \tag{27.30}$$

Herein, the assumption is made again, that slip values remain small (and therefore also no friction limits are considered). Now, for example, with the resulting representative driving performance diagram in Figure 27.12, the maximum velocity v_{max} that can be accomplished on a horizontal road, $\vartheta = 0°$, with full throttle applied and in fourth gear, N_{G4}, can be pointed out from the intersection of the corresponding curve and the curve representing rolling and aerodynamic resistance, $W_{total} = f_R G + W_L$ (see (27.10)).

The figure also shows the net driving forces necessary for grades $q = -10\%$, 0%, $+10\%$ ($\vartheta = -5.7°$, $0°$, $+5.7°$). For example, with engine drag (no throttle applied), represented by $K_{E,d}$ and N_{G3}, a steady-state downhill velocity of v_1 is possible for $q = -10\%$. It should be mentioned that the engine drag $K_{E,d}$, especially at low velocities, strongly depends on the idle engine performance. The acceleration capability of the vehicle can be observed by the difference in K_E between the respective driving resistance curve (including the influence of grade) and the curve of the full net driving force $K_{E,max}(v_x, N_{Gn})$; for example, at velocity v_2, W_{total} with $q = 10\%$ and second gear N_{G2}, $m\lambda a_{x,2}$ is available for maximum acceleration. Driving conditions in between can be achieved by applying the corresponding throttle position.

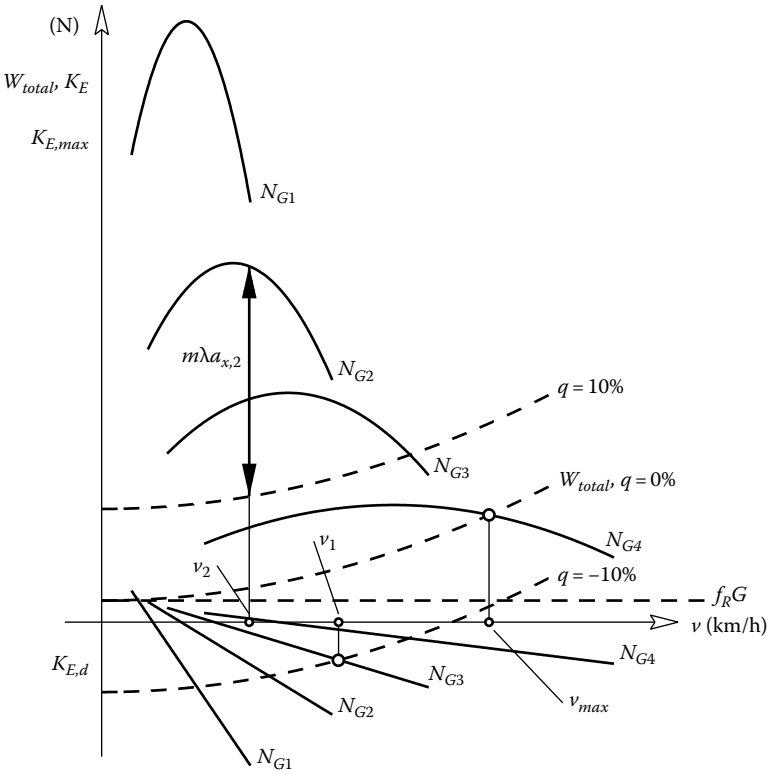

FIGURE 27.12 Driving performance diagram: principal characteristics for a passenger car with a gasoline engine; $K_{E,max}$, corresponding to maximum engine torques, are the upper four curves for the gears N_{Gn}; $K_{E,d}$ is the linear engine drag force at N_{Gn}.

The driving performance for starting at μ-split conditions (maximum longitudinal force coefficient, left side higher than/equal to right side: $\mu_{L,max} \geq \mu_{R,max}$) for different drive train configurations can be seen in Figure 27.13. Thereby, it is assumed that all wheels can work at their friction limits according to (27.20) and (27.23) through (27.25), still implying equal normal tire forces left and right. For a locked differential, the drive torques distribution is determined by the friction demands of the two wheels, while for the unlocked differential the friction limit of the wheel with the lower μ_{max} determines the longitudinal tire forces for both sides. For generalization, the dimensionless quantities a^*_{max}, W^* are introduced for the maximum acceleration (including grade and aerodynamic drag, see (27.25)) and the yaw moments due to the differences in longitudinal tire forces, see Figure 27.13,

$$W^* = \frac{(F_{x1} - F_{x2}) - (F_{x3} - F_{x4})}{Gl} \frac{s}{2} \tag{27.31}$$

The advantage of a higher traction capability for locked axle differentials at μ-split leads to increasing yaw moments due to different longitudinal forces at the left and right track. The induced yaw moments W^* has to be compensated by the driver's steering effort. For four-wheel drive (A), front-wheel drive (FD), and rear-wheel drive (RD), all without locked differentials, always the low friction side, respectively the corresponding longitudinal force, is responsible not only for the maximum possible a^*_{max} but also for $W^* = 0$, and principally no correction by the driver is necessary.

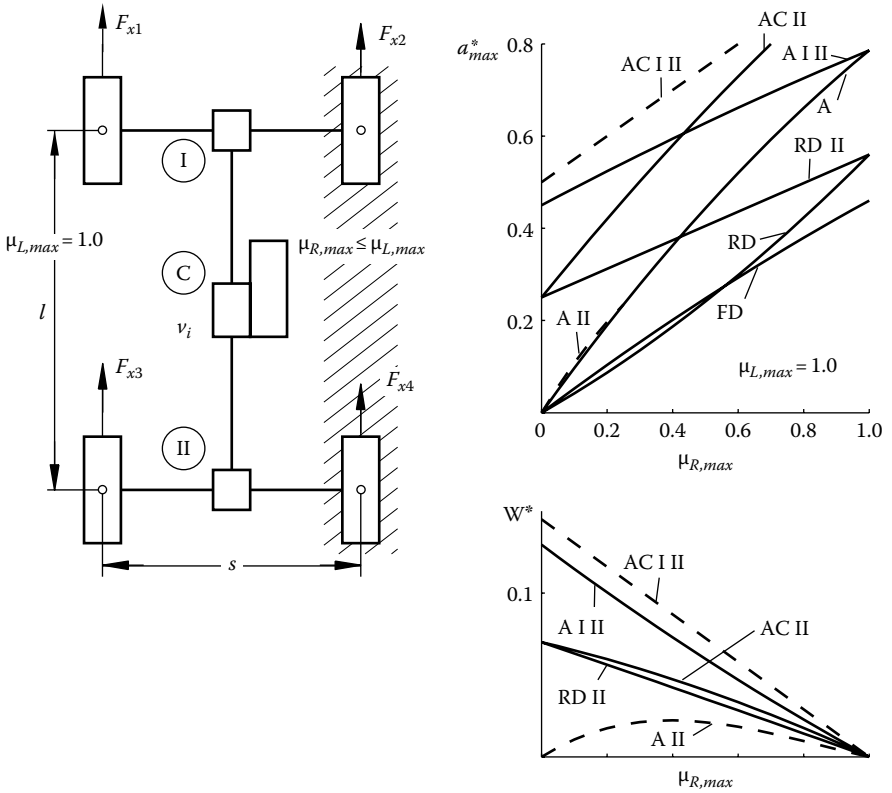

FIGURE 27.13 Starting on μ-split: Maximum possible g-normalized acceleration a^*_{max} and (necessary) normalized yaw moments W^* for rear-wheel drive (RD), front-wheel drive (FD), and four-wheel drive (A) with $\nu_F = \nu_R = 0.5$; C = locked central differential; I/II = locked axle differential front/rear.

Moreover, some more effects of a four-wheel drive vehicle can be noticed: if only one axle differential is locked (e.g., A II), there will be no real improvement in traction capability due to the interaction with the wheels at the unlocked axle; again the low friction side determines a^*_{max}, but there is still a noticeable W^*! Of course, the highest utilization of the available friction can be achieved with all differentials locked, AC I II; however, this configuration induces the largest interfering yaw moments.

27.2.4.2 Braking

In the following, "braking" is considered as a period of constant deceleration. The essential equations to represent braking dynamics have already been established in (27.2) and (27.23) through (27.25). Introducing dimensionless quantities and the effective normalized deceleration β (for small grade angles ϑ)

$$\frac{2F_{xi}}{G} = \bar{F}_{xi}, \quad \frac{h}{l} = \bar{h}$$
$$\frac{2F_{zi}}{G} = \bar{F}_{zi}, \quad \frac{l_i}{l} = \bar{l}_i, \quad i = F, R \tag{27.32}$$

$$a^* = \left(\frac{a_x}{g} + \vartheta + \frac{W_L}{G} \right), \quad \beta = -a^* > 0 \tag{27.33}$$

Equations (27.2) and (27.23) through (27.24) read

$$-\beta = \bar{F}_{xF} + \bar{F}_{xR} \tag{27.34}$$

$$\bar{F}_{zF} = \bar{l}_R + \beta\bar{h} \tag{27.35}$$

$$\bar{F}_{zR} = \bar{l}_F - \beta\bar{h} \tag{27.36}$$

and consequently

$$\bar{F}_{zF} + \bar{F}_{zR} = 1 \tag{27.37}$$

In these equations, small terms are neglected once again, see Section 27.2.2. It is assumed further that the vehicle and the environmental conditions (μ-conditions) are symmetric for the vehicle's longitudinal central plane.

For maximum deceleration, both the front and rear wheels need to utilize the existing friction conditions to their full extent at the same time. With equal conditions at both axles,

$$\mu_{F,max} = \mu_{R,max} = \mu_{max} \tag{27.38}$$

the braking forces are (braking means $\bar{F}_{xi} < 0$ ($i = F, R$))

$$\bar{F}_{xR} = -\mu_{max}\bar{F}_{zR}, \quad \bar{F}_{xF} = -\mu_{max}\bar{F}_{zF} \tag{27.39}$$

and by considering (27.37), (27.34) yields the maximum deceleration

$$\beta = \beta_{ideal} = \mu_{max} \tag{27.40}$$

and, with (27.35) and (27.36), the necessary braking force balance

$$\frac{-\bar{F}_{xR}}{-\bar{F}_{xF}} = \frac{\bar{l}_F - \bar{h}\mu_{max}}{\bar{l}_R + \bar{h}\mu_{max}} \tag{27.41}$$

It becomes evident that for each braking traction coefficient μ_{max}, another (ideal) braking force balance would be required for maximum deceleration (see Figure 27.14, [18,19]).

The diagonal lines in Figure 27.14, according to (27.34), represent all possible combinations of $-\bar{F}_{xR}$ and $-\bar{F}_{xF}$ that result in the same normalized deceleration β. The curved line is the selection of the points of the ideal braking force balance in (27.41), with regard to (27.38), with both braking forces utilizing μ_{max}.

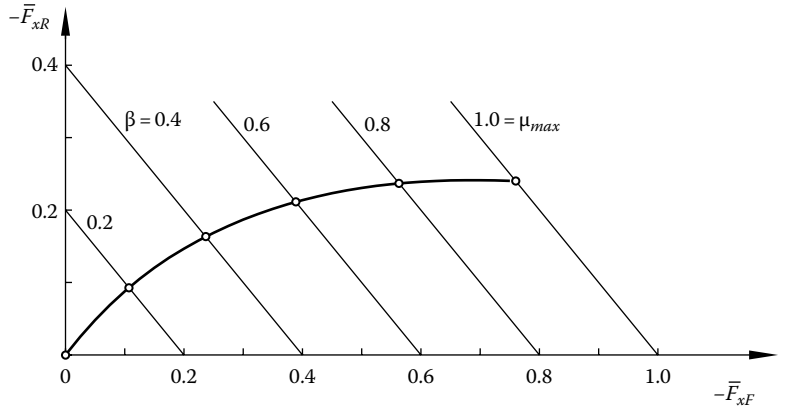

FIGURE 27.14 Ideal braking force balance for $\bar{l}_F = 0.52$, $\bar{h} = 0.28$.

If only the front wheels are operating at limit conditions

$$(-\bar{F}_{xF}) = \mu_{max}\bar{F}_{zF} \tag{27.42}$$

the rear braking force can be derived by using (27.34) and (27.35) to

$$(-\bar{F}_{xR}) = (-\bar{F}_{xF})\frac{1-\mu_{max}\bar{h}}{\mu_{max}\bar{h}} - \frac{\bar{l}_R}{\bar{h}} \tag{27.43}$$

Analogously, in case only the rear wheels are at the limit

$$(-\bar{F}_{xR}) = \mu_{max}F_{zR} \tag{27.44}$$

the front braking force is

$$(-\bar{F}_{xF}) = -(-\bar{F}_{xR})\frac{1+\mu_{max}\bar{h}}{\mu_{max}\bar{h}} + \frac{\bar{l}_F}{\bar{h}} \tag{27.45}$$

These two relations, (27.43) and (27.45), limit the applicable area for braking (see straight "limit" lines in Figure 27.15). Larger normalized braking forces are not possible due to the locking of either the front or the rear wheels.

If a constant braking torques balance between front and rear wheels is implemented in the braking system, with the braking forces approximately proportional to the braking torques (if slip changes are not too large), the following relation holds:

$$\frac{-\bar{F}_{xF}}{-\bar{F}_{xR}} = k \tag{27.46}$$

which corresponds to the straight line marked with (*c*) in Figure 27.15. With a specific set of the braking balance, for example, represented by point *A* on this line, the related value of the normalized deceleration β can be found by the intersection of the −45°-inclined line with the horizontal axis.

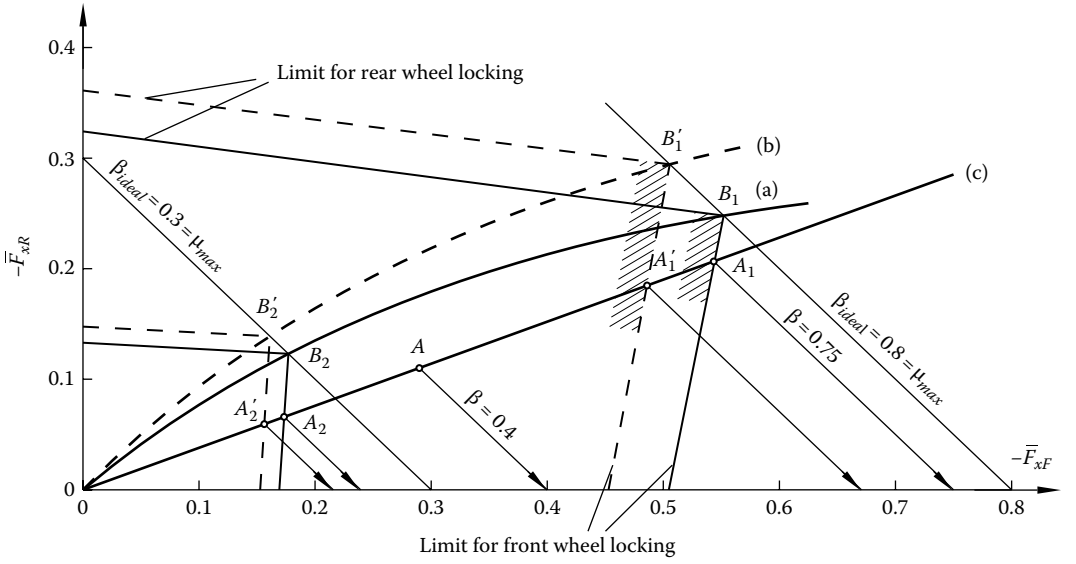

FIGURE 27.15 Braking force distribution diagram (with normalized braking forces $-\bar{F}_{xF}$, $-\bar{F}_{xR}$) for a passenger car for two loading conditions (curve (a): $\bar{l}_F = 0.47$, $\bar{h} = 0.2$; curve (b): $\bar{l}_F = 0.52$, $\bar{h} = 0.19$) and two braking traction coefficients $\mu_{max} = 0.3$; 0.8 with constant braking force balance (curve (c)): $-\bar{F}_{xF}/-\bar{F}_{xR} = k = 2.63$.

With the braking force distribution diagram of Figure 27.15, the performance of the braking system, including its limits due to friction conditions, can be demonstrated. The curves (a) and (b) represent the ideal braking force balance for two different loading conditions and therefore points B_1', B_1 and B_2', B_2 correspond to ideal tuning for the (normalized) braking forces. The implemented braking system (represented by line (c)) is set in such a way that with increasing braking pressure—that means going along line (c)—the front wheels will lock first, marked with A_1', A_1 and A_2', A_2. Looking on the possible normalized decelerations β, it becomes obvious that only less than the ideal deceleration $\beta_{ideal} = \mu_{max}$ can be achieved. Braking systems are typically designed in such a way that front wheels will lock first in order to avoid the spin-out of the vehicle at a critical braking maneuver—a vehicle with locked front wheels will usually move straight ahead. In this case, the loss of steering capability of the front wheels—due to a reduction in lateral forces for locked wheels—can be improved with an ABS! The shaded areas in Figure 27.15 indicate a possible working area for the ABS for $\mu_{max} = 0.8$. It does not enhance the possible deceleration substantially but avoids the locking of the wheels. Within the shaded areas, the ABSs aim to reach ideal braking. A detailed description of an ABS (and ESP) is presented in Chapter 30.

Besides the design of the braking system with constant $-\bar{F}_{xF}/-\bar{F}_{xR} = k$, there are various other possibilities, for example, a piecewise linear relation that can be closer to the ideal curves (a), (b) and therefore utilizes the available friction limits better (e.g., [12]).

27.2.5 Reaction, Braking Procedure, and Stopping

After the driver has recognized and decided that a braking action has to be executed, some time elapses until the deceleration of the vehicle becomes effective. This period is called prebraking time, t_{pre}, which is typically about 0.8–1.0 s [7,12], and consists of the reaction, transfer, and response time. For simplicity, half of the brake pressure build-up time, t_s, is usually included here as well.

The reaction time is the time between the defined incitement to action and the start of the first specifically targeted action, 0.2–0.3 s [12]. Then the driver requires about 0.2 s [8] to transfer the foot from the gas to the brake pedal (transfer time). Some more time elapses, called the response time, approximately 0.05 s [7], to transmit pressure from the brake pedal to the braking system and the braking action becomes effective. This period, $(t_1 - t_0)$, is illustrated in Figure 27.16.

The brake pressure is built up until t_1' and full deceleration becomes effective at t_2, $t_s = t_2 - t_1$, approximately 0.17 s [7].

After the "mean maximum retardation" period, $(t_3 - t_2)$, the brake release ends the braking operation at t_4. Thus, the interval, $(t_4 - t_1)$, is the total braking time t_B. As mentioned earlier, half of the

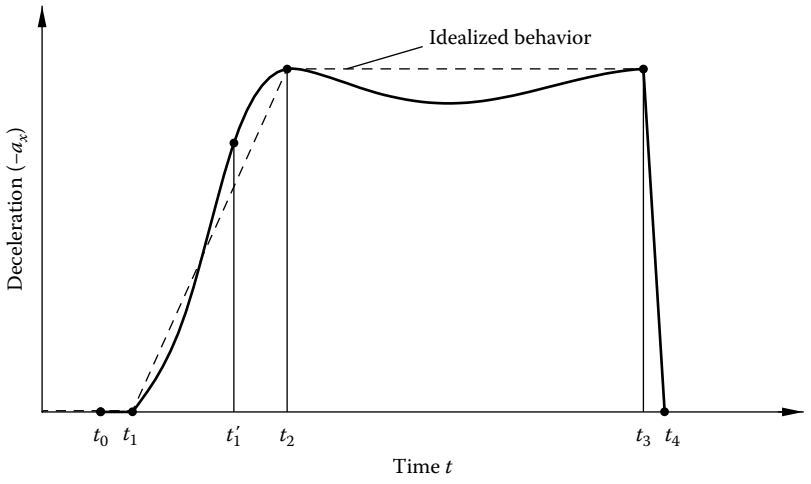

FIGURE 27.16 Characteristics of a braking procedure.

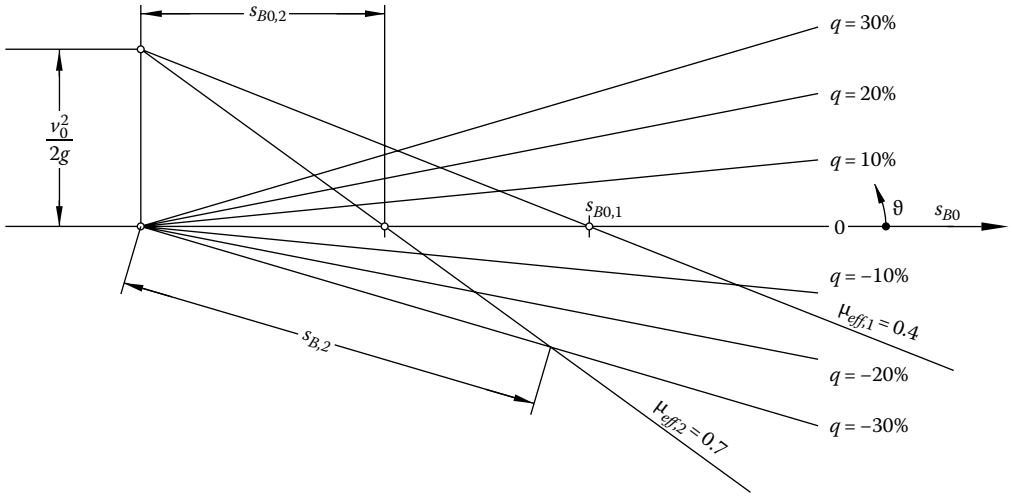

FIGURE 27.17 Braking distance s_{Bi} to standstill as a function of grade ϑ (for constant deceleration).

brake pressure build-up time, $t_s/2$, is usually drawn off to count for the prebraking time. Moreover, often the decline time, $(t_4 - t_3)$, is neglected compared to $(t_3 - t_2)$. An idealized braking behavior, which maps the time-dependent deceleration in a linear way, is plotted in Figure 27.16.

Finally, the stopping time of the vehicle is the sum of the prebraking time, t_{pre}, and the braking time, t_B. Consequently, the vehicle passes the distance $t_{pre} \cdot v$ during the first period, and together with the braking distance s_B during t_B, the full stopping distance.

For a time-varying deceleration, a time integration of the equations of motion is required in general, and, may be additionally, the locking of wheels needs to be taken into account. Nevertheless, as stated at the beginning of Section 27.2.4.2, many fundamental considerations are based on the assumption of a constant deceleration. In this way, ($\beta = -a_x = \text{const.} > 0$), the braking distance, s_B, can be estimated and derived by using (27.2) and (27.3) for different grades ϑ and no locking wheels, with an effective braking force coefficient

$$\mu_{eff} = \left| \frac{-(2F_{xF} + 2F_{xR})}{2F_{zF} + 2F_{zR}} \right| = \frac{m\beta - W_L - mg\sin\vartheta}{mg\cos\vartheta - W_Z} \tag{27.47}$$

Disregarding the aerodynamic effects ($W_L \approx 0$, $W_Z \approx 0$) with respect to the other quantities, the braking distance from the initial velocity v_0 to standstill is

$$s_B = \frac{v_0^2}{2g(\mu_{eff}\cos\vartheta + \sin\vartheta)}, \quad \text{for } \vartheta = 0: \quad s_{B0} = \frac{v_0^2}{2g\mu_{eff}} \tag{27.48}$$

Figure 27.17 illustrates for two different values of $\mu_{eff,j}$, the effect of different grades on the braking distance to standstill with respect to a horizontal road; thus, for $\mu_{eff,2} = 0.7$, the braking distance $s_{B,2}$ for a grade of $q = -30\%$ is nearly twice as long as the braking distance $s_{B0,2}$ on a horizontal road.

27.2.6 State-Space Description, Inverse Dynamics, and Basics for Longitudinal Control

By introducing simple linear characteristics for the determination of the applied longitudinal tire forces

$$F_{xi} = C_{si}s_i \quad i = F, R \tag{27.49}$$

with the slip stiffness C_{si} and the longitudinal slip (rolling radius r_i)

$$s_i = \frac{r_i\omega_i - v_x}{v_x} \quad i = F, R \tag{27.50}$$

and by recalling the equations of motion for the vehicle (27.2) through (27.4) and the simplified Euler's equations for the front and rear wheels (see (27.5), $M_{Fi} = 0$, $M_{Ai} = M_{Di} - M_{Bi}$ (i=F, R)) with the applied torques M_{Ai},

$$I_F\dot{\omega}_F = M_{AF} - f_R F_{zR} r_F - F_{xF} r_F \tag{27.51}$$

$$I_R\dot{\omega}_R = M_{AR} - f_R F_{zR} r_R - F_{xR} r_R \tag{27.52}$$

the equations of motion for the system can be stated in the form

$$\begin{gathered} \dot{\underline{x}} = \underline{f}(\underline{x}, \underline{u}) \\ \underline{x} = [v_x, \omega_F, \omega_R]^{\mathrm{T}}, \quad \underline{u} = [M_{AF}, M_{AR}]^{\mathrm{T}} \end{gathered} \tag{27.53}$$

with state-vector $\underline{x}$ and input vector $\underline{u}$. Setting $M_{AR} = 0$ or $M_{AF} = 0$ defines front- or rear-wheel drive, with a fixed relation M_{AR}/M_{AF}, both four-wheel drive and braking with a constant braking force balance can be taken into account.

By solving (27.53), which is generally a set of nonlinear differential equations, numerically, the vehicle performance can be investigated also for nonconstant deceleration, which has been assumed, for example, in Section 27.2.4.2. Also, locked wheels can be considered by $-F_{xi} = \mu_s F_{zi}$.

For given $v(t)$, for example, as a result from a driving test, the required torques M_{AF}, M_{AR} can be derived by solving (27.53) with respect to $\underline{u}$ ("inverse dynamics").

To linearize (27.53) with respect to a given $v_g = v_g(t)$, see [20]; here, quasi steady-state values v_s are used (and thus only moderate accelerations are presumed), and for horizontal roads,

$$v_x = v_s + \Delta v_x \tag{27.54}$$

$$\omega_i = \omega_{i,s} + \Delta\omega_i, \quad i = F, R \tag{27.55}$$

$$M_{Ai} = M_{Ai,s} + \Delta M_{Ai}, \quad i = F, R \tag{27.56}$$

Similar assumptions are made to derive (27.23) and (27.24); moreover, the normal tire forces are set constant for the determination of the rolling resistance, and the influence on C_{si} in (27.49) is neglected. The aerodynamic drag in (27.27) and (27.28) is included (for small longitudinal ambient wind $v_W \ll v_s$, $k_x = C_x A \varrho/2$) by

$$W_L = k_x(v_s + \Delta v_x + v_W)^2 \approx k_x v_s^2 + 2k_x v_s \Delta v + 2k_x v_s v_W \tag{27.57}$$

The linearized relation for (27.50) reads

$$s_i \approx \frac{r_i\omega_{i,s} - v_s}{v_s} + \frac{r_i\Delta\omega_i}{v_s} - \frac{\Delta v_x}{v_s} \quad i = F, R \tag{27.58}$$

when small longitudinal slip values with respect to steady-state conditions are assumed, which means $(r_i\omega_{i,s} - v_s)/v_s \ll 1$ or $r_i\omega_{i,s} \approx v_s$. For simplification, $r_F = r_R = r$.

The steady-state values for $M_{Ai,s}$ can be derived from $\underline{0} = \underline{f}(\underline{x}_s, \underline{u}_s)$ and balance rolling resistance, aerodynamic drag, and grade (here $\vartheta_{F,s} = 0$). Finally, the linearized system equations for the deviations from steady state are in state-space notation:

$$\dot{\underline{x}} = \mathbf{A}\underline{x} + \mathbf{B}\underline{u} + \underline{g}_w w \tag{27.59}$$

with

$$\underline{x} = \begin{bmatrix} \Delta v_x \\ \Delta\omega_F \\ \Delta\omega_R \end{bmatrix}, \quad \mathbf{A} = \begin{bmatrix} -\dfrac{2\left(C_{sF} + C_{sR} + k_x v_s^2\right)}{m v_s} & \dfrac{2rC_{sF}}{m v_s} & \dfrac{2rC_{sR}}{m v_s} \\ \dfrac{rC_{sF}}{I_F v_s} & -\dfrac{r^2 C_{sF}}{I_F v_s} & 0 \\ \dfrac{rC_{sR}}{I_R v_s} & 0 & -\dfrac{r^2 C_{sR}}{I_R v_s} \end{bmatrix}$$

$$\underline{u} = \begin{bmatrix} \Delta M_{AF} \\ \Delta M_{AR} \end{bmatrix}, \quad \mathbf{B} = \begin{bmatrix} 0 & 0 \\ \dfrac{1}{I_F} & 0 \\ 0 & \dfrac{1}{I_R} \end{bmatrix}, \quad \underline{g}_w = \begin{bmatrix} \dfrac{1}{m} \\ 0 \\ 0 \end{bmatrix}, \quad w = -2k_x v_s v_w - mg\Delta\vartheta_F$$

Stability of (27.59) can be analyzed by calculating the eigenvalues λ_i of the system matrix $\mathbf{A}$ from solving the characteristic equation $|\mathbf{A} - \lambda\mathbf{I}| = 0$. In a symbolic way, the asymptotic stability of the linearized system (and as a consequence also locally of the nonlinear system) can be proved by applying Hurwitz' stability theorem. As the stability margin is quite small, (initial) disturbances vanish only slowly and controlled dynamics may be advisable. This can be achieved by applying an input vector $\underline{u} = -\mathbf{K}\underline{x}$, where $\mathbf{K}$ can easily be determined with the afore-listed matrices and elementary control theory methods (see Chapter 6). As constant disturbances still will not decay, a PI-state controller may be recommended.

27.3 LATERAL VEHICLE BEHAVIOR

27.3.1 Application and Vehicle Model Features

A simple model for basic analysis of lateral vehicle behavior (for more advanced models and analysis see Chapter 28) is the (linearized) two-wheel vehicle model in Figure 27.18 (e.g., [1,2,5,6,7,8,9,10,20]), where the two wheels of an axle are substituted by one wheel in the vehicle's central plane. The resulting two substitutive wheels for the two axles of a passenger car are assumed to be included into the vehicle mass and inertia (neglecting inertia effects due to wheel spin), and comprise not only the properties of the tires but also those of the wheel suspensions.

The limits for the validity of the model, for example, with respect to the lateral acceleration, and what kind of applications can be studied, depend on the additional model characteristics. In general, investigations based on a two-wheel (or a simplified four-wheel) vehicle model are as follows:

1. Steady-state cornering, steering behavior, and characterization by standardized quantities (e.g., understeer gradient)
2. Frequency response
3. Stability analysis

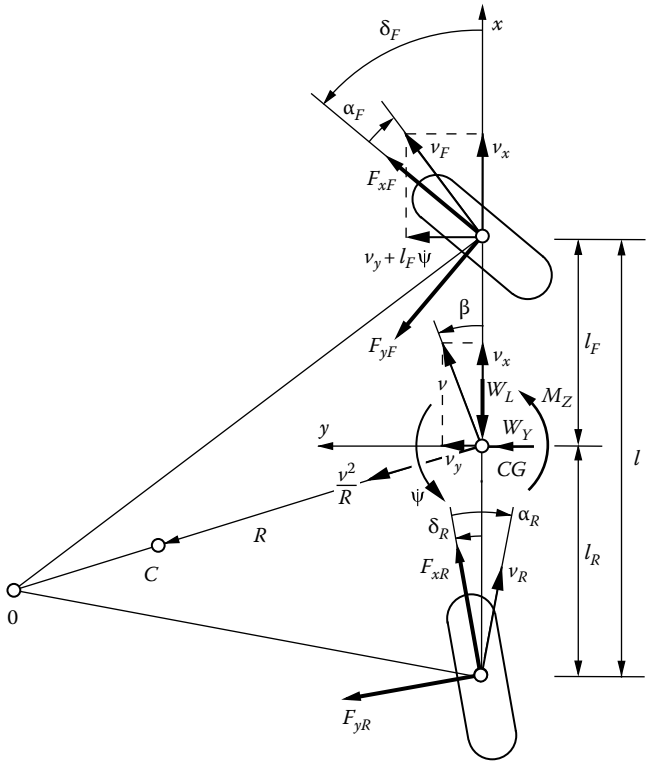

FIGURE 27.18 Two-wheel vehicle model (with possible rear-wheel steering).

4. Open-loop simulations with given steering angle and velocity (profile), closed-loop simulations, for example, driving along a given trajectory
5. Control model for design of driver-assistance systems or driver models
6. Basic influences of vehicle and suspension design
7. Identification of essential vehicle parameters based on measurements

Typically, for applications 1–5, the vehicle moves on a horizontal flat surface. Further, the velocity v_x is often assumed constant and the front-wheel steering angle δ_F (with rear-wheel steering $\delta_R = 0$ or $\delta_R = \delta_R(\delta_F, v_x, \ldots)$) is considered an input variable.

For applications 6 and 7, the model is extended by including the vehicle body motion, especially the roll motion based on the assumption of a fixed roll axis, and/or sometimes nonlinear tire characteristics as well.

27.3.2 Linear Two-Wheel Vehicle Model

In English literature, the two-wheel vehicle model often referred to as "bicycle model" or "single track model," but both terms can be misunderstood in the narrow sense of the word. In the following, a basic understanding and analysis of the (in most cases) linear two-wheel vehicle model is presented.

27.3.2.1 Equations of Motion

To explain the principal lateral behavior of a two-axle vehicle, the two-wheel vehicle model is used in any basic lectures of vehicle dynamics. It is based on the model shown in Figure 27.18, linearized with respect to an undisturbed straight ahead driving with constant longitudinal velocity v_x.

Thus, angles δ_F, δ_R, α_F, α_R, and β are assumed to be small. Then, the linearized equations of motion are

$$ma_x = (F_{xF} - F_{yF}\delta_F) + (F_{xR} - F_{yF}\delta_R) - W_L \tag{27.60}$$

$$ma_y = (F_{xF}\delta_F + F_{yF}) + (F_{xR}\delta_R + F_{yR}) + W_Y \tag{27.61}$$

$$I_Z\ddot{\psi} = (F_{xF}\delta_F + F_{yF})l_F - (F_{xR}\delta_R + F_{yR})l_R + M_Z \tag{27.62}$$

with the total vehicle mass m and moments of inertia I_Z with respect to the z-axis at the center of gravity CG. The yaw rate $r = \dot{\psi} = \dot{\psi}(t)$ describes the rotational motion of the vehicle (fixed frame x–y–z) with respect to the inertial frame. Note that the instantaneous center 0 of rotation/zero velocity of the vehicle and the center C of curvature ($1/R$) of the trajectory of CG do not coincide in the general case, but for steady-state cornering! Presuming that the longitudinal tire forces remain small, the terms $F_{xi}\delta_i$ ($i = F, R$) in (27.61) and (27.62) can also be neglected and (27.60) is no longer relevant for the lateral vehicle motion, reducing the equations of motion for neglected aerodynamics, $M_Z = 0$, $W_L = 0$, $W_Y = 0$, to

$$ma_y = F_{yF} + F_{yR} \tag{27.63}$$

$$I_z\ddot{\psi} = F_{yF}l_F - F_{yR}l_R \tag{27.64}$$

For a given velocity, the longitudinal tire forces F_{xi} are constraint forces. They can be obtained from (27.60), with a_x, for example, from (27.67), considering front-, rear-, or all-wheel drive, respective, and the rolling resistance. The lateral tire force F_{yi} of a substitutive tire in (27.63) and (27.64) is described by a linear approach using the side slip angle α_i of the respective axle and the effective cornering stiffness C_i:

$$F_{yi} = C_i\alpha_i, \quad i = R, F \tag{27.65}$$

Looking at the kinematics of the vehicle and considering the yaw angular velocity $\dot{\psi}$ of the body fixed frame x–y–z to the inertial system, yields for the accelerations

$$a_y = \dot{v}_y + \dot{\psi}v_x \tag{27.66}$$

$$a_x = -\dot{\psi}v_y \tag{27.67}$$

and for the linearized side slip angles

$$\alpha_F = \delta_F - \frac{v_y + l_F\dot{\psi}}{v_x}, \quad \alpha_R = \delta_R - \frac{v_y - l_R\dot{\psi}}{v_x} \tag{27.68}$$

Alternatively to the 2 degrees of freedom (DOFs) v_y and $\dot{\psi}$, the lateral velocity v_y of the vehicle can be replaced by the side slip angle β of the vehicle,

$$\beta = \frac{v_y}{v_x}, \quad \dot{\beta} = \frac{\dot{v}_y}{v_x} \tag{27.69}$$

leading to

$$a_y = v_x(\dot{\beta} + \dot{\psi}) \tag{27.70}$$

$$\alpha_F = \delta_F - \beta - \frac{l_F\dot{\psi}}{v_x}, \quad \alpha_R = \delta_R - \beta + \frac{l_R\dot{\psi}}{v_x} \tag{27.71}$$

After incorporating the kinematic relations (27.66) and (27.68) and the lateral tire force description (27.65) in the equations of motion (27.63) and (27.64), the set of linear differential equations read in state-space notation

$$\dot{\underline{x}} = \mathbf{F}\underline{x} + \mathbf{G}\underline{\delta} \tag{27.72}$$

with the state vector $\underline{x} = [v_y,\ \dot{\psi}]^T = [v_y,\ r]^T$, the input vector $\underline{\delta} = [\delta_F,\ \delta_R]^T$, the system matrix

$$\mathbf{F} = \begin{bmatrix} -\dfrac{C_F + C_R}{mv_x} & -\dfrac{(l_F C_F - l_R C_R)}{mv_x} - v_x \\ -\dfrac{\left(l_F C_F - l_R C_R\right)}{I_Z v_x} & -\dfrac{l_F^2 C_F + l_R^2 C_R}{I_Z v_x} \end{bmatrix} \tag{27.73}$$

and the input matrix

$$\mathbf{G} = \begin{bmatrix} \dfrac{C_F}{m} & \dfrac{C_R}{m} \\ \dfrac{l_F C_F}{I_Z} & \dfrac{l_R C_R}{I_Z} \end{bmatrix} \tag{27.74}$$

The rear-wheel steering angle δ_R may be included for investigations with respect to a four-wheel steering or other steering effects due to suspension characteristics.

Equation in (27.72), with $\delta_R = 0$, can also be written as two linear second-order differential equations for the yaw rate r and side slip angle β of the vehicle by applying (27.69) and a separation of variables [21],

$$\ddot{\beta} + 2K_1\dot{\beta} + K_2\beta = \frac{C_F}{mv_x}\dot{\delta}_F - \frac{C_F\left(l_F m v_x^2 - C_R l_R l\right)}{I_Z m v_x^2}\delta_F \tag{27.75}$$

$$\ddot{r} + 2K_1\dot{r} + K_2 r = \frac{l_F C_F}{I_Z}\dot{\delta}_F + \frac{C_F C_R l}{I_Z m v_x}\delta_F \tag{27.76}$$

with

$$K_1 = \frac{I_Z(C_F + C_R) + m\left(C_F l_F^2 + C_R l_R^2\right)}{2I_Z m v_x} \tag{27.77}$$

$$K_2 = \frac{l^2 C_F C_R + (C_R l_R - C_F l_F) m v_x^2}{I_Z m v_x^2} \tag{27.78}$$

This form may then be used to easily derive transfer functions to switch from time to frequency domain or, for instance, for the analysis of vehicle stability with respect to parameter influences.

27.3.2.2 Steady-State Cornering

For comparability reasons with the standard definitions and interpretations, [6,17], a front-steered vehicle is considered further on only ($\delta_R = 0$).

At steady-state cornering with radius R and trim conditions,

$$\beta_{st} = \text{constant}, \quad r_{st} = \text{constant}, \quad a_{y,st} = \frac{v_x^2}{R} \tag{27.79}$$

the equations of motion (27.75) through (27.78) result in

$$\delta_{F,st} = \delta_{F0} + \frac{C_R l_R - C_F l_F}{C_R C_F l} m a_{y,st} \tag{27.80}$$

$$\beta_{st} = \beta_0 - \frac{l_F}{C_R l} m a_{y,st} \tag{27.81}$$

with the front-wheel steering angle δ_{Fo} (Ackermann steering angle δ_a) and side slip angle β_0 of the vehicle for trim $v_x \approx v \to 0$, according to Figure 27.19. Since ideally in this case no lateral tire forces are acting at the substitutive tires and therefore also no tire side slip angles, the angles β_0 and $\delta_{F0} = \delta_a$ may be calculated directly from the geometric situation of the vehicle. For small angles, one yields

$$\beta_0 = \frac{l_R}{R} \tag{27.82}$$

$$\delta_a = \delta_{F0} = \frac{l}{R} \tag{27.83}$$

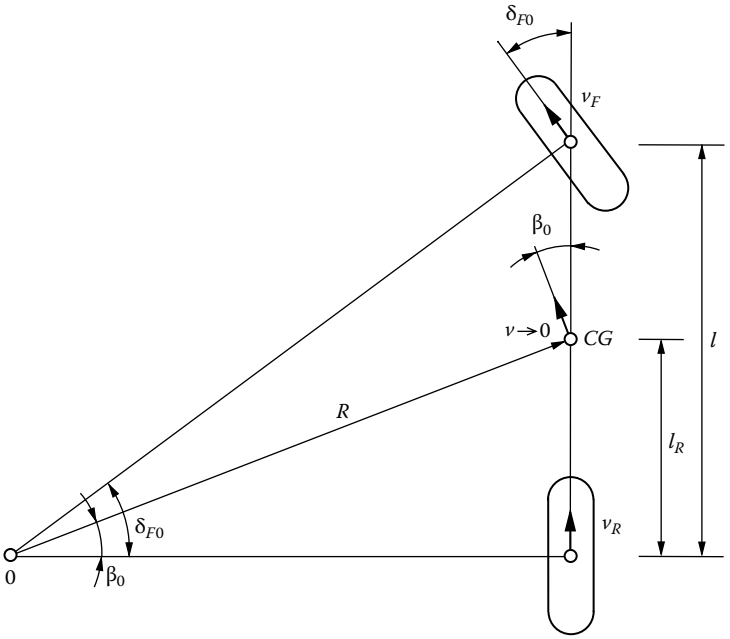

FIGURE 27.19 Steady-state cornering for $v \to 0$.

or after eliminating R

$$\delta_a = \frac{l}{v_x^2} a_{y,st} \tag{27.84}$$

In some standard definitions, the steering angle of the hand wheel δ_H appears as well and follows from the overall steering ratio i_s

$$\delta_H = i_s \delta_F \tag{27.85}$$

A very useful quantity to describe handling and steering behavior is the understeer/oversteer gradient K_{US} (see also SAE J670e, [6,17], or DIN 70 000 for "Eigenlenkgradient" $EG = K_{US}/l$), which is to be obtained by subtracting the Ackermann steering angle gradient from the ratio of the steering wheel angle gradient to the overall steering ratio, that is,

$$K_{US} = \frac{1}{i_s} \frac{\mathrm{d}\delta_{H,st}}{\mathrm{d}a_{y,st}} - \frac{\mathrm{d}\delta_a}{\mathrm{d}a_{y,st}} \tag{27.86}$$

Combining (27.86) and (27.80) gives the steering angle for the linear system

$$\frac{\delta_{H,st}}{i_s} = \delta_{F,st} = \delta_a + K_{US} a_{y,st} \tag{27.87}$$

with the understeering gradient

$$K_{US} = \frac{m(C_R l_R - C_F l_F)}{l C_R C_F} \tag{27.88}$$

The steering/handling properties are then characterized by the value of K_{US}:

$$\begin{aligned} K_{US} &> 0 \quad \text{understeer} \\ K_{US} &= 0 \quad \text{neutral steer} \\ K_{US} &< 0 \quad \text{oversteer} \end{aligned} \tag{27.89}$$

Another way to interpret the steering behavior makes use of the difference of the side slip angles of the respective substitutive wheels. According to Figure 27.20, there follows for small angles

$$\delta_{F,st} = \frac{l}{R} + (\alpha_F - \alpha_R) = \delta_a + (\alpha_F - \alpha_R) \tag{27.90}$$

$$\beta_{st} = \frac{l_R}{R} - \alpha_R = \beta_0 - \alpha_R \tag{27.91}$$

From (27.90), it can be seen that the radius R of the turn depends on $(\alpha_F - \alpha_R)$ for a given steering angle and the wheel base l.

For steady-state cornering, α_F, α_R can directly be derived from the (27.63) through (27.65), with $\ddot{\psi} = 0$:

$$\alpha_F = \frac{l_R}{l C_F} m a_y, \quad \alpha_R = \frac{l_F}{l C_R} m a_y \tag{27.92}$$

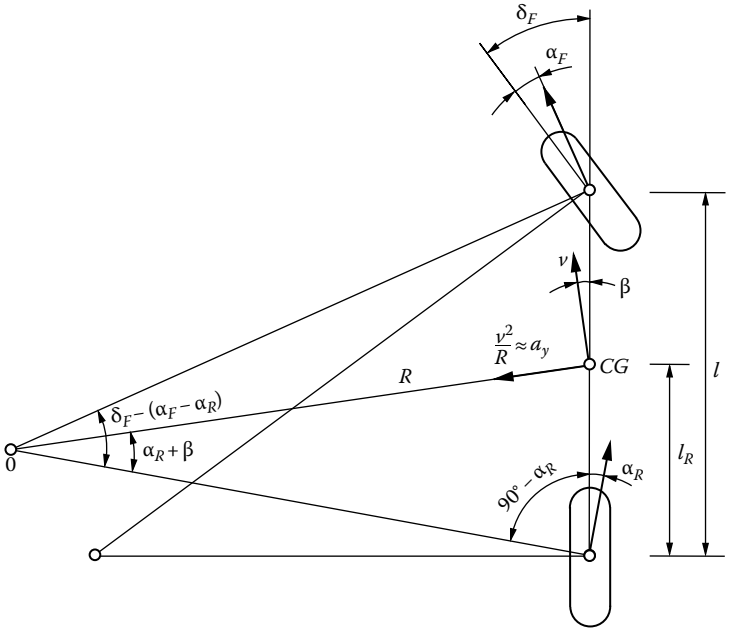

FIGURE 27.20 General steady-state cornering situation with center of rotation 0.

Comparing (27.90) with (27.87) results in

$$(\alpha_F - \alpha_R) = K_{US} a_{y,st} \tag{27.93}$$

and for $a_{y,st} > 0$, the relations and definitions for over/under/neutral steer in (27.89) are equally valid for $(\alpha_F - \alpha_R)$ instead of K_{US}.

The characterization of the steady-state behavior of a vehicle can now be seen in the plots of Figure 27.21. In Figure 27.21a, the driving velocity is kept constant and the increase in lateral acceleration is achieved by a change in the steering angle, while in Figure 27.21b the velocity is increased at constant radius R. For vehicle B with understeer characteristics, the steering angle has to be increased to keep radius R = constant with increasing velocity and has to be reduced for vehicle A with oversteer characteristics. In the latter case, the steering angle may even change sign at v_{crit}, (27.96), and countersteering will be necessary, if the velocity can further be increased. The required parameters for the two-wheel vehicle model of two different vehicles A and B are listed in Table 27.1.

In Figure 27.21c also, the side slip angles of the vehicles corresponding to Figure 27.21b are shown. Starting at $\beta = \beta_0$, (27.81) and (27.82), both curves $\beta = \beta\,(a_{y,st})$ change sign, and despite the different steering characteristics, the characteristics are in principal similar. Usually, the vehicle with oversteer characteristics shows larger absolute values of β with increasing $a_{y,st}$. Obviously, the side slip angle of the vehicle cannot be used for the characterization of the steering properties only.

With respect to a nonlinear system behavior, Figure 27.22 shows the steering characteristics and its common interpretation, for example, [6,7,17], for different types of vehicles, analogously to Figure 27.21a, for fixed velocity v_x. Gradient $d\delta_a/da_y = l/v_x^2$ decides between over- and understeer (see (27.86) and (27.89)). The condition for stability at fixed velocity v_x is $\partial\delta_F/\partial(l/R) > 0$ (see Section 27.3.3 for more details). Again, an unstable driving behavior may only occur for a vehicle with oversteer characteristics (see also Section 27.3.2.3).

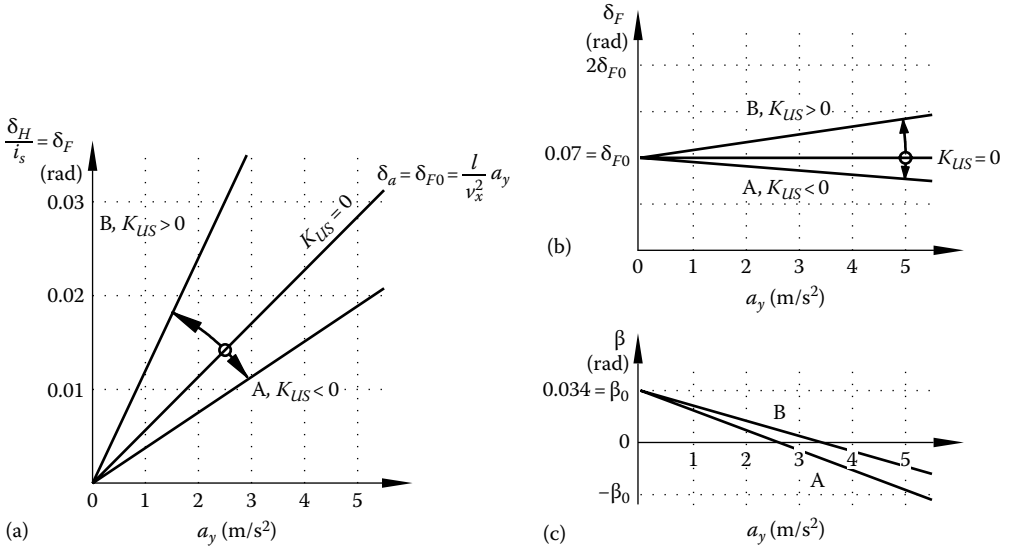

FIGURE 27.21 Steady-state steering characteristics, linear-handling diagram, vehicle parameters corresponding to Table 27.1: (a) for v = constant = 80 km/h; (b) for R = constant = 40 m; (c) side slip angles of the vehicle corresponding to (b).

TABLE 27.1
Vehicle Data for the Linear Two-Wheel Vehicle Model

Vehicle	A	B
m	1,900 kg	1,900 kg
I_Z	2,900 kg m²	2,900 kg m²
l_F	1.44 m	1.44 m
l_R	1.36 m	1.36 m
C_F	90,000 N/rad	60,000 N/rad
C_R	80,000 N/rad	110,000 N/rad
K_{US}	-1.96×10^{-3} rad s²/m	$+6.50 \times 10^{-3}$ rad s²/m
Steering characteristics	Oversteer	Understeer

Other characteristic quantities for steady-state cornering can be derived from transfer functions, like $G_r(s) = r(s)/\delta_F(s)$, $G_\beta(s) = \beta(s)/\delta_F(s)$, derived from Laplace transformation of (27.75) and (27.76). There results the steady-state (static) yaw velocity gain with respect to the input from steering hand wheel:

$$G_{r,st} = \left.\frac{r}{\delta_H / i_s}\right|_{st} = \frac{v_x}{l + K_{US} \cdot v_x^2} \tag{27.94}$$

The principally different behavior of vehicles with over- and understeer characteristics becomes apparent in Figure 27.23, where areas of stable or unstable system behavior are indicated as well (more details are provided later in this section).

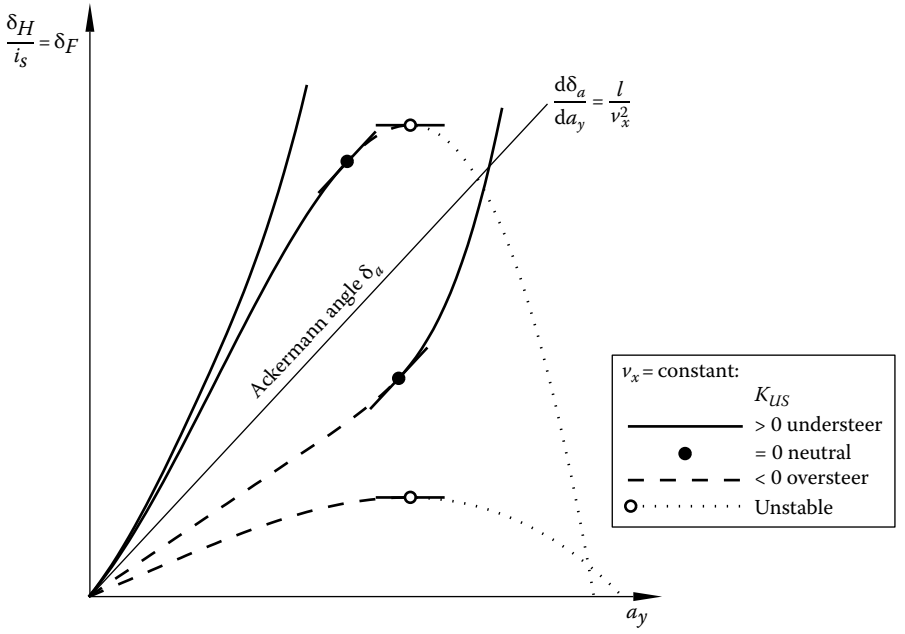

FIGURE 27.22 Principal nonlinear handling diagram, for v_x = constant, i_s = constant.

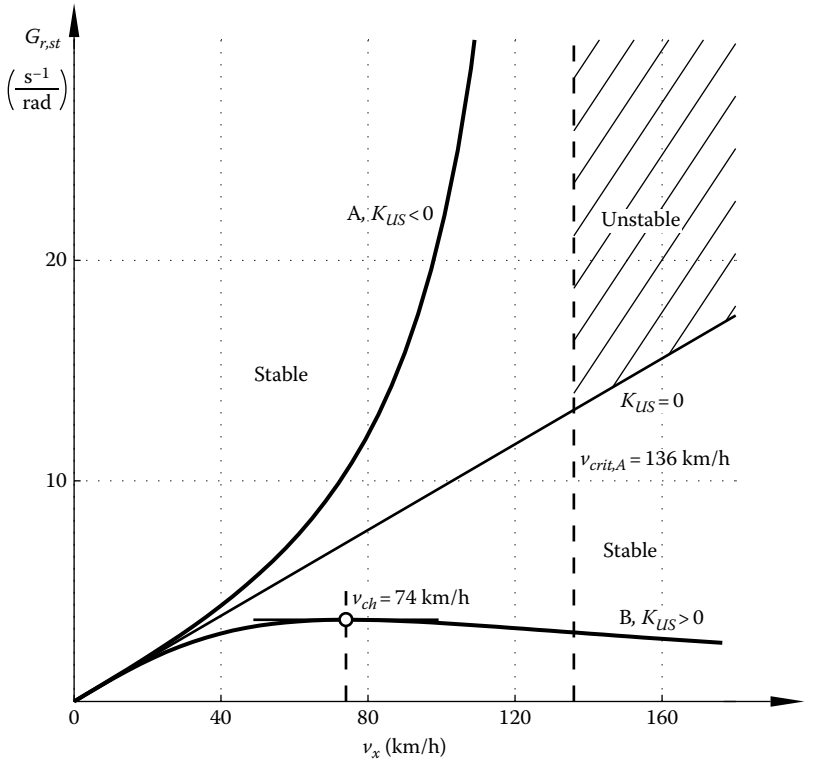

FIGURE 27.23 Behavior of vehicles with over-, neutral, and understeer characteristics with respect to the static yaw velocity gain; data for vehicles A and B according to Table 27.1.

For $K_{US} > 0$, vehicle B with understeer characteristics, the characteristic speed v_{ch} is defined by

$$\left.\frac{\partial G_r}{\partial v_x}\right|_{v_x = v_{ch}} = \frac{l - K_{US} v_{ch}^2}{(l + K_{US} v_{ch}^2)^2} := 0$$
$$\Rightarrow v_{ch}^2 = \frac{l}{K_{US}}, \quad K_{US} > 0 \tag{27.95}$$

and $G_{r,st}|_{v_x = v_{ch}} = v_{ch}/(2l)$ is half the one of a vehicle with neutral steer at $v_x = v_{ch}$.

For vehicle B with oversteer characteristics and $K_{US} < 0$, the static yaw velocity gain in (27.94) becomes infinity at the critical speed $v_x = v_{crit}$

$$G_{r,st}\big|_{v_x = v_{crit}} \to \infty$$
$$\Rightarrow v_{crit}^2 = -\frac{l}{K_{US}}, \quad K_{US} < 0 \tag{27.96}$$

The vehicle with neutral steer, $K_{US} = 0$, shows a steady increase in $G_{r,st}$ with velocity.

Consequently, one can find for the vehicles listed in Table 27.1:

$$v_{crit,A} = 37 \text{ m/s } (136 \text{ km/h}) \tag{27.97}$$

$$v_{ch,B} = 21 \text{ m/s } (74 \text{ km/h}) \tag{27.98}$$

In general, modern vehicles do not show oversteer characteristics for a wide range of conditions (and understeer behavior for at least the linear region of steering characteristics); thus, it is essential to choose a proper characteristic velocity v_{ch}. At this speed, the vehicle is most sensitive to steering inputs w.r.t. yaw motion. In [22], a range between 65 and 100 km/h is therefore recommended.

As a matter of fact, even with this kind of simple vehicle model, first conclusions can be drawn of how to increase or improve understeer characteristics of a car from a practical point of view. A quick look at the definition of the understeer gradient K_{US} in (27.88) reveals the constitutive term $(C_R l_R - C_F l_F)$ thereof, and consequently, $C_R l_R$ has to be increased and/or $C_F l_F$ decreased. Keeping in mind that the effective cornering stiffness comprises both tire and suspension behavior, the (elasto) kinematic design of the front and rear suspension and different tire characteristics (dimension, inflation pressure, etc.) are effective ways to influence the steering and handling characteristics by C_F,C_R. The application of traction forces will reduce the cornering stiffness; thus, for example, a trend toward understeer can be attained for a vehicle with front-wheel drive. Putting more load on the rear wheel(s) will decrease l_R and increase C_R considering nonlinear tire characteristics for this purpose. Due to the nonlinear relation between C_i $(i = F, R)$ and the tire load, the increase of C_R is less than the decrease of C_F and K_{US} will be reduced toward more oversteer. A similar explanation holds for a change in the tire load distribution at one axle. The force distribution at the front axle can be increased by applying stiffer spring characteristics of the suspension and/or a torsion bar and thus C_F of the substitutive front wheel can be reduced. Although the understeer gradient is raised in this way, the stiffer suspension may influence ride comfort adversely. For details on the effects of suspension design, see Chapter 21.

The steady-state (static) lateral acceleration gain $G_{ay,st}$ directly follows from (27.94)

$$a_{y,st} = r_{st} \cdot v_x$$
$$G_{ay,st} = \left.\frac{a_y}{\delta_H / i_s}\right|_{st} = G_{r,st} \cdot v_x = \frac{v_x^2}{l + K_{US} \cdot v_x^2} \tag{27.99}$$

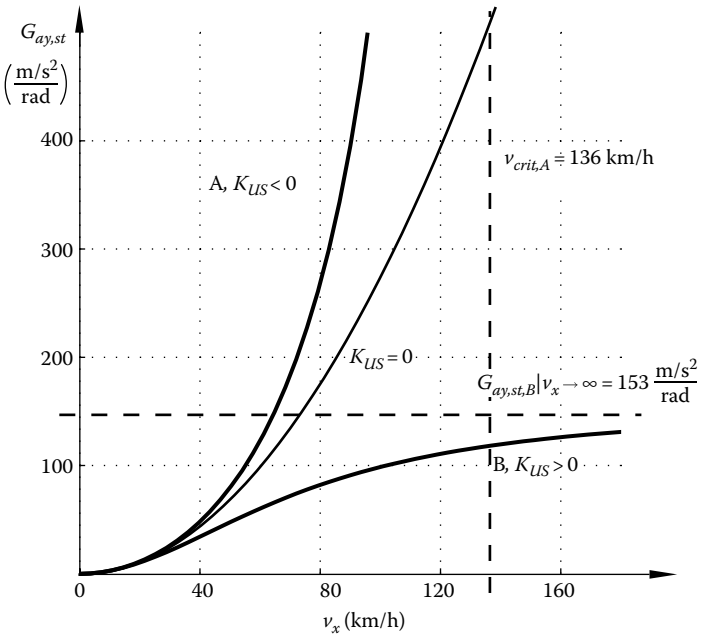

FIGURE 27.24 Behavior of vehicles with over-, neutral, and understeer characteristics with respect to the static lateral acceleration gain; data for vehicles A and B according to Table 27.1.

and consequently $G_{ay,st} \to \infty$ at the same velocity v_{crit} for $K_{US} < 0$, vehicle A in Figure 27.24. For vehicle B with understeer characteristics, $K_{US} > 0$, no equivalent of v_{ch} can be found; here, the gain $G_{ay,st}$ converges to a finite value for large velocities. For neutral steer, $K_{US} = 0$, the gain increases to ∞ with $v_x \to \infty$.

Considering the steady-state gains $G_{r,st}$ and $G_{ay,st}$, Figures 27.23 and 27.24, it becomes obvious that a vehicle with understeer characteristics has a more moderate response compared to the vehicle with oversteer. The steady-state (static) side slip gain $G_{\beta,st}$ of the vehicle may easily be taken from (27.75).

27.3.2.3 Stability and Nonsteady-State Vehicle Behavior

Based on (27.72) through (27.74) or (27.75) through (27.78), the stability behavior of the vehicle, the vehicle response to harmonic steering input (Bode diagrams), and a steering step input will be discussed. The yaw velocity transfer function to steering input $G_r(s)$ is a common way to characterize nonsteady-state vehicle behavior [7,22]. Considering (27.76) and taking into account (27.94) yields

$$\begin{aligned} G_r(s) = \frac{r(s)}{\delta_F(s)} &= G_{r,st} \frac{1 + T_Z s}{\omega_0^2 + 2D\omega_0 s + s^2} \cdot \omega_0^2 \\ &= G_{r,st} \frac{1 + T_Z s}{1 + (2D/\omega_0)s + \left(s^2/\omega_0^2\right)} \end{aligned} \tag{27.100}$$

with

$$\begin{aligned} T_Z &= \frac{m v_x l_F}{C_R l} \\ \omega_0^2 = K_2 &= \frac{C_F C_R l^2}{I_Z m v_x^2} \left(1 + \frac{K_{US} v_x^2}{l}\right) \\ D\omega_0 &= K_1 \end{aligned} \tag{27.101}$$

K_1, K_2 from (27.77), (27.78). The eigenfrequency ω of the damped system is

$$\omega^2 = \omega_0^2(1-D^2) \tag{27.102}$$

By applying (27.84) and (27.87) in (27.101), it can be concluded directly from steady-state steering properties to the eigenfrequency ω_0 of the undamped system:

$$\omega_0^2 = \frac{C_F C_R l^2}{I_Z m v_x^2}\left(\frac{\delta_{F,st}}{\delta_a}\right) = K_2 \tag{27.103}$$

Stability of the vehicle behavior is determined by the equal homogeneous parts of the differential equations (27.75) and (27.76) or by the system matrix $\mathbf{F}$ in (27.73) from (27.72); the eigenvalues $\lambda_{1,2}$

$$\lambda_{1,2} = -K_1 \pm \sqrt{K_1^2 - K_2} \tag{27.104}$$

can for instance easily be derived from setting the denominator in (27.100) to zero or from $|\mathbf{F}-\lambda\mathbf{I}|=0$, that is the characteristic equation. Since always $K_1 > 0$, according to (27.77), the sign of $K_2 = \omega_0^2 = K_2\left(v_x^2\right)$ determines the stability of the motion of the system with respect to small disturbances in the initial conditions. This directly follows from the Hurwitz stability criterion for a second-order differential equation, $K_1 > 0$, $K_2 > 0$. Essentially, stability means that the system trajectory can be kept arbitrarily close to the equilibrium state by starting sufficiently close to it ("Lyapunov stability").

The eigenfrequency $\omega_{0|u}$ of the undamped system for a vehicle with understeer characteristics, with $K_{US} > 0$ and $v_{ch}^2 = l/K_{US} > 0$, (27.95), is

$$\omega_{0|u}^2 = K_2 = \frac{C_F C_R l^2}{I_Z m v_x^2}\left(1 + \frac{v_x^2}{v_{ch}^2}\right) > 0 \tag{27.105}$$

and the steady-state motion of the vehicle is stable for all driving velocities ($K_2 > K_1^2$ resulting in a negative complex pair of eigenvalues, $K_2 < K_1^2$ in two negative real eigenvalues).

For a vehicle with oversteer characteristics, $K_{US} < 0$, and

$$\begin{aligned} v_{crit}^2 &= -\frac{l}{K_{US}} \\ \omega_{0|0}^2 = K_2 &= \frac{C_F C_R l^2}{I_Z m v_x^2}\left(1 - \frac{v_x^2}{v_{crit}^2}\right) \begin{matrix} \leq \\ \geq \end{matrix} 0 \end{aligned} \tag{27.106}$$

it becomes obvious that $\omega_{0|0}^2 < 0$, for velocities $v_x > v_{crit}$, and the steady-state motion of the vehicle will then become unstable with one positive and one negative real eigenvalue. Please notice that the steady-state motion of a vehicle with oversteer characteristics is not unstable a priori, but there is a stability margin at a certain speed v_{crit}!

In Figure 27.25, natural damping factor D and eigenfrequencies ω_0, ω are plotted for the two vehicles A and B, Table 27.1, as a function of the driving velocity v_x. Due to $D > 1$ for vehicle A with oversteer characteristics, there does not exist an eigenfrequency of the damped system—the system has aperiodic solutions. For a typical vehicle with understeer characteristics, vehicle B, the eigenfrequency of the damped system starts from infinity to a finite value for $v_x \to \infty$; the natural damping factor $D < 1$ decreases with increasing velocity. Therefore, a driver may handle oscillations of the yaw rate, induced, for example, by an evasive maneuver on a highway, with difficulties, as the vehicle motion is less damped at high speed, as might be expected by the driver; also, eigenfrequencies vary with speed.

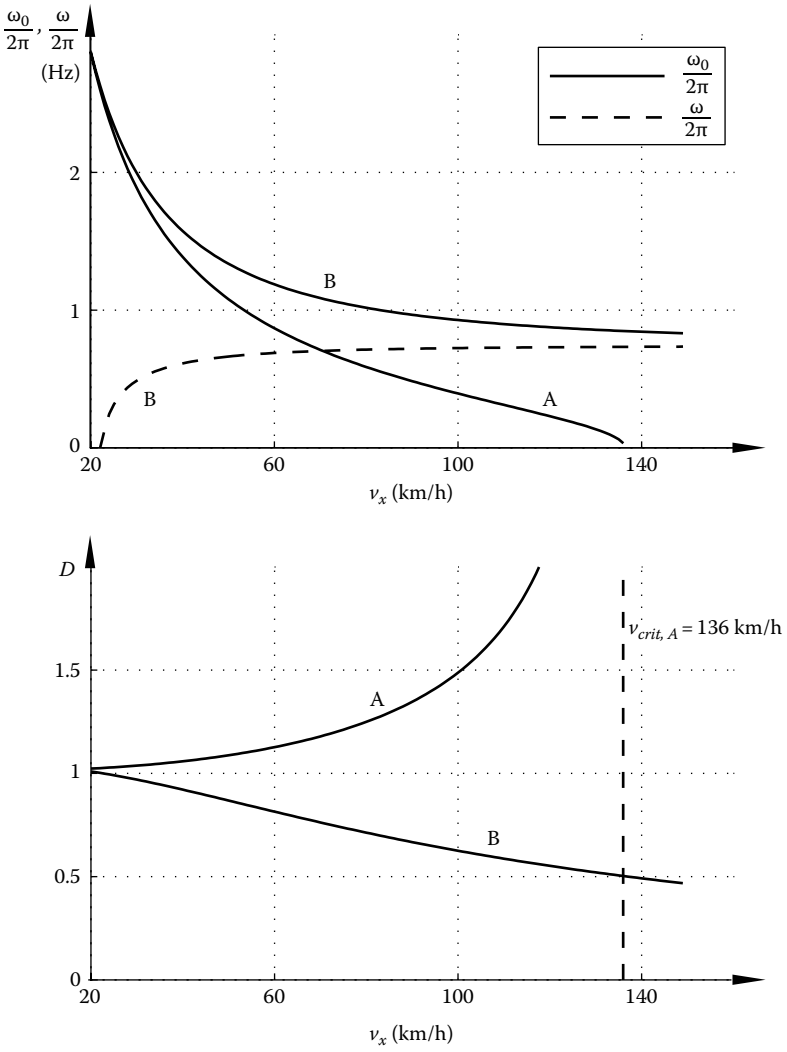

FIGURE 27.25 Eigenfrequency $f_0 = \omega_0/2\pi$, eigenfrequency $f = \omega/2\pi$ of the damped system, and damping factor D as a function of velocity v_x for vehicles A and B (data according to Table 27.1).

The response of the vehicle to a *steering step input*, respectively a very quick application of a specific steering angle (*steering ramp*) at real test conditions, is often used to analyze its sensitivity with respect to handling maneuvers. It is characterized by parameters illustrated principally in Figure 27.26, according to test procedures of road vehicles in ISO 7401. An important quantity therein is the peak-response-time T_{rmax} (typically 200–400 ms in modern passenger cars, [22]), as it shows a good correlation to the subjective evaluation of the steering step/ramp response behavior.

The plotted time history is typical for a damped system of second order, (27.76), with a negative complex pair of eigenvalues, $K_2 > K_1^2$ in (27.104), and corresponds therefore to a vehicle with understeer characteristics. The transient response for a steering step input, for example, [7,22], with D, ω, ω_0, T_Z from (27.101), is then

$$\frac{r(t)}{\delta_{H,st}/i_s} = G_{r,st}\left[1 - \mathrm{e}^{-D\omega_0 t}\left(\cos\omega t + \frac{D - T_Z\omega_0}{\sqrt{1-D^2}}\sin\omega t\right)\right] \tag{27.107}$$

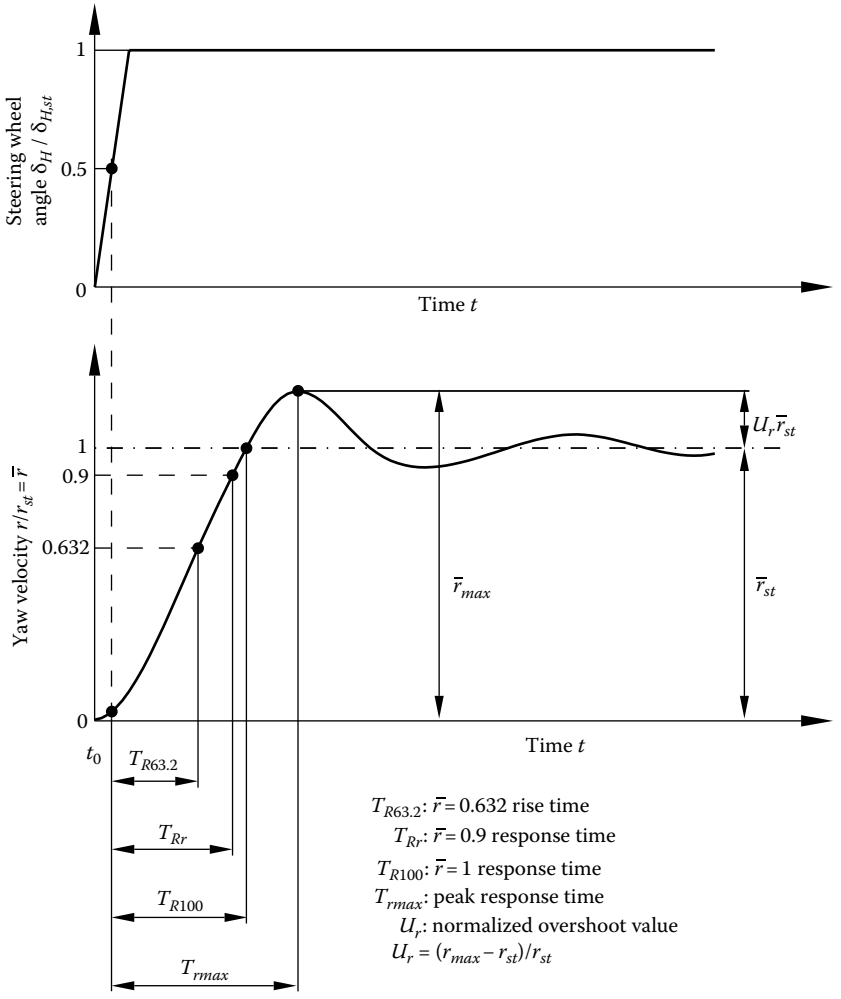

FIGURE 27.26 Transient yaw motion characteristics after steering ramp.

The initial gradient is determined by $\dot{r}(0)/(\delta_{H,st}/i_s) = (C_F l_F)/I_Z$, directly from (27.74) in (27.72) with $v_y(0) = r(0) = \delta_R = 0$, for vehicles with understeer or oversteer characteristics. For both characteristics and $0 < K_2 > K_1^2$ in (27.104), the two negative real eigenvalues result in an aperiodic yaw motion to $G_{r,st}$ for $t \to \infty$. According to Figure 27.23, $G_{r,st}$ is substantially larger and therefore the radius of the finally resulting steady-state cornering is smaller for a vehicle with oversteer than with understeer characteristics for the same steering input at the same speed. If the speed of the vehicle with oversteer is beyond v_{crit} and a steering step/ramp is applied, the vehicle will turn-in with exponentially increasing yaw rate, and the driver has to interact appropriately.

For the yaw rate response, a limited area was proposed by Experimental Safety Vehicle (ESV) (see [12] and Figure 27.27 for a van). The two plotted curves of experimental tests indicate where critical points in the area may occur. The origin at $t = 0$ should coincide with t_0 of Figure 27.26.

Active body control, additional rear wheel steering, and other active control systems can be designed to improve the handling and stability behavior and may enhance the response of the

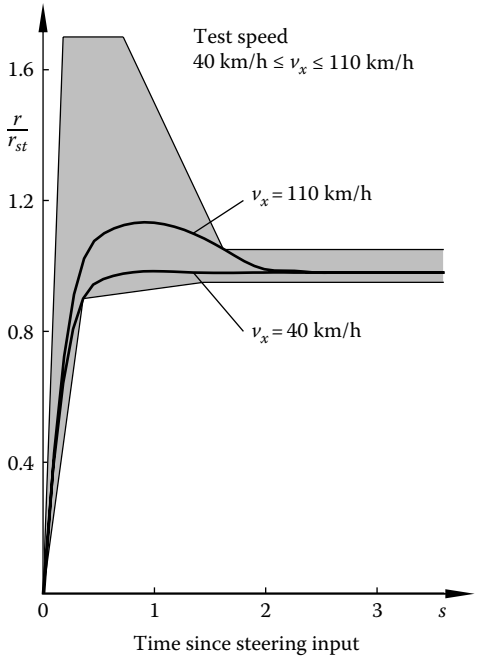

FIGURE 27.27 ESV limits for a steering step/ramp input ($\dot{\delta}_H \approx 500°/s$) with final steady-state lateral acceleration ($a_{y,st} \approx 0.4\ g$).

vehicle with respect to the input of the driver [23]. Then the driver may need to adapt himself to the changed steering behavior as well (Figure 27.27).

The dynamic behavior can also be analyzed with *frequency responses* (*Bode diagrams*). It is an alternative, if at very high speeds, steering step inputs cannot be performed. The Bode diagram of the yaw velocity with respect to harmonic steering input can be derived directly from the transfer function (27.100) and by replacing s with $i\nu$ (ν is excitation frequency, $i^2 = -1$),

$$\left.\frac{r(s)}{\delta_F(s)}\right|_{s=i\nu} = G_r(i\nu) = G_{r,st}\,\frac{1+T_Z(i\nu)}{1+\left(2D/\omega_0\right)(i\nu)+(i\nu)^2/\omega_0^2} \tag{27.108}$$

Therefrom, the magnitude $A(\nu) = |G_r(i\nu)|$ or $A(\nu) = 20\ \log\ |G_r(i\nu)|$ in dB and phase diagram $\phi(\nu) = \arctan[\Re(G_r(i\nu))/\Im(G_r(i\nu))]$ can be plotted.

Measured frequency responses of a vehicle with understeer and K_{US} very close to vehicle B are shown in Figure 27.28 [22]. The frequencies start from 0.2 to about 3 Hz, the feasible range for a human driver.

On the left side of Figure 27.28, the Bode diagram of the yaw rate is shown. At $\nu = 0$, the magnitude is, in theory, equal to $G_{r,st} = G_{r,st}(v_x)$; its increase at moderate speeds, here from $v_x = 60$–80 km/h, becomes obvious, and for higher speeds above the characteristic velocity at $v_{ch} = 76$ km/h, not much influence on the velocity can be noticed (compare with Figure 27.23). The theoretically horizontal tangent to $A(\nu)$ at $\nu = 0$ is indicated by a small increase in magnitude for $\nu \to 0$ in the measured plot. The behavior of magnitude and amplification of resonance around the eigenfrequency depend notably on the natural damping factor D, which are both functions of v_x, compare with Figure 27.25, and what is clearly reflected in the figure. The phase angle and the considerable delay of the yaw rate with respect to the steering angle input for higher frequencies is illustrated in the bottom left plot.

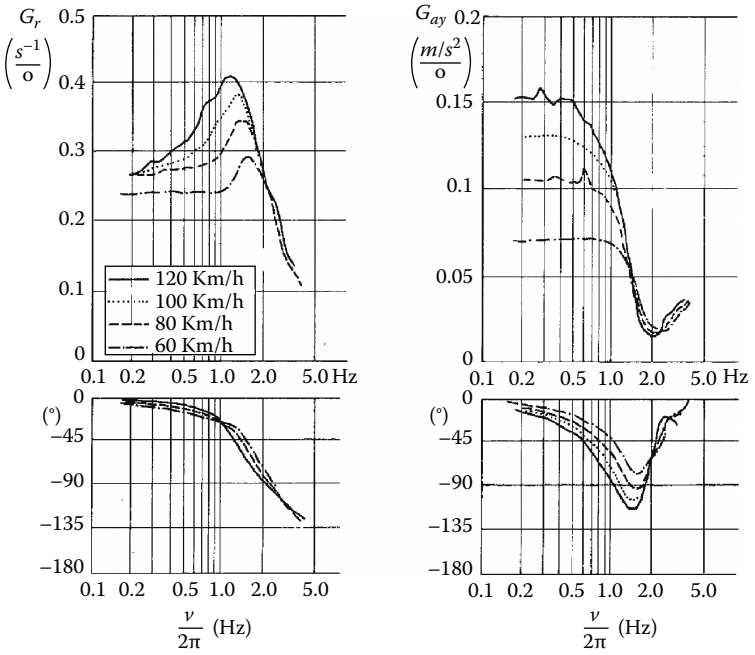

FIGURE 27.28 Measured yaw velocity and lateral acceleration frequency responses of a vehicle with understeer characteristics ($K_{US} = 0.00620$ rad s^2/m, $v_{ch} = 76$ km/h) for different driving velocities v_x. (From Zomotor, A., *Fahrwerktechnik: Fahrverhalten*, Reimpell, J. (ed.), Vogel Buchverlag, Würzburg, Germany, 1987.)

The frequency response of the side slip angle of the vehicle may be derived from (27.75) without much effort, but in general the frequency response of the lateral acceleration is of more interest. The three frequency responses are related to each other by their transfer functions (see (27.70)),

$$\frac{a_y(s)}{\delta_F(s)} = v_x\left[\frac{r(s)}{\delta_F(s)} + \frac{s\beta(s)}{\delta_F(s)}\right]$$

There follows the frequency response of the lateral acceleration

$$\left.\frac{a_y(s)}{\delta_F(s)}\right|_{s=i\nu} = G_{ay}(i\nu) = G_{ay,st}\,\frac{1+T_1(i\nu)+T_2(i\nu)^2}{1+(2D/\omega_0)(i\nu)+(i\nu)^2/\omega_0^2} \tag{27.109}$$

with

$$T_1 = \frac{l_R}{v_x}, \quad T_2 = \frac{I_Z}{C_R l}$$

The measured Bode diagram of the lateral acceleration is presented on the right side of Figure 27.28. The magnitudes start at $\nu \to 0$ at very different levels of $G_{ay,st} = G_{ay,st}(v_x)$, see also Figure 27.24, keep more or less constant, before a very strong decline can be observed, without pronouncing eigenfrequencies. On the one hand, the drop in the magnitude may not be at too low frequencies to keep the vehicle sensitive for the driver's steering input; on the other hand, the constant magnitude in the range of moderate steering frequencies at moderate velocities accounts for an easier controllability. The influence of velocity on the phase delay of the lateral acceleration is more distinct than that of the yaw rate.

Finally, the Bode diagram of the $G_{ay,st}$-normalized lateral acceleration for vehicle A and B is shown in Figure 27.29. The characteristics of vehicle B with understeer are very similar to the

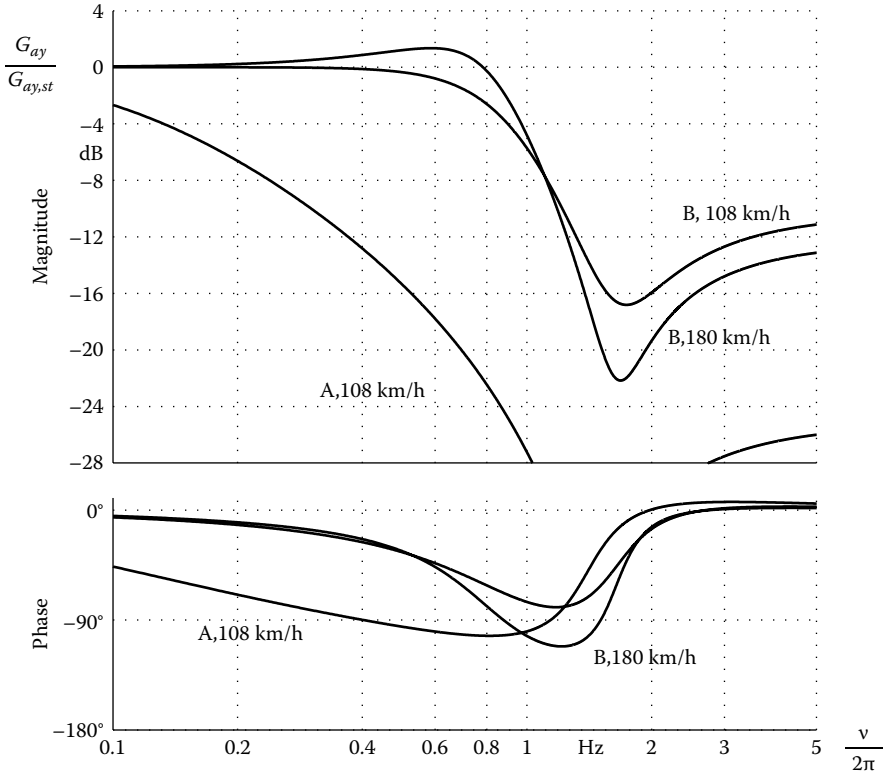

FIGURE 27.29 Normalized lateral acceleration frequency response of vehicle A with oversteer and vehicle B with understeer characteristics (see Table 27.1).

previous one discussed in Figure 27.28. Only for very high speeds, 180 km/h, when the damping coefficient becomes small according to Figure 27.25, a resonance peak can be noticed at the magnitudes corresponding to the eigenfrequency in Figure 27.25. Since the velocity of 108 km/h is already close to the critical speed v_{crit} = 136 km/h of vehicle A with oversteer, (27.97), the response of this vehicle in the area of convenient, normal steering until about 1 Hz very much depends on the frequency (exhibited by a strong decline) and reveals an increased phase lag. Since 180 km/h is above the critical speed of vehicle A, the corresponding characteristics are omitted for this vehicle. Vehicle B with understeer characteristics provides a much more driver-friendly behavior with small changes in magnitude and smaller phase delay angles, even for a velocity of 180 km/h. For $\nu > 1$ Hz, even vehicle B with understeer characteristics displays major changes in magnitude.

27.3.3 Nonlinear Two-Wheel Vehicle Model

The assumptions for the application of a linear two-wheel vehicle model hold for moderate lateral accelerations up to about 4 m/s^2 on a high friction surface and constant velocity (or small longitudinal accelerations). Exceeding these limits calls for more complex vehicle models, in particular, a four-wheel vehicle model. Nowadays, vehicle models on the basis of multibody-system formulation and programs are often employed (see Chapter 2) rather than simplified four-wheel vehicle models with a symbolic representation of the equations of motion (e.g., [7,8]). The complex vehicle model allows for a detailed representation of all essential subsystems of the vehicle to analyze and simulate subsystem and global vehicle system dynamics efficiently; therefore, please refer to Chapter 28.

Between these ends, the nonlinear two-wheel vehicle model is an intermediate stage, providing still enough simplicity to understand basic (nonlinear) phenomena without neglecting the most crucial nonlinearities, which are—most often—nonlinear tire characteristics. Besides linearized tire

characteristics, geometrical linearization of trigonometric functions, for example, $\sin\delta \approx \delta$, $\cos\delta \approx 1$, and $\tan\delta \approx \delta$, facilitates an easier interpretation of the system equations. While the later linearization holds up to angles of about 10°–15°, the former applies for side slip angles up to about 5° only, necessitating a nonlinear tire model beyond. In the following, these two simplifications are partially or fully abandoned to derive and evaluate the *nonlinear steady-state handling diagram* still on the basis of a two-wheel vehicle model.

The nonlinear steady-state equations of the vehicle model in Figure 27.18 are ($M_z = W_Y = \delta_R = 0$, $a_x \approx 0$)

$$-m\frac{v^2}{R}\sin\beta = F_{xF}\cos\delta_F - F_{yF}\sin\delta_F + F_{xR} - W_L \tag{27.110}$$

$$m\frac{v^2}{R}\cos\beta = F_{xF}\sin\delta_F + F_{yF}\cos\delta_F + F_{yR} \tag{27.111}$$

$$I_Z\ddot{\psi} = 0 = (F_{xF}\sin\delta_F + F_{yF}\cos\delta_F)l_F - F_{yR}l_R \tag{27.112}$$

The influence of the side slip angle of the vehicle on the aerodynamic drag coefficient in W_L is usually neglected. Forces $F_{xi}(i = F, R)$ are either rolling resistance or traction force (of a front- or rear-wheel drive) for constant velocity v at steady-state cornering with constant radius R. The lateral axle forces $F_{yi}(i = F, R)$ depend on the respective side slip angles, on the vertical axle loads $F_{zi}(i = F, R)$, and on the longitudinal tire forces, but the latter are often not taken into account:

$$F_{yF} = F_{yF}(\alpha_F, F_{zF}) \tag{27.113}$$

$$F_{yR} = F_{yR}(\alpha_R, F_{zR}) \tag{27.114}$$

$$F_{zF} = mg\frac{l_R}{l}, \quad F_{zR} = mg\frac{l_F}{l} \tag{27.115}$$

These characteristics can for instance be described by the magic formula [8]

$$F_y = D\sin\{C\arctan[B\alpha - E(B\alpha - \arctan(B\alpha))]\} \tag{27.116}$$

with parameters μ, c_α, C, E, the peak lateral substitutive tire/axle force $D = \mu F_z$, and the corresponding stiffness $C_\alpha = BCD = c_\alpha F_z$; therefore, $B = c_\alpha/(C\mu)$. Other tire models are to be found in [24].

The nonlinear relations for (27.90) and (27.91) in Figure 27.20 are as follows:

$$\delta_F = \arctan\left[\frac{l_F + R\sin\beta}{R\cos\beta}\right] - \alpha_F \tag{27.117}$$

$$\beta = \arcsin\left[\frac{l_R\cos\alpha_R}{R}\right] - \alpha_R \tag{27.118}$$

For given v, the seven equations (27.110) through (27.114), (27.117), and (27.118) can now be numerically solved for the zeros: β, α_F, α_R, δ_F, or R (depending on problem), F_{yF}, F_{yR}, F_{xF}, or F_{xR} (for front- or rear-wheel drive). Alternatively, an iterative solution scheme can be applied, which is very

effective and usually converges quickly [19]. Therefore, (27.110) through (27.112) are rewritten for a vehicle with front-wheel drive

$$\begin{bmatrix} \cos\delta_F & -\sin\delta_F & 0 \\ \sin\delta_F & \cos\delta_F & 1 \\ l_F\sin\delta_F & l_F\cos\delta_F & -l_R \end{bmatrix} \begin{bmatrix} F_{xF} \\ F_{yF} \\ F_{yR} \end{bmatrix} = \begin{bmatrix} -m\dfrac{v^2}{R}\sin\beta - F_{xR} + W_L \\ m\dfrac{v^2}{R}\cos\beta \\ 0 \end{bmatrix} \tag{27.119}$$

and there follows

$$\begin{aligned} F_{xF} &= m\frac{v^2}{Rl}[l_R\sin\delta_F\cos\beta - l\cos\delta_F\sin\beta] - (F_{xR} - W_L)\cos\delta_F \\ F_{yF} &= m\frac{v^2}{Rl}[l_R\cos\delta_F\cos\beta + l\sin\delta_F\sin\beta] + (F_{xR} - W_L)\sin\delta_F \\ F_{yR} &= m\frac{v^2}{Rl}l_F\cos\beta \end{aligned} \tag{27.120}$$

Analogously for rear-wheel drive,

$$\begin{aligned} F_{xR} &= m\frac{v^2}{Rl\cos\delta_F}[l_R\sin\delta_F\cos\beta - l\cos\delta_F\sin\beta] + W_L - \frac{F_{xF}}{\cos\delta_F} \\ F_{yF} &= m\frac{v^2 l_R\cos\beta}{Rl\cos\delta_F} - F_{xF}\tan\delta_F \\ F_{yR} &= m\frac{v^2}{Rl}l_F\cos\beta \end{aligned} \tag{27.121}$$

Iteration starts by applying $\delta_{F0} = l/R$ and $\beta_0 = l_R/R$ for low-speed steering in (27.120) or (27.121) to derive the forces. The side slip angles α_F, α_R of the axles are obtained from the tire characteristics, (27.113) and (27.114), where the interaction between longitudinal and lateral tire forces may also be taken into account. Finally, (27.117) and (27.118) yield new starting values δ_F and β for the next iteration step. In this way, the nonlinear handling diagram according to Figure 27.22 is computed.

A very illustrative method to construct the nonlinear handling diagram, see [8], can be applied, when angles are small and the linear relation (27.90) still holds, and further $F_{xF}\sin\delta_F$ can be neglected in (27.111) and (27.112). Nevertheless, either a nonlinear mathematical representation of the lateral axle characteristics, for example, (27.116), or measured axle characteristics including suspension, steering, and other effects can be involved.

The steady-state lateral axle forces are derived from (27.63) and (27.64) with $\ddot{\psi} = 0$ to $F_{yF} = (ma_y l_R)/l$, $F_{yR} = (ma_y l_F)/l$, and applying (27.115) yields

$$\frac{F_{yF}}{F_{zF}} = \frac{F_{yR}}{F_{zR}} = \frac{a_y}{g} = \frac{v^2}{Rg} \tag{27.122}$$

These ratios can also be plotted using numerical tire characteristics, (27.113) through (27.115), respectively (27.116), or measured axle characteristics as a function of the side slip angle (see top plot

in Figure 27.30). Subtracting these characteristics horizontally from each other gives $\alpha_F - \alpha_R$ for the respective normal acceleration $v^2/(Rg)$ according to (27.122), left part of the bottom plot of the figure. For fixed $v^2/(Rg)$ and wheel track l, the diagram is extended to the right by plotting various fixed velocity v lines relating to $l/R = \delta_a$ (to quantify the radius R), and the corresponding steering angle can finally be read off from the sum $\delta_{F,v} = l/R + (\alpha_F - \alpha_R)$, (27.90), that is the distance between the handling curve and the respective straight velocity line. In other words, for a point on a given constant velocity line, a_y/g is found on the vertical axis, l/R on the right horizontal axis, and δ_F on the horizontal line cut by the handling curve. The nonlinear handling diagram is completed by running through various lateral accelerations (Figure 27.30), with points on the lower half plane belonging to negative R, a right-hand turn. The handling diagram presented corresponds to vehicle A (with oversteer) in Table

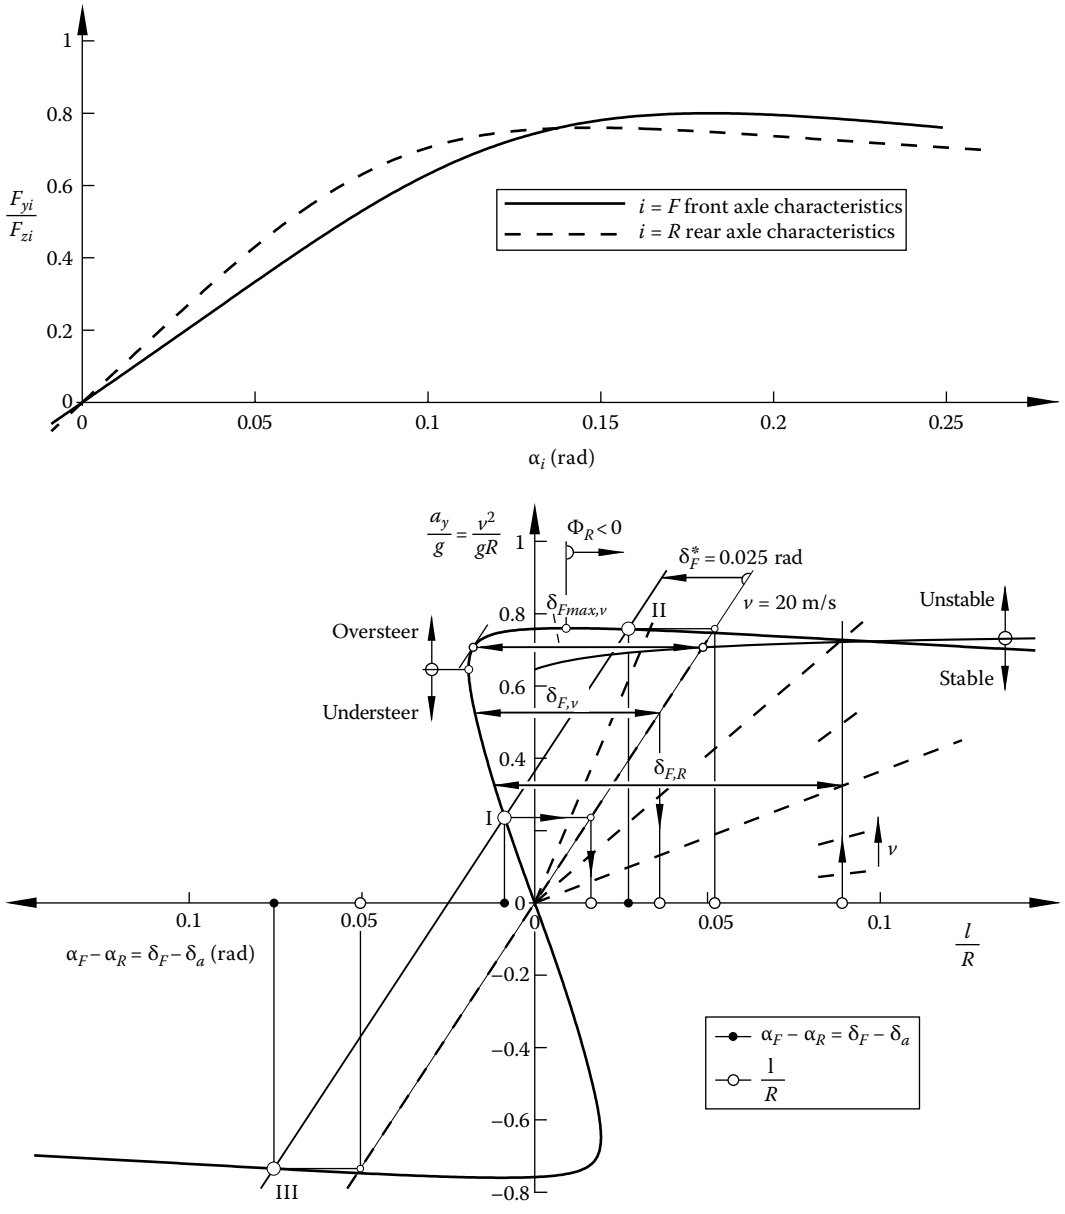

FIGURE 27.30 Nonlinear handling diagram.

27.1, and the (changed) normalized tire characteristics are plotted on top of Figure 27.30. The lower maximum of the two curves defines the maximum possible lateral acceleration a_y/g in the handling diagram.

If the radius R of the turn is kept constant, l/R is given; the required steering angle $\delta_{F,R}$ follows from the distance between the handling curve and the straight vertical line at l/R at the intersection with the selected velocity (line).

The definition of the understeer gradient in (27.86) following SAE J670e [17] does not explicitly mention the test conditions, which has no effect in the linear case. But for nonlinear tire characteristics [25], it makes a difference if v or $1/R$ is considered as an independent variable:

$$\left.\frac{\mathrm{d}(\delta_F - l/R)}{\mathrm{d}a_y}\right|_{v=\text{const.}} = \frac{gl}{v^2}\left[\frac{\partial \delta_F}{\partial (l/R)} - 1\right] \tag{27.123}$$

$$\left.\frac{\mathrm{d}(\delta_F - l/R)}{\mathrm{d}a_y}\right|_{R=\text{const.}} = \frac{gR}{2v}\frac{\partial \delta_F}{\partial v} \tag{27.124}$$

The condition $\mathrm{d}(\delta_F - l/R)/\mathrm{d}a_y = 0$ for neutral (and related over-/understeer) steer characteristics yields $\partial\delta_F/\partial(l/R)|_{v\,=\,\text{const.}} = 1$ from (27.123), and $\partial\delta_F/\partial v|_{R\,=\,\text{const.}} = 0$ from (27.124), which may result in different operating points. While Figure 27.22 is based on (27.123), Figure 27.30 refers to (27.124) and consequently defines a tangent to the handling curve with a slope to the left as understeer ($\partial\delta_F/\partial v > 0$) and to the right as oversteer characteristics ($\partial\delta_F/\partial v < 0$); the gradient at the origin corresponds to the linear(ized) system with the understeer gradient K_{US} in (27.93). Thus, the shape of the tire characteristics or rather the axle characteristics, which include effects from the suspensions, traction force, etc., determine handling and stability characteristics of the vehicle. If the shapes show a maximum with a downward slope at large side slip angles, the handling curve becomes more complex, and apart from the main branch through the origin, other (isolated) branches may occur (see [8]). Here, the normalized tire characteristics are cut early enough for reasons of simplification.

For stability analysis [8], the nonlinear equations of motion, (27.110) through (27.112), as well as the normalized nonlinear tire characteristics are linearized, $\Phi_i = (1/F_{zi})(\partial F_{yi}/\partial\alpha_i)|_{st}$ ($i = F, R$), with respect to steady-state solutions ($|_{st}$). The Hurwitz criterion, necessary and sufficient, then yields two conditions for stability (compare to (27.77) and (27.78)):

$$(I_Z + ml_F^2)l_R\Phi_F + (I_Z + ml_R^2)l_F\Phi_R > 0 \tag{27.125}$$

$$\Phi_F\Phi_R\left.\frac{\partial \delta_F}{\partial (l/R)}\right|_{v=\text{const.}} > 0 \tag{27.126}$$

The first condition is usually of minor importance: the absolute value of a negative slope Φ_i is in most cases much smaller than the positive slope. Since Φ_F and Φ_R are of the same sign in virtually all practical operating conditions, they are often dropped in the second condition (27.126). That implies for Figure 27.22, instability can only occur, when the vehicle shows oversteer characteristics and $\partial\delta_F/\partial(l/R)|_{v\,=\,\text{const.}} < 0$. In the handling diagram of Figure 27.30, the stability boundary can be constructed pointwise according to (27.126) by finding the tangent to the handling curve that runs parallel to the velocity (line) considered. Stability is maintained as long as δ_F increases with increasing l/R for constant velocity; beyond the maximum $\delta_{Fmax,v}$, the motion becomes unstable. The handling curve beyond its maximum, wherefrom $\Phi_R < 0$, is still associated with unstable motions, as $\partial\delta_F/\partial(l/R)|_{v\,=\,\text{const.}} > 0$ and $\Phi_F > 0$.

For a predefined velocity ($v = 20$ m/s) and steering angle ($\delta_F^* = 0.025$ rad), corresponding radii to steady-state cornering can be picked from the handling diagram (Figure 27.30) without much effort. The respective velocity line is shifted in parallel over a distance corresponding to δ_F^* to the left. The three resulting intersection points I, II, and III mark the three possible points of equilibrium; the related cornering radii, l/R, are found by returning to the velocity line and to the abscissa. Condition III belongs to a right-hand curve with negative cornering radius. While the motion in I is stable, it is unstable for II and III, considering the curve of the boundary for stability in the figure; more on stability is revealed in the following. The intersection points of the velocity lines through the origin with the handling curve represent steady-state solutions with zero δ_F, the one in the origin refers to a (stable) straight ahead motion.

Numerical integration of the system equations (27.63) and (27.64) with (27.66) and respective (nonlinear) axle characteristics, (27.113) through (27.115) with (27.68), yields for a given constant velocity and steering angle $\delta_F = \delta_F(t)$, the state variables $\dot{\psi} = r = r(t)$, and $v_y = v_y(t)$, and by further integration the trajectory of CG and the yaw angle $\psi = \psi(t)$ of the vehicle. Also, stability may be addressed in that way. Phase-plane analysis of a nonlinear second-order system is a graphical method to draw conclusions regarding stability after large disturbances without the complete integration of the system. Also, the nature (node, focus, saddle, limit cycle) of the equilibrium points (singular points) can be determined, boundaries of the domain of attraction may be found, if they exist, and therefrom concluded to local stability (with stability boundaries) or global stability in certain cases.

For that purpose, time is eliminated from (27.63) and (27.64) with (27.66):

$$\frac{\mathrm{d}v_y}{\mathrm{d}r} = \frac{I_Z}{m}\,\frac{F_{yF} + F_{yR} - mrv_x}{F_{yF}l_F - F_{yR}l_R} \tag{27.127}$$

As $F_{yF} = F_{yF}(\alpha_F, F_{zF})$, $F_{yR} = F_{yR}(\alpha_R, F_{zR})$, state variables α_F, α_R are more convenient. There follows from (27.68) and (27.127),

$$\begin{aligned}\frac{\mathrm{d}\alpha_R}{\mathrm{d}\alpha_F} &= \frac{(\mathrm{d}v_y/\mathrm{d}r) - l_R}{(\mathrm{d}v_y/\mathrm{d}r) + l_F} = \\ &= \frac{(I_Z/m)[F_{yF} + F_{yR} - m(v_x^2/l)(\delta_F - \alpha_F + \alpha_R)] - l_R(l_F F_{yF} - l_R F_{yR})}{(I_Z/m)[F_{yF} + F_{yR} - m(v_x^2/l)(\delta_F - \alpha_F + \alpha_R)] + l_F(l_F F_{yF} - l_R F_{yR})}\end{aligned} \tag{27.128}$$

This relation and respective axle characteristics can now be used to plot trajectories in the $\alpha_F - \alpha_R$ phase-plane by applying isoclines. Also, time integration of the equations of motion for various initial conditions yields the phase-plane diagram, which is displayed in Figure 27.31 corresponding to Figure 27.30 for $v_x \approx v = 20$ m/s and constant $\delta_F^* = 0.025$ rad. The course of the trajectories is indicated by arrows.

Setting numerator and denominator in (27.128) to zero results in governing equations for isoclines with horizontal and vertical tangents to the trajectories; setting the fraction to one yields the isocline with 45° tangents and $\dot{r}$ will vanish according to (27.64). The three isoclines are shown as dotted lines in Figure 27.31, and the intersections of them give singular points, where $\mathrm{d}\alpha_F = \mathrm{d}\alpha_R = 0$ and the motion is in a steady state, $\dot{\alpha}_F = \dot{\alpha}_R = \dot{v}_y = \dot{r} = 0$. The three equilibrium points I, II, and III in the figure correspond to the same as in Figure 27.30. Point I is a stable focus and represents a negative complex pair of eigenvalues of the characteristic equation of the system linearized at that respective point; points II and III are unstable saddle points corresponding to a real pair of eigenvalues, one of which is positive. Further, the different types of attraction of trajectories starting from inside or outside the domain bounded by indicated

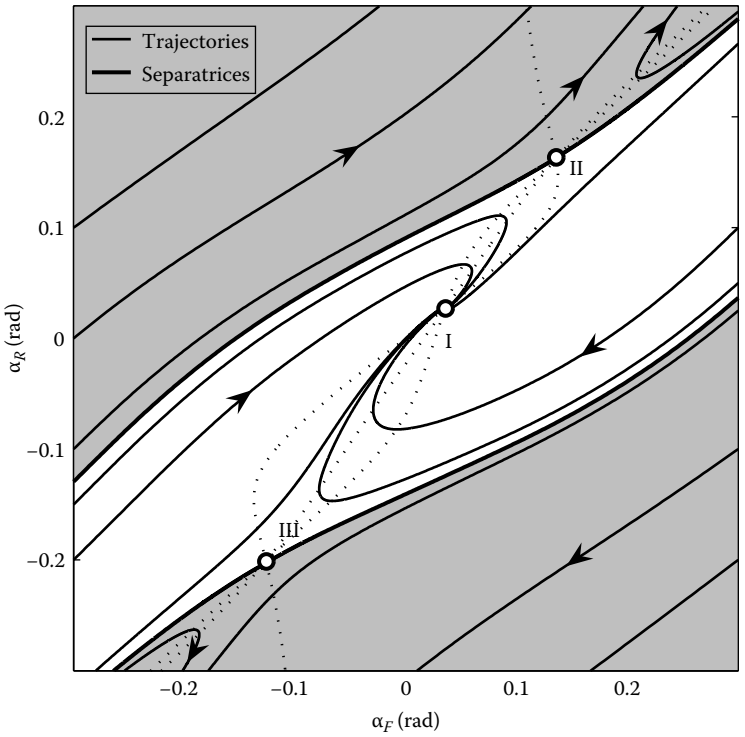

FIGURE 27.31 Phase-plane diagram corresponding to the handling diagram of Figure 27.30 for $v = 20$ m/s and $\delta_F^* = 0.025$ rad resulting in the same singular points I, II, and III.

separatrices can be observed. In this example, the trajectories starting from outside this region (in the shaded area) tend toward very large side slip angles, corresponding to an unstable motion, and trajectories from inside the domain run to the steady-state motion. However, this may not be generalized, in particular, when the front axle/tire characteristics drops below the rear axle/tire characteristics at high side slip angles. Anyway, only the domain within the separatrices is normally of interest from a technical point of view. For limited disturbances, a stability margin may be derived and the effects of different axle/tire characteristics and other parameters studied.

27.4 SUBSYSTEMS AND VEHICLE–TRAILER COMBINATION

With simple models, not only a basic understanding of the dynamics of the full vehicle can be obtained but they may also be used to explain mechanisms or phenomena originating in subsystems of the vehicle. Two examples thereof are presented. The chapter is concluded by a brief stability analysis of an articulated vehicle, a vehicle–trailer combination.

27.4.1 Braking of a Wheel until Lock-Up

Locked tires of a vehicle may not only elongate its stopping distance but stability of the motion of the vehicle can be lost as well. Only very limited lateral tire forces can be transferred ($F_y \approx \mu_s F_z \sin \alpha$), and thereby maneuverability of the vehicle is reduced considerably. Consequently, a full lock-up of wheels needs to be avoided, which is the objective of an ABS. Basically, this system recognizes a potentially locking wheel by the preceding rapid increase in the angular acceleration of the wheel, which will be revealed here, following [7].

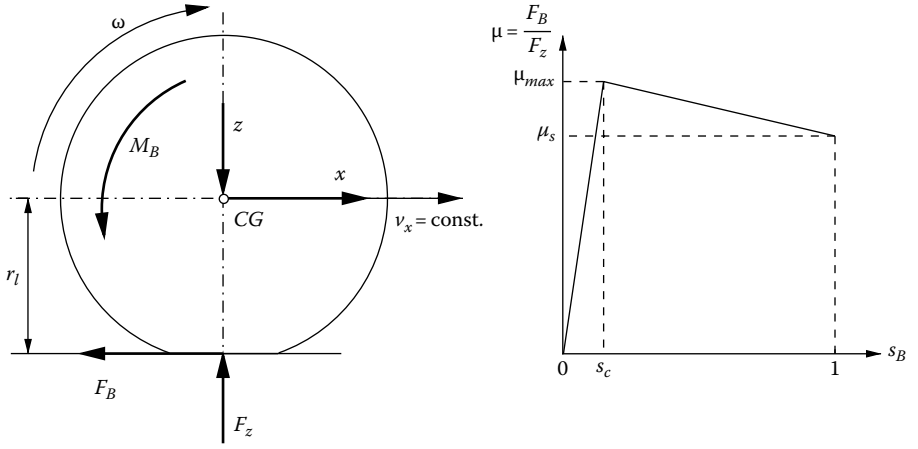

FIGURE 27.32 Forces and moments acting on the braked wheel; bilinear characteristics of braking force coefficient μ.

Euler's equation for the wheel according to Figure 27.32 is

$$I\dot{\omega} = -M_B + F_B r_l \tag{27.129}$$

with the momentum of inertia I of the wheel for the spin axis. The applied braking moments $M_B = c_B t$ is considered to increase linearly with time t until wheel lock-up. This period is presumed to be short and the decrease in velocity can be neglected; thus, v_x = constant. Also, the tire load F_z is assumed constant.

To allow for an analytical solution of the equation of motion (27.129), the braking force coefficient $\mu = F_B/F_z$ is given bilinear characteristics (see Figure 27.32), with respect to the braking slip

$$s_B = \frac{v_x - r\omega}{v_x} = 1 - \frac{\omega}{\omega_0} \tag{27.130}$$

where r is the effective rolling radius of the tire at zero slip, $v_x = r\omega_0$. Two cases are defined, when substituting bilinear $F_B = \mu(s_B)F_z$ in (27.129):

$0 \le s_B \le s_c$, $0 \le t \le t_c$:

The equation of motion for the wheel now reads

$$\dot{\omega} + \frac{\mu_{max} F_z r_l}{s_c I \omega_0}\omega = \frac{\mu_{max} F_z r_l}{s_c I} - \frac{c_B}{I} t \tag{27.131}$$

and the analytical solution becomes

$$\frac{\omega(t)}{\omega_0} = 1 - \frac{c_B s_c}{\mu_{max} F_z r_l}\left[t - \frac{s_c I \omega_0}{\mu_{max} F_z r_l}\left(1 - e^{\frac{-\mu_{max} F_z r_l}{s_c I \omega_0} t}\right)\right] \tag{27.132}$$

It can be seen from $\omega(t)$ in the numerical example in Figure 27.33 that the exponential function can be neglected after a transition period; then the period t_c to reach μ_{max}, the corresponding braking slip $s_c = 1 - \omega_c/\omega_0$, respectively, can be found as follows:

$$t_c \approx \frac{s_c I \omega_0}{\mu_{max} F_z r_l} + \frac{\mu_{max} F_z r_l}{c_B} \tag{27.133}$$

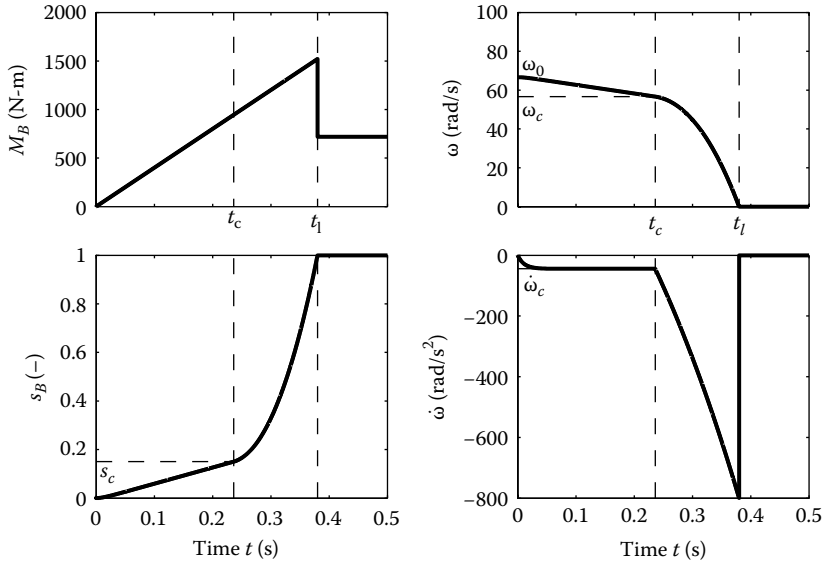

FIGURE 27.33 Braking a wheel until lock-up; model parameters $I = 1$ kg m^2, $F_z = 3000$ N, $c_B = 4000$ N-m/s, $r_1 \approx r = 0.3$ m, $v = 20$ m/s, $s_c = 0.15$, $\mu_{max} = 1$, $\mu_s = 0.8$.

And after derivation of (27.132) w.r.t. time, the corresponding angular acceleration $\dot{\omega}_c$ at t_c becomes

$$\dot{\omega}_c \approx -\frac{s_c c_B}{\mu_{max} F_z r_l}\omega_0 \tag{27.134}$$

The decrease from ω_0 toward ω_c is almost linear and therefore $\dot{\omega} \approx \dot{\omega}_c \approx$ constant before t_c.

The period between t_c and t_l is determined by the second case:

$s_c \le s_B \le 1$, $t_c \le t \le t_l$:

The analytical solution of the corresponding Euler's equation

$$\dot{\omega} - \frac{(\mu_{max} - \mu_s) F_z r_l}{(1 - s_c) I \omega_0}\omega = -\left[\frac{c_B s_c \omega_0}{\mu_{max} F_z r_l} + \frac{(\mu_{max} - \mu_s) F_z r_l}{I} + \frac{c_B}{I}(t - t_c)\right] \tag{27.135}$$

is

$$\frac{\omega(t)}{\omega_0} = \frac{(1 - s_c) c_B}{(\mu_{max} - \mu_s) F_z r_l}\left[\frac{(\mu_{max} - \mu_s) F_z r_l}{c_B} + (t - t_c) + \frac{I(\mu_{max} - s_c \mu_s)\omega_0}{\mu_{max}(\mu_{max} - \mu_s) F_z r_l}\left(1 - e^{\frac{(\mu_{max} - \mu_s) F_z r_l}{(1 - s_c) I \omega_0}(t - t_c)}\right)\right] \tag{27.136}$$

In this case and presuming $(\mu_{max} - \mu_s) > 0$, the exponential function accounts for a very quick drop in the angular velocity, with very large angular acceleration in particular, until they are both zero at t_l; when the wheel is fully locked-up, $s_B = 1$. At the locked wheel, the braking moments is not set by the driver anymore, but by the sliding tire, $M_B = r_l F_B = r_l \mu_s F_z$.

As a consequence, the ABS needs to detect angular accelerations larger than a specific limit beyond $\dot{\omega}_c$, when the wheel tends to lock-up quickly and braking pressure needs to be released.

If $s_c < s_B < 1$, the corresponding eigenvalue of (27.135) is positive, revealing a possible unstable motion. In particular, when measuring steady-state tire characteristics on a tire test bench, the unstable range $\mu_{max} < \mu < \mu_s$ induces a fast transition from μ_{max} to μ_s, as the tire cannot be operated in stable (quasi) steady-state conditions within this area!

27.4.2 Wheel Shimmy

Wheel shimmy is a self-excited, oscillatory, combined lateral-yaw motion of the wheel about a (nearly) vertical steering axis (negligible caster angle) caused by the interaction between the dynamic behavior of the tire and the suspension of the wheel. This kind of (unstable) motion may occur, for example, at the front wheels of an automobile [8], at the landing gears of an aircraft [26], or as a related phenomenon in a motorcycle (called wobble mode, Chapter 35). The trailing wheel model in Figure 27.34 is the simplest model to illustrate wheel shimmy, following [8] and [26] and for continued analysis of the phenomenon.

The moments of inertia for the vertical axis at point A is denoted by $I_A = I_C + me^2$ (wheel mass m, wheel moments of inertia I_C), caster length with e, and linear stiffness and damping constant with c_ψ and d_ψ, respectively. The hinge point A moves along the x-axis with constant velocity v and the yaw angle ψ is a DOF of the system:

$$I_A\ddot{\psi} = -d_\psi\dot{\psi} - c_\psi\psi - F_y e - M_z \tag{27.137}$$

The straight tangent tire model is applied to account for the transient tire behavior. Thereby, the approximated shape of a single deflected string, representing the tire, is a straight line tangent to the actual contact line at the leading edge. The corresponding deformation angle α_t is another DOF. Considering small deviations from a straight-line motion, the transient tire model follows to

$$\sigma\dot{\alpha}_t + v\alpha_t = v\psi - a\dot{\psi} + \dot{y}_C \tag{27.138}$$

$$F_y = C_F\alpha_t \tag{27.139}$$

$$M_z = C_M\alpha_t \tag{27.140}$$

with $\dot{y}_C = e\dot{\psi}$, relaxation length σ, half of the tire contact length a, cornering stiffness C_F, self-aligning stiffness C_M, and consequently the pneumatic trail $t = M_z/F_y = C_M/C_F$.

The characteristic equation of the linear third-order system (27.137) through (27.140) is as follows:

$$a_0 s^3 + a_1 s^2 + a_2 s + a_3 = 0 \tag{27.141}$$

$$\text{with } a_0 = \sigma I_A \tag{27.142}$$

$$a_1 = vI_A + \sigma d_\psi \tag{27.143}$$

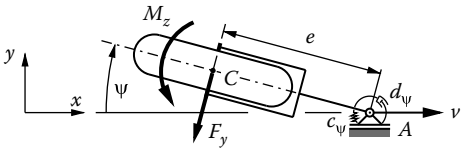

FIGURE 27.34 Trailing wheel model.

$$a_2 = \sigma c_\psi + C_F(e-a)(e+t) + v d_\psi \tag{27.144}$$

$$a_3 = v c_\psi + C_F v(e+t) \tag{27.145}$$

According to the Hurwitz (and Stodola) criterion, $a_i > 0$ (i = 0–3) and $H_2 = a_1 a_2 - a_0 a_3 > 0$, and assuming only positive parameters but the mechanical trail e, the conditions for a stable motion without damper, $d_\psi = 0$, finally result in

$$a_3 > 0: \quad e > -\left(t + \frac{c_\psi}{C_F}\right) = e_1 \tag{27.146}$$

$$H_2 > 0: \quad e < -t = e_2 \quad \text{or} \quad e > \sigma + a = e_3 \tag{27.147}$$

Thus, the system is oscillatory unstable (H_2 to become negative first, [27]) for $-t < e < \sigma + a$, independent from v, I_A, c_ψ, C_F (but changing the eigenfrequency)! If $c_\psi = 0$, the stable region for negative mechanical trail disappears. If $e < -t - c_\psi/C_F$, meaning that the steering axis lies behind the contact center, the system becomes monotonically unstable (a_3 to become negative first, [27]) and the wheel turns back around the swivel axis to a trailing motion. These analytical findings are illustrated for the numerical example in Figure 27.35, top left plot. The top right plot shows the root locus for $d_\psi = 0$ and increasing mechanical trail from $e = -0.6$ m, indicated by "*", to $e = 0.6$ m, marked with "o". Although the stability margins for e (e_1, e_2, e_3) are independent from velocity v, when no yaw damping ($d_\psi = 0$) is considered, natural frequency and degree of stability very well depend thereon, demonstrated by the two root loci for v = 15 m/s and v = 30 m/s. Note, all root loci for different velocities cross the imaginary axis at the same points.

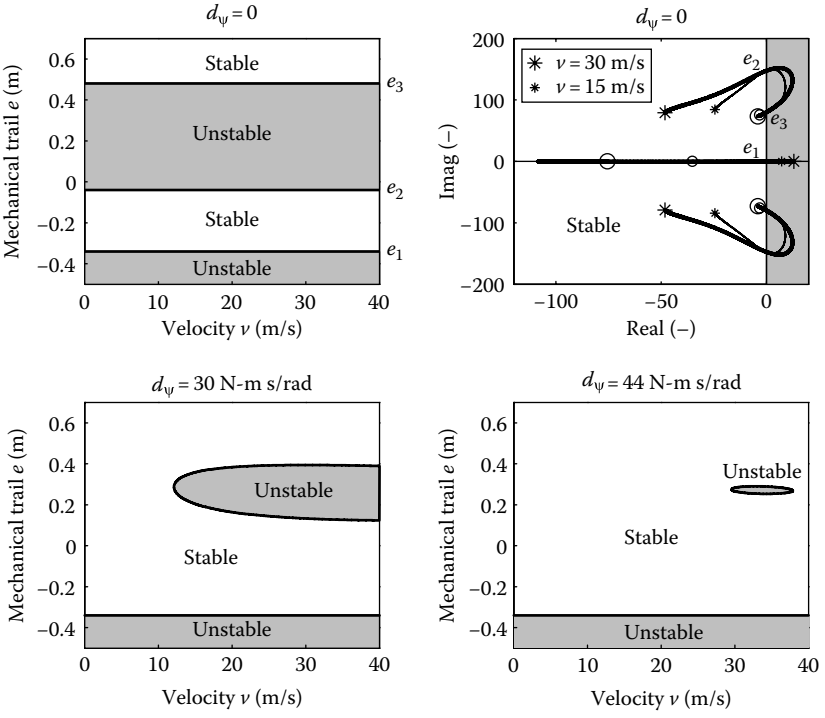

FIGURE 27.35 Stability map of the trailing wheel system in Figure 27.34 for $d_\psi = 0$, d_ψ = 30 N-m s/rad, d_ψ = 44 N-m s/rad; root locus for −0.6 m (*) < e < 0.6 m (o); model parameters I_C = 0.65 kg m², m = 25 kg, C_F = 50,000 N/rad, c_ψ = 15,000 N-m/rad, σ = 0.36 m, a = 0.12 m, t = 0.04 m.

By introducing yaw damping (bottom plot in Figure 27.35), the unstable area between $-t < e < \sigma + a$ for $d_\psi = 0$ can be reduced and disappears completely, when damping is sufficiently high. Nevertheless, the unstable area for large negative mechanical trails $e < -t - c_\psi / C_F$ remains. For a given trail, the stability of the motion may now depend on velocity!

27.4.3 Vehicle–Trailer Combination

A final example for a basic stability analysis is the motion of a vehicle–trailer combination. The linear two-wheel vehicle model in Figure 27.18 is coupled with a model of the trailer based on the same level of complexity and modeling assumptions (Figure 27.36).

The 2 DOFs of the towing vehicle, lateral velocity $v_y = v\beta$ and yaw rate $\dot{\psi} = r$ of the vehicle, are completed by the articulation angle $\varphi = \psi - \psi_T$ between the vehicle and trailer. The velocity $v \approx v_x$ of the towing vehicle is considered a constant parameter. Then, the linear system equations in matrix notation read

$$\mathbf{E}\dot{\underline{x}} = \mathbf{A}\underline{x} + \mathbf{B}\delta_F \tag{27.148}$$

with state vector $\underline{x} = [v_y, r, \varphi, \dot{\varphi}]^T$, front-wheel steering angle δ_F, and matrices (with trailer mass, m_T, moments of inertia, I_T, and cornering stiffness, C_T)

$$\mathbf{A} = \begin{bmatrix} -(C_F + C_R + C_T)\dfrac{1}{v} & -(m + m_T)v - C_F\dfrac{l_F}{v} + C_R\dfrac{l_R}{v} + C_T\dfrac{h+b}{v} & -C_T & -C_T\dfrac{b}{v} \\ -C_F\dfrac{l_F}{v} + C_R\dfrac{l_R}{v} + C_T\dfrac{h}{v} & m_T h v - C_F\dfrac{l_F^2}{v} - C_R\dfrac{l_R^2}{v} - C_T\dfrac{h(h+b)}{v} & C_T h & C_T\dfrac{bh}{v} \\ 0 & 0 & 0 & 1 \\ -C_T\dfrac{b}{v} & -m_T a v - C_T\dfrac{b(b+h)}{v} & -C_T b & -C_T\dfrac{b^2}{v} \end{bmatrix} \tag{27.149}$$

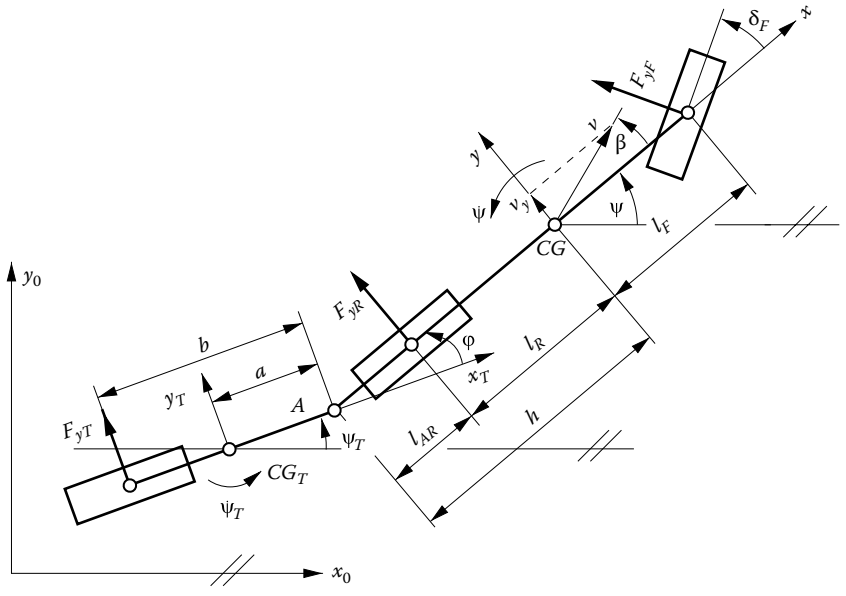

FIGURE 27.36 Vehicle–trailer model.

$$\mathbf{B} = \begin{bmatrix} C_F \\ C_F l_F \\ 0 \\ 0 \end{bmatrix} \tag{27.150}$$

$$\mathbf{E} = \begin{bmatrix} (m+m_T) & -m_T(h+a) & 0 & m_T a \\ -m_T h & I_Z + m_T h(h+a) & 0 & -m_T h a \\ 0 & 0 & 1 & 0 \\ m_T a & -(I_T + m_T a^2) - m_T a h & 0 & I_T + m_T a^2 \end{bmatrix} \tag{27.151}$$

and may be used, for instance, to design a control system or to study handling characteristics or stability issues. If one is interested in the stability of the steady-state motion, the eigenvalues, resulting numerically from $|\mathbf{A} - \lambda\mathbf{E}| = 0$, may be consulted. If one requires to evaluate system parameters with respect to stability by preparing a stability map, the coefficients a_i of the characteristic equation, $a_0\lambda^4 + a_1\lambda^3 + a_2\lambda^2 + a_3\lambda + a_4 = 0$, may (symbolically) be derived. Then, asymptotic stability is guaranteed for all $a_i > 0$ ($i = 0$–4) and $H_3 = a_1a_2a_3 - a_1^2a_4 - a_0a_3^2 > 0$ (Liénard-Chipart and Stodola criterion).

In Figure 27.37, stability maps for a small vehicle trailer model, data are listed in the caption of the figure, towed by vehicle A with parameters from Table 27.1, are shown. The additional load on the rear facilitates a towing vehicle with oversteer characteristics; therefore, this type of vehicle has been selected.

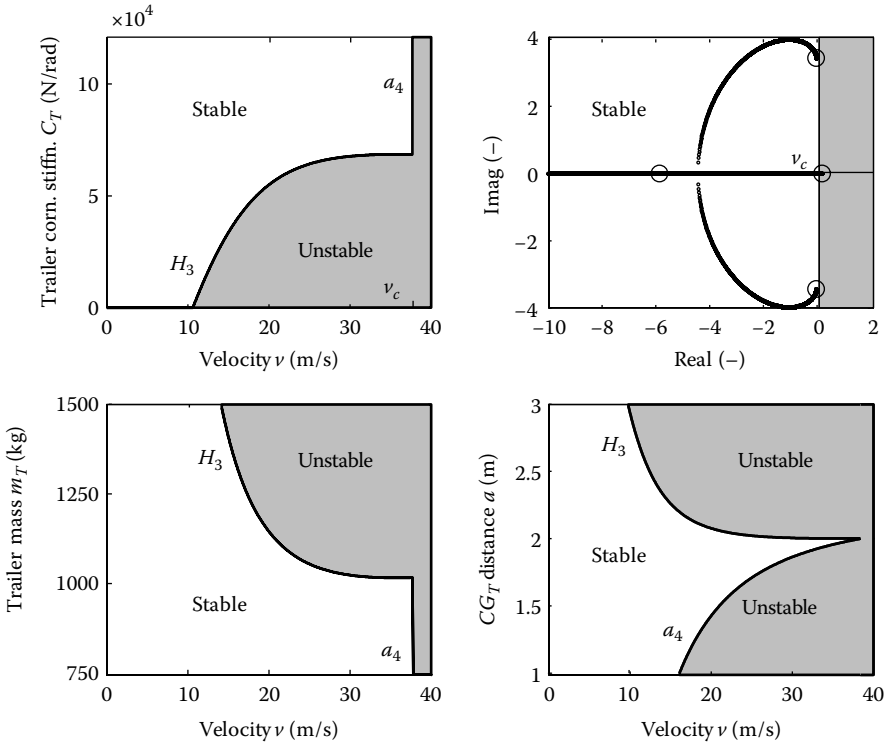

FIGURE 27.37 Stability maps of vehicle–trailer model in Figure 27.36; towing vehicle: vehicle A according to Table 27.1; trailer: $m_T = 1000$ kg, $I_T = 1{,}440$ kg m^2, $C_T = 70{,}000$ N/rad, $a = 2$ m, $b = 2$ m, $h = 2$ m; root locus for $v \to 40$ m/s (marked by "0").

From the top left plot in Figure 27.37, it can be concluded that decreasing the cornering stiffness of the trailer promotes oscillatory instability. Note, if the parameters are varied beginning within the region of asymptotic stability, the stability boundary is reached, when $a_4 H_3 = 0$, [27]. Here, $a_4 = 0$ characterizes the monotone marginal stability, $H_3 = 0$ the oscillatory marginal stability, and the respective stability boundaries are indicated by "a_4" and "H_3" in the plots. Thus, for low cornering stiffness of the trailer, a "snaking" oscillatory motion may be initiated after exceeding the stable region, "H_3." Large (initiated) amplitudes will increase the side slip angle, and as a consequence of the degressively, actually nonlinear lateral tire characteristic, the "average" cornering stiffness is decreased (further), encouraging snaking. As a result, the vehicle–trailer combination may even fallover [8]. For high cornering stiffness, divergent instability may occur, when velocity is increased just beyond the critical speed v_c, indicated by the vertical line, "a_4"; $v_c = 37.8$ m/s does not depend on the cornering stiffness C_T. As an example, the locus of eigenvalues is plotted for increasing velocity with fixed $C_T = 70{,}000$ N/rad (see top right plot in the figure). At $v = v_c$, monotone marginal stability is reached, followed by divergent instability until $v = 40$ m/s, marked by "0".

The left plot on the bottom of Figure 27.37 depicts an increasing stable area with decreasing total mass m_T of the trailer. It should be mentioned that the graph "a_4" does not depend on m_T in this specific case, when $a = b = h$!

Moving the load of the trailer toward the front end of the trailer (smaller distance a) supports stability, although it seems there is a kind of optimal position of the trailer's center of gravity with respect to the hinge, respectively the axle of the wheels.

Details are to be found in [8], and the stability analysis of a nonlinear vehicle–semitrailer combination is covered in [28] and [29].

28.1 INTRODUCTION

The vehicle dynamics design and adjustment of present-day road vehicles are intended to ensure the following:

- The vehicle can be controlled with precision and is robust with regard to disturbances.
- The driver can master practically all driving situations.
- Vehicle responses are predictable for the driver.
- Comfort, traction, stability, and, if applicable, off-road characteristics appropriate to the vehicle type can be realized.

In order to be able to comply with these ever-more complex requirements, the use of efficient and sometimes complex analytical tools is indispensable [1–3]. This applies, in particular, to the vehicle and system design, but increasingly also to the support and optimization of test series and to the appropriate adjustment for the customer [4,6].

28.1.1 Model-Based Vehicle Dynamics and Chassis Development

Within the context of vehicle and chassis development, analysis by means of simulation technology forms the starting point and backbone of the development process, as illustrated in Figure 28.1.

The analysis using modeling and simulation allows the functional properties and experiences from the relevant predecessor or reference vehicle to be compiled in a development model and to be configured specific to the target vehicle. New or heavily modified components are analyzed by means of rig tests, prepared in line with the model technology and integrated into the overall system analysis.

If technical innovations impact upon the interaction between the driver and vehicle, these aspects can be dealt with within the framework of driving simulator evaluations and preoptimized long before elaborate overall vehicle hardware is available [8].

Based on this preliminary work, a large proportion of the necessary design and adjustment issues can be resolved systematically by means of simulation technology; this applies, in particular, to the functioning and robustness of the design and the remaining adjustment scope. The concluding prototype phase is primarily intended not only for the validation of the results under real driving

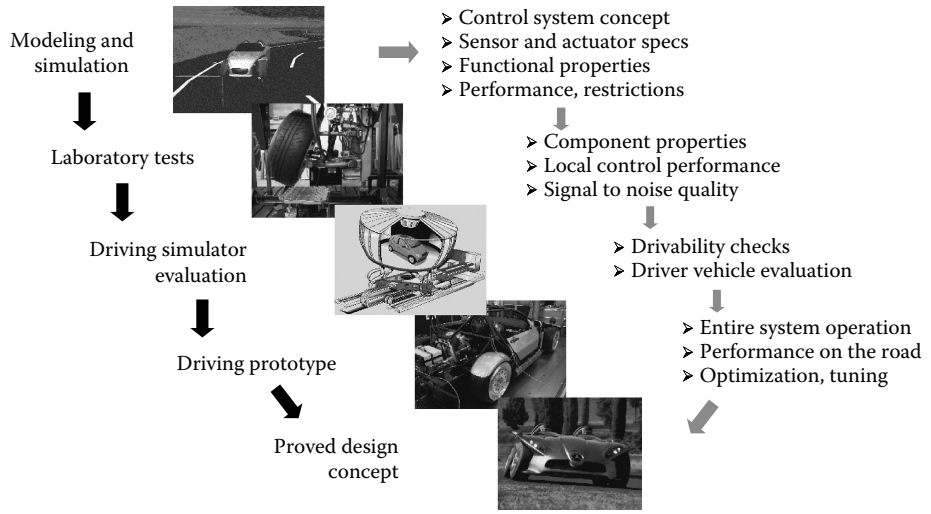

FIGURE 28.1 Process concept of a model-based vehicle dynamics and chassis development.

conditions but also for checking and fine tuning, as the technical evaluation criteria available today still only cover part of the human perception. Vehicle evaluation and sensitive adjustments by experienced test drivers are therefore indispensable parts of the development process.

All in all, at the end of the development process chain, we have a vehicle or system concept that is mature with regard to function, robustness, and adjustment options and which therefore forms the basis for low-risk and timely industrial realization.

28.1.2 Vehicle Dynamics and Chassis Simulation

The vehicle dynamics as a whole involve the complex interaction between driver and vehicle, including the integrated vehicle dynamics, ride comfort, and driving safety systems, as well as the disturbance and control behavior of the vehicle in relation to the vehicle environment, as illustrated in Figure 28.2.

Given the complexity of the vehicle dynamics analysis and the heterogeneity of the tasks in hand, three main model categories of differing complexity have evolved for the description and explanation of vehicle dynamics phenomena and the solution of adjustment problems (refer to Figure 28.3):

- Vehicle behavior models
- Handling models
- Detailed ride analysis models (including axle dynamics properties)

Vehicle behavior models such as single-track (bicycle models) models or quarter-vehicle models each approximate certain aspects of vehicle behavior, for example, the low-frequency lateral dynamics or the suspension characteristics and the disturbance transfer of road irregularities.

In contrast, handling and chassis dynamics models for the complete vehicle are prepared and are suitable for the analysis of any driving situation. Both model classes are designed for driving on any type of road; they are designed to provide plausible results for any type of (mechanically compatible) driver input and to describe the vehicle behavior in the relevant validation range with defined quality/precision.

28.1.3 Coordinate Systems for the Description of Vehicle Movement

The spatial movement of the vehicle body or structure is described based on a vehicle-fixed coordinate system *B* (*B*: Body), that is, which moves along with the vehicle (refer to Figure 28.4).

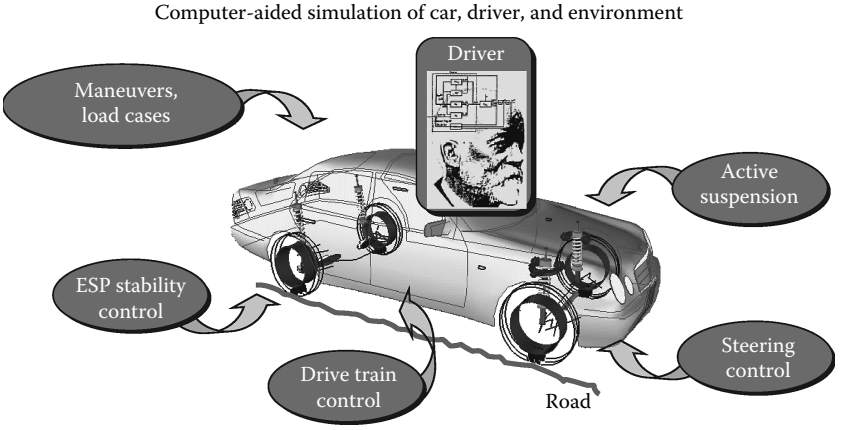

FIGURE 28.2 Interaction between driver, vehicle, and environment within the context of evaluation of vehicle dynamics.

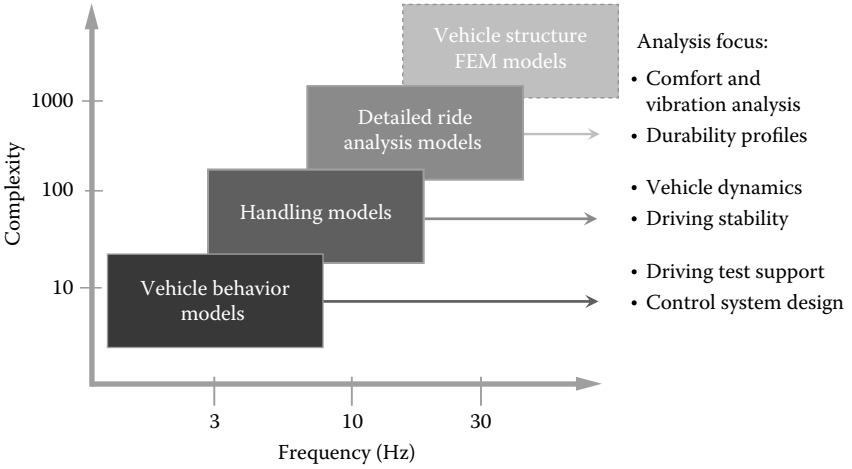

FIGURE 28.3 Model classes for vehicle dynamics analysis, arranged according to complexity and main primary analysis frequency range.

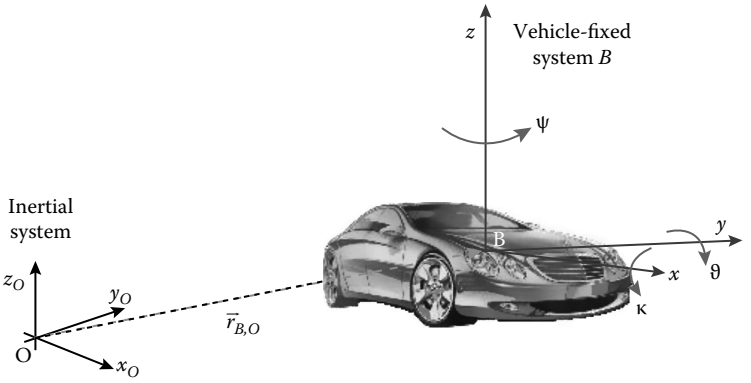

FIGURE 28.4 Description of vehicle motions in space: vehicle-fixed system *B*, aligned to the longitudinal, lateral, and vertical vehicle axis.

The vehicle center of gravity—at a defined reference load—lends itself as reference point. Although this does not simplify the dynamics equations significantly, it facilitates the interpretation of the analytical results. The vehicle body motion is characterized by the inertial position and speed values of reference point *B*

$$\vec{r} = \begin{pmatrix} x \\ y \\ z \end{pmatrix} = \vec{r}_{B,O}; \quad \vec{v} = \begin{pmatrix} \dot{x} \\ \dot{y} \\ \dot{z} \end{pmatrix} = \vec{v}_{B,O} \lim_{x \to \infty} \tag{28.1}$$

and the angle and angular velocity values of the consecutive body rotations around the vertical, lateral, and longitudinal axis:

$$\vec{\varphi} = \begin{pmatrix} \kappa \\ \vartheta \\ \psi \end{pmatrix}; \quad \dot{\vec{\varphi}} = \begin{pmatrix} \dot{\kappa} \\ \dot{\vartheta} \\ \dot{\psi} \end{pmatrix}; \quad \vec{\omega} = \begin{pmatrix} \omega_x \\ \omega_y \\ \omega_z \end{pmatrix} = \begin{pmatrix} 1 & 0 & -\sin\vartheta \\ 0 & \cos\kappa & \sin\kappa\cos\vartheta \\ 0 & -\sin\kappa & \cos\kappa\cos\vartheta \end{pmatrix} \dot{\vec{\varphi}} \tag{28.2}$$

Using reference point values $\vec{r}_B$, $\vec{v}_B$, and a rotation matrix $\bar{T}$, all relevant quantities of body system B can be transformed into the inertial system O and vice versa, for example,

$$\vec{r}_{P,O} = \vec{r}_{B,O} + \bar{T}\Delta\vec{r}_{P,B}; \quad \vec{v}_{P,O} = \vec{v}_{B,O} + \bar{T}\Delta\vec{v}_{P,B} + \vec{\omega}\times\bar{T}\vec{r}_{P,B} \tag{28.3}$$

The rotation matrix $\bar{T}$ results from consecutive rotations of the basic system around the coordinate axes:

$$\bar{T} = \begin{pmatrix} \cos\psi & -\sin\psi & 0 \\ \sin\psi & \cos\psi & 0 \\ 0 & 0 & 1 \end{pmatrix} \times \begin{pmatrix} \cos\vartheta & 0 & \sin\vartheta \\ 0 & 1 & 0 \\ -\sin\vartheta & 0 & \cos\vartheta \end{pmatrix} \times \begin{pmatrix} 1 & 0 & 0 \\ 0 & \cos\kappa & -\sin\kappa \\ 0 & \sin\kappa & \cos\kappa \end{pmatrix} \tag{28.4}$$

28.1.4 Wheel Motions

The principal motions of the wheels relative to the vehicle body concern the degrees of freedom jounce z_e, wheel steering δ_R, and the wheel rotation φ_R, $\dot{\varphi}_R = \omega_R$, as illustrated in Figure 28.5.

These types of wheel movements are possible due to axle kinematics and enable larger displacements or angle ranges. It should be noted, however, that the basic chassis design generally provides for deviations to the main vehicle axes. The wheel axis around toe-in $\Delta\delta_R$ and camber γ_R, for example, is twisted against the transverse vehicle axis. During jounce or rebound z_e, the longitudinal and lateral position x_{RC}, y_{RC} of the wheel contact patch changes. The former results from the chassis-specific acceleration/braking compensation, while the latter corresponds with the so-called roll center height. (The roll center is generally defined as the center of rotation between the axle and vehicle under free rolling motions.)

With known wheel kinematics of a single-wheel suspension, all wheel carrier motions, that is, the longitudinal and lateral displacement as well as the wheel carrier camber γ_R and the wheel carrier pitch angle φ_{WC}, can be determined from the jounce motion z_e and the (projected) wheel steering angle δ_R:

$$x_{RC} = x_{RC}(z_e, \delta_R); \quad y_{RC} = y_{RC}(z_e, \delta_R) \tag{28.5}$$

$$\gamma_R = \gamma_R(z_e, \delta_R); \quad \varphi_{WC} = \varphi_{WC}(z_e, \delta_R) \tag{28.6}$$

In the case of rigid axles, the conditions are somewhat more complex. Here, four-dimensional characteristics are generally required, as the jounce and steering status of both wheels of an axle influence

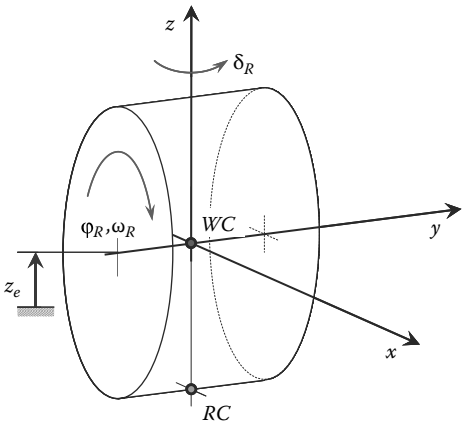

FIGURE 28.5 Primary kinematic wheel degrees of freedom, here as relative coordinates defined in relation to the vehicle system B (*RC*, wheel contact patch; *WC*, wheel center point).

the wheel guidance. Three-dimensional characteristics frequently suffice, however, as the steering movements between the left-hand and right-hand axle side are normally kinematically coupled.

Besides these major wheel motions, force and torque balances determine the actual wheel position in other directions (refer to Section 28.4).

28.2 ROAD MODELING

Driving comfort analyses as well as spring–damper adjustments and the design of semi-active and active suspensions must take road excitations into account. In practice, this is either achieved on the basis of deterministic test obstacles or specified road profiles or by measured or synthetically generated "stochastic" road profiles.

28.2.1 Deterministic Road Irregularities

The spectrum of deterministic irregularity excitations ranges from short, high-frequency irregularity excitations such as cleats and simulated slab joints (vertical steps) via simulations of potholes and speed bumps right thru to extended ramp types (along the straight or in corners) to produce stronger body excitations (refer to Figure 28.6). Typical disturbances in the transverse road profile include lateral slopes or lane groove profiles. Road-building-related road characteristics and profiles with their customary transition spirals (clothoids) between different curvatures, related transverse slopes, and curve banking as well as incline and descent profiles are also normally assigned to the deterministic road excitations. By making minor additions, the road construction descriptions also allow the definition of racetracks and high-bank curve sections. The latter are particularly important for the assurance of driving dynamics control systems, as they allow potential weak points in the estimation of the driving condition at more steeply inclined locations to be uncovered.

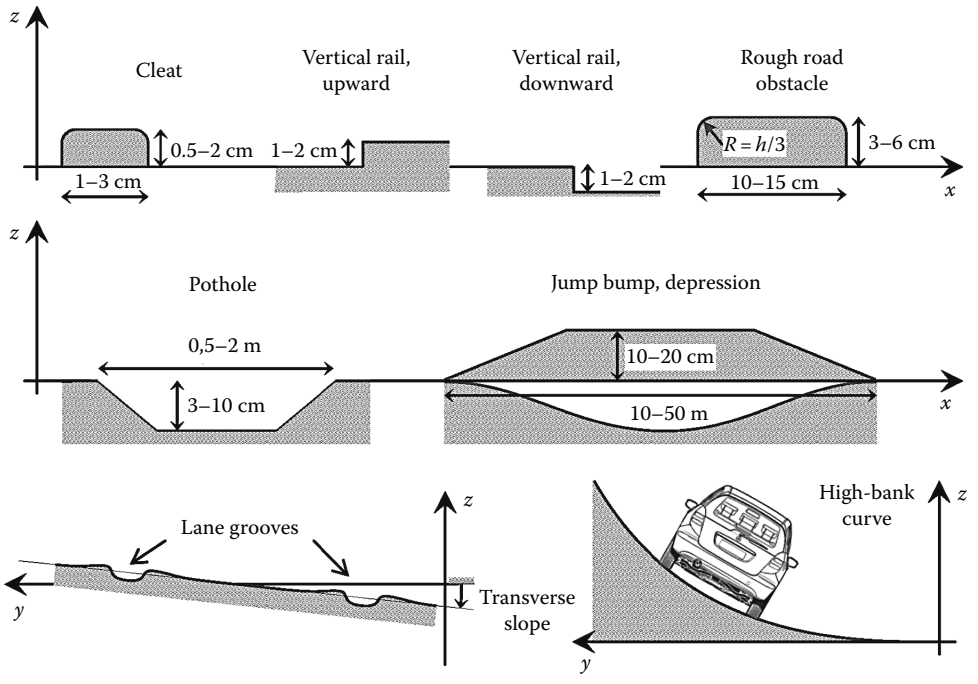

FIGURE 28.6 Selection of deterministic road irregularity excitations for ride comfort and vehicle dynamics analyses.

28.2.2 Stochastic Road Irregularities

The construction and wear-related irregularities of country roads and highways fit in quite well with the model of a random process ξ_s, which is in steady state over travel distance s and shows a Gaussian distribution. (In stochastic processes, the ordinal variable is normally used as index number—in contrast to the bracketed notation for deterministic processes.) The knowledge of the related power spectral density $S_{\xi\xi}(\Omega)$ therefore suffices to describe the road characteristics completely in longitudinal direction [16,20].

A number of analyses [12,18,20] prove that most road surfaces are approximated quite well by spectra of the type

$$S_{\xi\xi}(\Omega) = S_0 \left(\frac{\Omega_0}{\Omega} \right)^w ; \quad \Omega_0 = \frac{1}{m} \tag{28.7}$$

In double-logarithmic representation, this expression results in a straight line. The amplitude parameter S_0 therefore assumes values between 1 and 200 cm^3. For the "waviness" parameter (slope in double-logarithmic-scaled diagrams), values in the range of w = 1.8–3.8 have been determined, whereby larger waviness values have been found for very good roads and smaller amplitude parameters S_0. At a given vehicle speed v, the road spectrum can be transformed into an equivalent time-domain power spectral density (Figure 28.7):

$$S_{\xi\xi}(\omega) = \frac{S_0}{v} \left(\frac{\Omega}{\Omega_0 v} \right)^{-w} ; \quad \text{or} \quad \text{for } w = 2\text{: } S_{\xi\xi} = \frac{v S_0 \Omega_0^2}{\omega^2} \tag{28.8}$$

As can be seen for waviness w = 2, the power input of the road excitation increases proportionally to the vehicle speed; the excitation amplitudes therefore increase with $\sqrt{v}$. Above the excitation frequency, the intensity decreases quadratically. If instead of the road excitation ξ_t we observe its formal time derivative $\dot{\xi}_t$, a uniform white spectrum $S_{\dot{\xi}\dot{\xi}} = v S_0 \Omega_0^2$ results for w = 2. This is therefore also known as white speed noise. Speed-sensitive chassis parts such as shock absorbers or chassis

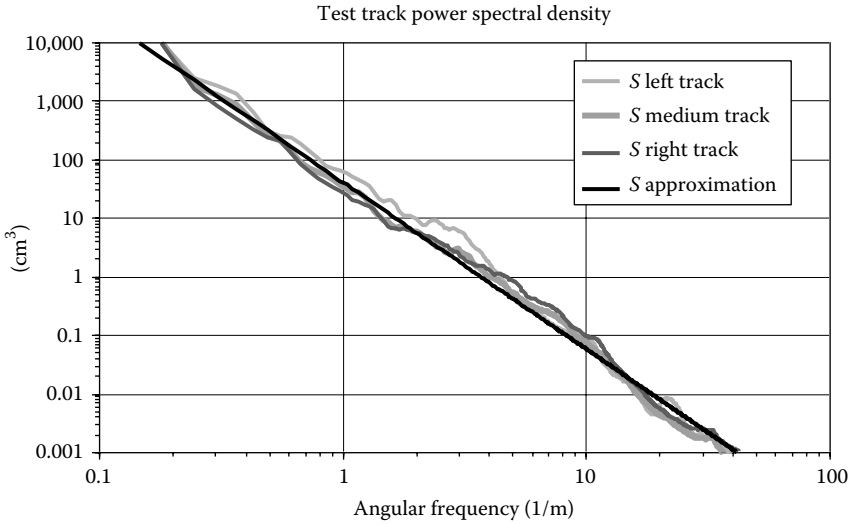

FIGURE 28.7 Power spectral density of a typical comfort evaluation testing ground, different tracks.

mounts are therefore subject to very broadband excitations. Altogether, the road excitation affects all frequency bands equally—each potential resonance in the chassis or in the overall vehicle is reliably excited.

From a theoretical point of view, model spectra of types (28.7) or (28.8) suffer from a severe deficit: The related processes ξ_s are not defined, and their variance is infinitely large. In practice, this problem hardly surfaces, however, as the disturbing, extreme low-frequency excitation content—for example, for $\Omega \leq 0.01$/m—is blanked out or—and this has the same effect—only distances of some 100 m length are used for the analysis. (The valleys and peaks along the natural road course are therefore removed from the stochastic part of the road modeling and assigned to the deterministic profile content.)

28.2.3 Road Characteristics in Transverse Direction

The road characteristics in transverse direction and the correlations in the excitations of the left and right track (or vehicle side) are described by the coherence γ of the excitations [15,18]:

$$\gamma(\rho;\Omega) = \frac{S_{lr}(\Omega)}{\sqrt{S_{ll}(\Omega)\,S_{rr}(\Omega)}}. \tag{28.9}$$

where

indices *r*,*l* are the right and left track of the vehicle

ρ is the track width

Figure 28.8 shows the typical coherence function characteristics for different track widths.

As the database for real coherence characteristics is still weak and as the theory of two-dimensional stochastic processes, on the other hand, does not leave much leeway when the longitudinal spectra are defined, it is expedient to use a synthesis of the not quite applicable isotropic model results and the plausible road data evaluations for determining coherence. This can be achieved most easily if the coherence is initially determined conforming to the isotropic model and then somewhat compressed or stretched in longitudinal road direction in order to model the longitudinal

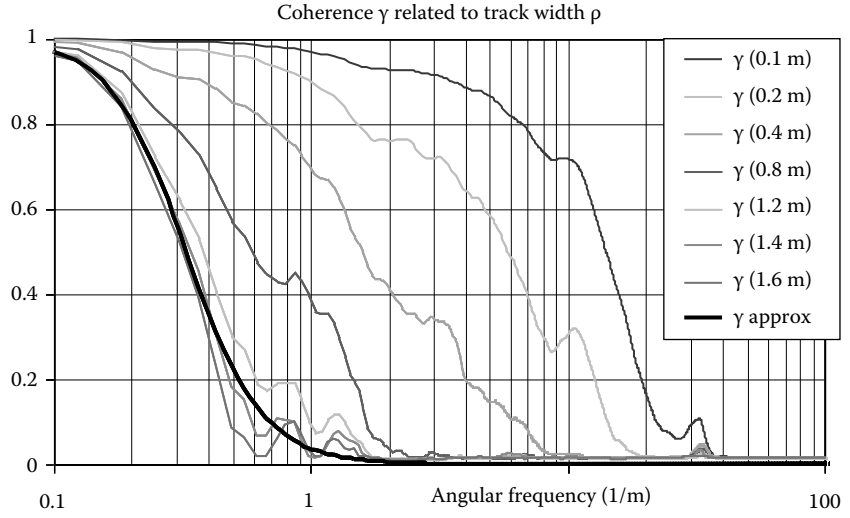

FIGURE 28.8 Coherence functions of a typical comfort evaluation testing ground for different track widths.

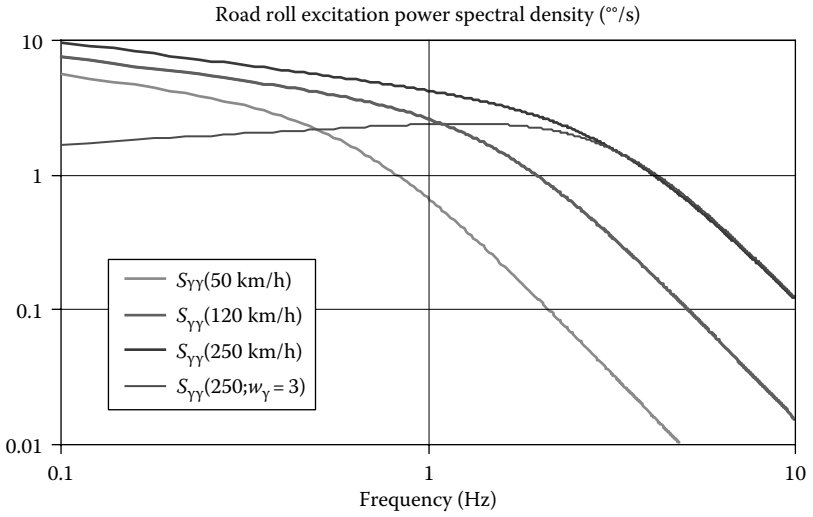

FIGURE 28.9 Roll excitation spectra for different vehicle speeds determined for waviness w = 2.84 and coherence parameter Ω_γ = 0.3/m, w_γ = 2.5.

orientation of the individual disturbances observed in practice. The results of this process are coherence approximations of the type

$$\gamma = \frac{\Omega_\gamma^{w_\gamma}}{\Omega_\gamma^{w_\gamma} + \Omega^{w_\gamma}}; \quad \Omega_\gamma \approx \frac{0{,}5 \cdots 1}{\rho}; \quad w_\gamma = w_\gamma(\rho) \approx (0{,}5 \cdots 1{,}5) w \tag{28.10}$$

The practical significance of the coherence function becomes evident, among others, when we look at the development of the roll excitations over the vehicle speed based on the aforementioned principles. The relevant power spectral density $S_{\gamma\gamma}(\omega)$ results as follows:

$$S_{\gamma\gamma}(\omega) = \frac{2}{\rho^2} \frac{S_0}{v} \left(\frac{\omega}{\Omega_0 v} \right)^{-w} \left(1 - \gamma\left(\rho; \frac{\omega}{v} \right) \right) \tag{28.11}$$

Figure 28.9 shows the power spectral densities of the roll excitation for different vehicle speeds v. It becomes clear that significant roll excitations of the vehicle body are to be expected, above all, at higher speeds. For $w_\gamma > w$, a pronounced excitation maximum occurs near the natural vehicle roll frequency.

28.2.4 Road Height Profile Modeling

Two different approaches are widely discussed in literature for the modeling of road irregularities:

1. Synthesis using harmonic functions and randomly distributed phases [12]
2. Synthesis on the basis of noise-excited linear dynamic systems [13,16]

Both methods can be used for single or multitrack model processes; the achievable model quality is equivalent in principle. Linear filters seem more practical, however, for online generation as they

minimize the data management and require less computational input. A road excitation process with waviness $w = 2$ can already be generated by means of a simple first-order filter, for example:

$$\dot{\xi} + \omega_g \xi = \sqrt{v S_0 \Omega_0^2}\, z; \quad z \equiv z(k\Delta t) = \sqrt{\frac{12}{\Delta t}} Z_k; \quad k = 0,1,2,\ldots \tag{28.12}$$

whereby Z_k is a random number sequence in the range of [−0,5;0,5] which is called up in sufficiently small time intervals Δt. The road excitation ξ approximates the desired target spectrum for frequencies above $f \succ f_g = \omega_g / 2\pi$ with intensity S_0 and waviness $w = 2$. For more refined approaches toward filter approximation of road spectra, refer, for example, to [12,14,19].

28.2.5 Synthesis of Two-Track Excitations

Two-track road excitations with coherence characteristics close to reality are generated through a straightforward mixing function. Two independent excitations ξ_1, ξ_2 are used as input signals which are already adjusted to the desired longitudinal direction spectrum. From these signals, two coupling signals η_1, η_2 are generated through first-order filters:

$$\eta_1' + \Omega_{\Delta y} \eta_1 = \Omega_{\Delta y} \xi_1; \quad \eta_2' + \Omega_{\Delta y} \eta_2 = \Omega_{\Delta y} \xi_2 \tag{28.13}$$

Thereby and with the original excitations ξ_1, ξ_2, the desired road excitations ξ_l, ξ_r are generated:

$$\xi_l = \xi_1 - \left(1 - \frac{\sqrt{2}}{2}\right)\eta_1 + \frac{\sqrt{2}\eta_2}{2}; \quad \xi_r = \frac{\sqrt{2}\eta_1}{2} + \xi_2 - \left(1 - \frac{\sqrt{2}}{2}\right)\eta_2 \tag{28.14}$$

The synthesis maintains the longitudinal spectra and generates for the cross-spectrum/coherence:

$$S_{lr} = S_{rl} = \gamma S_{\xi\xi} = \frac{\Omega_\gamma^2}{\Omega^2 + \Omega_\gamma^2} S_{\xi\xi} \tag{28.15}$$

and therefore a characteristic familiar for road coherences ($w_\gamma = 2$).

28.3 TIRE MODELS

The development of tire models for vehicle dynamics and ride comfort analyses has progressed significantly over the last few years, both with regard to the model quality and the introduction of quasi standards. Three major model classes with differing complexity and application spectra have now become evident [28]:

1. Map-type models (Pacejka-type models and others) [22]
2. Part-physical models, brush and ring models (e.g., BRIT, MF-SWIFT [32])
3. Detailed tire structure models (e.g., FTyre, RMOD-K [29,30]) (Figure 28.10)

Tire models more or less completely include the elements required for tire analysis:

- Steady-state tire force and torque characteristics
- Vertical stiffness (and damping) properties

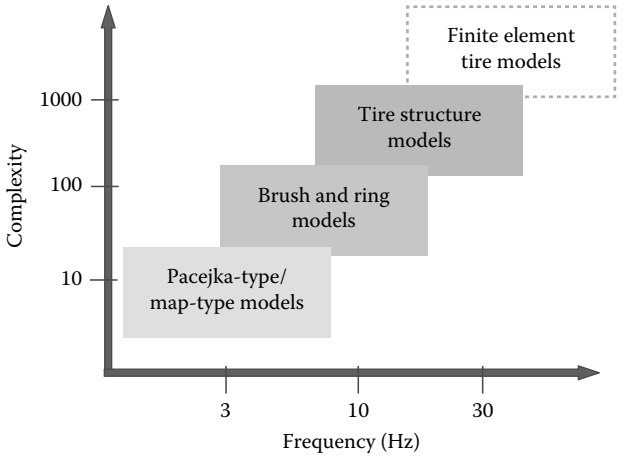

FIGURE 28.10 Rough classification of tire model designs.

- 3D-kinematics analysis/calculation
- Road surface contact evaluation
- Contact patch kinematics and kinetics modeling
- Tire dynamics/vibrations modeling concepts

28.3.1 Application Scope and Related Demands/Requirements

The approved operating range of the different model types overlap nowadays due to constant improvements. Basically, map-type models are primarily suited to typical vehicle dynamics and handling analyses. Part-physical models are required when the database is weaker, but also where severe control system interventions—for example, ABS or ESP interventions—form the focus of the analysis. For comfort and/or vibration analysis, and also for the calculation of durability load profiles, on the other hand, detailed tire structure models must be used in order to attain reliable results. From the current perspective, this model class is still in its industrialization phase. However, practice-related validations against test drive results have not yet been completed. Figure 28.11 gives an overview of the application scope of different tire models [27].

28.3.2 Road, Tire, and Vehicle Interfaces

In vehicle dynamics and driving comfort simulation, tire models are normally formulated as generalized force elements. The input values are the position $\vec{r}_c$, angle $\vec{\varphi}_c$, and speed variables $\vec{v}_c$, $\vec{\omega}_c$ of the rim center imposed by the vehicle. The tire provides feedback from the resulting tire forces $\vec{F}_c$ and torques $\vec{M}_c$, as illustrated in Figure 28.12. During this process, the internal tire contact conditions to the road surface are determined and evaluated. For this purpose, the tire model requires additional information about the road surface contour and, if required, the traction conditions.

28.3.3 Tire Model Parameterization

The parameterization and validation of tire models generally pose a number of problems, as both driving measurements and sophisticated test rig measurements are associated with insecurities and errors. In the case of road measurements, for example, the local friction values cannot be documented reliably, the lateral speed data are relatively imprecise, and the resolution of the force and torque measurements leaves a lot to be desired. Test rig measurements are normally better with regard to the aforementioned issues due to the laboratory environment. However, tire test machines

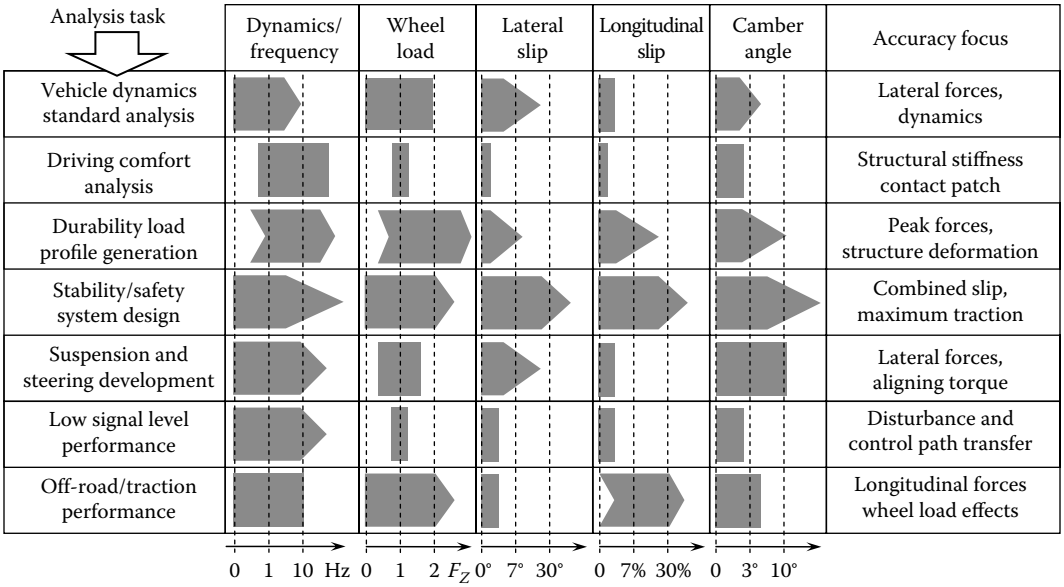

FIGURE 28.11 Application scopes and requirements for tire models for vehicle dynamics, driving comfort analyses, and for durability load profile generation.

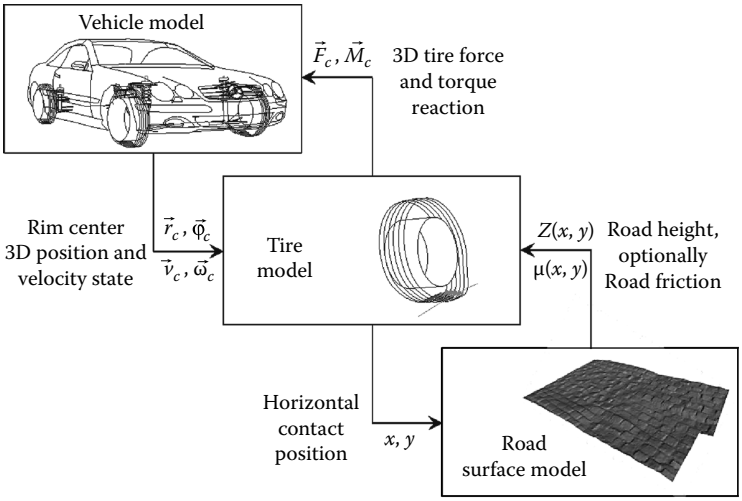

FIGURE 28.12 Vehicle–tire interface and tire–road interaction (refer to Sec. R).

always involve compromises with regard to the road contour (drum curvature, external or internal drum), the road surface (synthetic linings on flat surface and external drum test rigs), and the thermal stressing of the tires. In addition, test rigs are not normally capable of simulating dynamic load cases (exception: road disturbances such as cleats or vertical steps on internal drum test rigs).

Due to these measuring technology restrictions, some tire properties are very well known, others only sketchily. Steady-state tire characteristics have been relatively well researched and can be measured reliably for different wheel loads F_z and different camber angles γ:

- Lateral force side slip characteristics $F_q(\alpha;F_z)$
- Aligning torques side slip characteristics $M_R(\alpha;F_z)$
- Longitudinal force slip characteristics $F_l(s;F_z)$

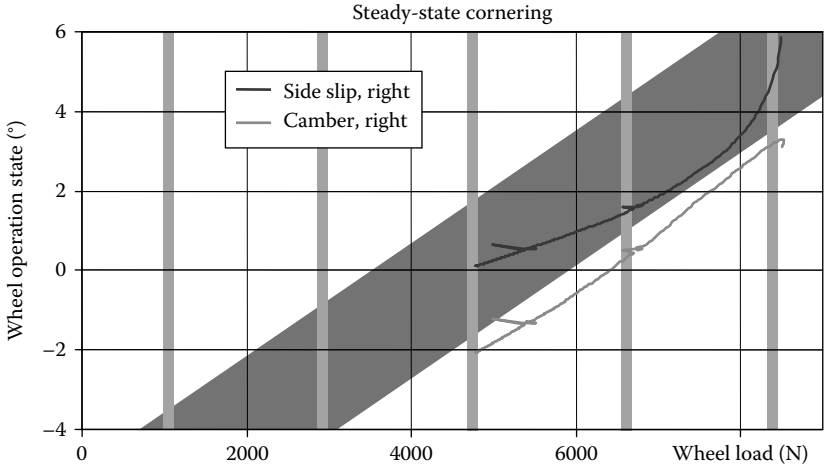

FIGURE 28.13 Comparison of the measuring ranges between conventional tire measurement procedures at constant wheel load (light grey, vertical) and the TIME measuring procedure (dark grey), which is focused on the slip angle–camber–wheel load combinations achievable in dynamically steady state (e.g., steady-state cornering).

This also applies to some extent to combined load cases, for example, $F_q(\alpha;F_z)$ for fixed longitudinal slip s or $F_l(s;F_z)$ for fixed slip angle α.

Measurements at constant wheel load F_z support our understanding of the tire behavior and are well suited to tire model parameterization. Constant wheel loads are not so interesting during driving operation, however. This is why the TIME group has suggested an alternative, vehicle-dynamics-related measuring procedure. The TIME procedure focuses on typical cornering maneuvers, where side slip and camber angle variations are correlated, as illustrated in Figure 28.13.

The TIME concept has two central objectives:

1. To raise as many measuring values as possible in operating points that are dynamically relevant and achievable
2. To protect the measuring tire from high thermal loads, that is, reduction of the measuring range itself to a minimum, reduction of the vehicle speed during measurement, as the related faults are smaller than the effects of excessive tire stress

In the meantime, Pacejka model approaches specifically matching this measuring scheme have been suggested for the approximation of the tire force characteristics [23]. It would be desirable for approaches of this type to establish themselves as standards. However, even in this case, any wider use in the future must demonstrate whether the restriction of the measuring data to essential vehicle dynamics operating points is adequate to determine the tire behavior with sufficient completeness.

28.3.4 Tire Dynamics and Low-Speed Properties

In order to simulate the dynamics of the lateral and longitudinal force generation, the map-type models must (at least) be expanded. In the case of a known lateral tire stiffness c_q^R, this can be realized as follows, for example, for the lateral force dynamics:

$$\frac{\dot{F}_q}{c_q^R|v|} + F_{q,stat}^{-1}(F_q) = \alpha; \quad F_{q,stat}(\alpha) = \mu_{\max} F_z^{eff} f\left(\frac{\alpha}{\alpha_{\max}\mu_{\max}}\right) \tag{28.16}$$

This physical lateral force dynamics approach is based on the fact that the tire road contact patch is coupled via the lateral tire stiffness c_q^R to the rim. Herein, the steady-state tire force $F_{q,stat}$ is defined by a simple map-type approach, based on the friction coefficient μ_{max}, the vertical force F_z^{eff}, a normalized tire force shape function $f(\ldots)$, and the side slip angle α_{max} at side force maximum.

For small displacements, the approach is equivalent to the established relaxation length concept. In contrast, type ($T1$) results—physically consistently—in faster contact force changes for higher slip angles. In addition, the wheel load influence on the lateral and longitudinal force dynamics is represented consistently: This is a typical parameter excitation in the denominator of the first-order system. This explains not only the fast lateral force response to wheel load reductions but also the delayed lateral force build-up in case of wheel load increases. In the same way, the longitudinal force dynamics can be modeled as well. (It is expedient to use steady-state radial forces for the unstable part of the radial force characteristic in order to avoid model-induced limit cycles.)

Another problematic field of tire-modeling technology is the operation at low speeds or at standstill. Phenomenological models generate infinite stiffness values during standstill as the crucial input values—longitudinal slip and side slip—explode as a result of the $|v|$ division. The models are prepared for operation at low speeds by means of more or less elegant numerical tricks such as restrictions of the minimum speed. (This is not a problem for physical models as they use the actual material and structural properties.) The quality of the $v \Rightarrow 0$ implementation can easily be tested by simulating stopping and restarting on a slope, for example, or by steering with different steering rates during standstill. The latter should always yield the same turnslip torques at small steering rates. At the beginning and when the steering direction is changed, the (approximately) constant stiffness of the belt–rim coupling should become visible.

28.3.5 Friction Behavior and Modeling

Tire analyses are most frequently carried out on dry, high-grip road surfaces. Some in-depth studies are available for moist and wet roads [24], and the same applies to tire behavior on snow and ice. However, it can be assumed that the properties of tires have improved in the meantime compared with what is suggested by some studies which are a few years old [25].

Most tire models now allow the overall tire-to-road traction to be specified, that is, to be parameterized. This option allows, for example, to adjust the tire model traction characteristics to specific test track properties.

Looking at part-physical tire models or tire structure models based on the brush model principle, it is necessary to know the actual friction conditions between tire rubber and road in order to be able to parameterize the models sensibly.

The sliding friction properties of the rubber are a small problem in this context, as it has been shown within the framework of the TIME analysis that the vehicle speed has little influence on the tire characteristics (i.e., the sliding speeds attainable in the tire contact area are comparatively small). The sliding friction properties can be regarded as almost constant within the framework of the relevant speed range (exception: driving stability test procedures). They can therefore be reliably identified from the global tire characteristics.

The determination of the (material) friction conditions between tire rubber and road raises more problems on the other hand. Due to the strong coupling with the ground pressure distribution in the model, pure identification approaches are prone to errors. In order to avoid this dilemma, individual direct measurements of the rubber–road friction have been taken on surfaces similar to roads [26], as illustrated in Figure 28.14. These show that the static friction coefficient—in line with the brush model concept—can reach significantly higher values than the global tire–road friction. It also becomes clear that the local ground pressure and therefore the homogeneity of the ground pressure distribution significantly influences the road adhesion potential of the tire.

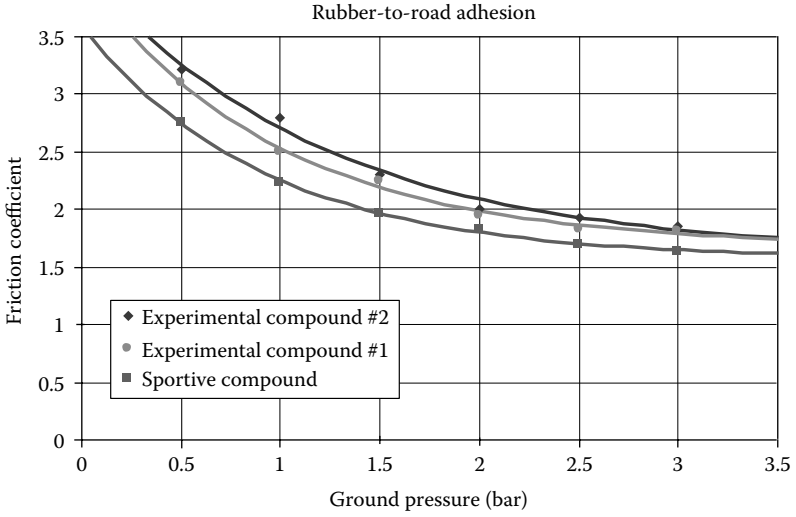

FIGURE 28.14 Material friction capability of a ground-in tire rubber rib on a high-grip road surface (experimental rubber compounds and sportive compound).

28.3.6 Tire Comfort Behavior and Modeling

The tire comfort properties are usually discussed by analyzing the disturbance transfer behavior. In this context, the vertical tire spring rate and the tire dynamics while driving across cleats or—closer to practice—vertical steps are crucial. Figure 28.15 shows such a test rig drive across vertical steps at 80 km/h under side slip stress (equivalent to 30% of the maximum lateral force).

The force and torque curves clearly show the belt vibrations of the tire at different frequencies, from 35 to 350 Hz. The tire vibrations only decrease slowly. This results in the real adverse effect on comfort, as these road-induced vibrations excite other vehicle components in the chassis and body so that it takes some time (despite the higher-frequency excitation) until the whole system calms down again.

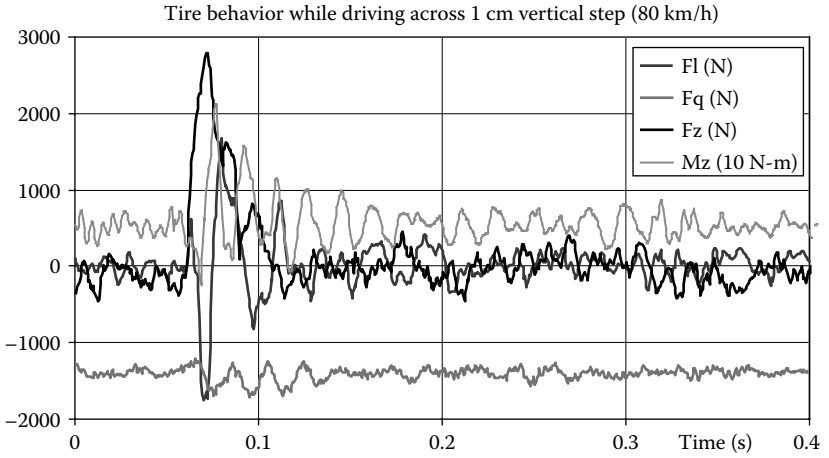

FIGURE 28.15 1 cm–Standard passenger car tire driven at 0.06 s across a vertical step at 80 km/h; for obstacle type, refer to Figure 28.16.

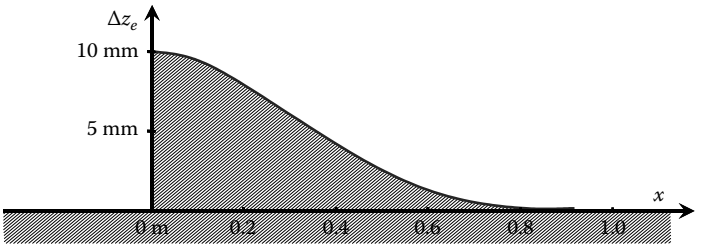

FIGURE 28.16 1 cm–Vertical excitation (+1 cm spontaneous increase, then drop to zero according to second-order system with axle frequency adjustment).

In principle, tire structure–related models such as FTyre or RMOD-K are capable of describing phenomena of this type with sufficient precision. They therefore form the basis for systematic optimization of the tire–chassis–body comfort (Figure 28.16).

Similarly, driving situations for durability analyses should become capable of simulation. It must be taken into account, however, that the force and excitation amplitudes are higher by more than a factor of ten in these cases. Relevant test cases for test rig analyses and validations are currently being examined. It can be assumed that the conventional tire models must be expanded in some form or another in order to supply correct results even under extreme loads. (As the durability of a component typically degenerates with the fourth power of the force amplitude, such simulations need to be extremely precise.)

28.3.7 Challenges in Future Tire Modeling

Some tire properties and phenomena will probably be difficult or impossible to integrate into vehicle/axle dynamics tire models or remain restricted to purely qualitative estimates. This applies in particular to the thermal conditioning of the tire while driving and the related changes in the coefficient of friction, as the necessary flow information is not normally available [37]. This similarly applies to certain comfort effects such as the reduction in the radial stiffness during rolling as against tests during standstill (caused by micro-distortions of the contact patch against the road surface), thermally induced settling effects such as flat spotting, or more generally the prediction of tire comfort characteristics at different operating temperatures.

Instead, the focus will continue to lie on the more precise modeling of the tire at one or a few selected reference temperatures. A measuring program for the largely comprehensive documentation of the tire properties relevant to chassis design requires comparatively elaborate measurements even under these restrictions [27]:

1. Steady-state properties
   a. Steady-state tire force and torque characteristics
   b. Vertical stiffness and damping properties
   c. Standstill aligning torque (turnslip operations)
2. Dynamic properties
   a. Lateral pull experiments (lateral stiffness)
   b. Step steer excitations
3. Vibration and high load properties
   a. Cleat excitations and/or vertical step excitations
   b. Durability load obstacles
   c. Structural stiffness measurements

Another modeling field in the next few years is likely to be a more precise simulation of run-flat tires, as these systems, on the one hand, require the understanding of tire behavior at extremely low

air pressures and, on the other hand, increasingly transfer the load-carrying function from the traditional air suspension-type concept toward a complex rubber-fiber compound structure.

28.4 AXLES: CHASSIS COMPONENTS

The wheel suspension ensures that the translational and rotary displacements of the wheel/road contact associated with jounce and steering motions do not as a whole impair the vehicle behavior, or have a positive influence. This is normally achieved by adjusting the basic kinematics such that vertical road disturbances only exert a small influence on the wheel position and therefore on the force transmission. In analogy, the centers of rotation crucial for the drive and brake-force transmission are selected such that the related pitch and lift motions are largely suppressed.

Besides the kinematics, chassis systems make varied use of the elasticity and damping of chassis mounts and axle components in order to

- Optimize vehicle response in critical driving situations
- Improve ride comfort
- Shape and adjust basic vehicle characteristics such as straight-line stability, precise steering response, crosswind response, etc. in a targeted way

As an example, Figure 28.17 shows the front and rear suspension of a typical mid-class passenger car.

The perceivable ride characteristics of a vehicle are therefore increasingly more dependent on the properties of plastic and rubber materials than conventional metals.

28.4.1 Chassis Mounts and Bearings

In general, three different types of connection elements are typically used as chassis mounts:

- Rubber bushings
- Hydro mounts (in particular for the connection of subframe and body)
- Ball joints

The dynamic properties of rubber mounts and of hydro mounts cannot sufficiently be described in terms of mechanical base elements such as springs, viscous damping elements, or masses. The main reason for this is the complex material properties of rubber products. Under quasi-static load, rubber

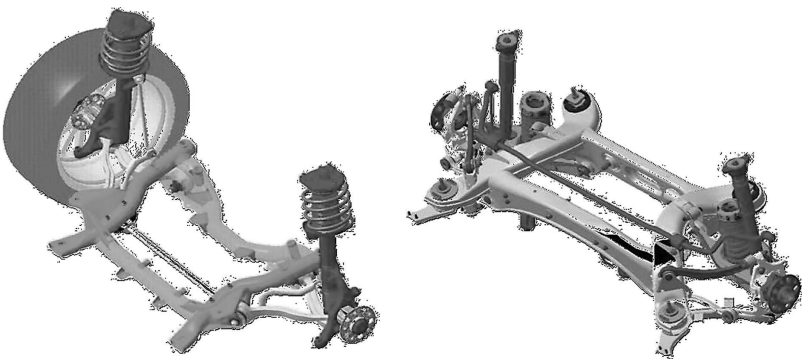

FIGURE 28.17 Wheel suspension of a typical compact model inclusive of subframe and suspension system (front: spring-and-damper wheel location; rear: multilink rear suspension).

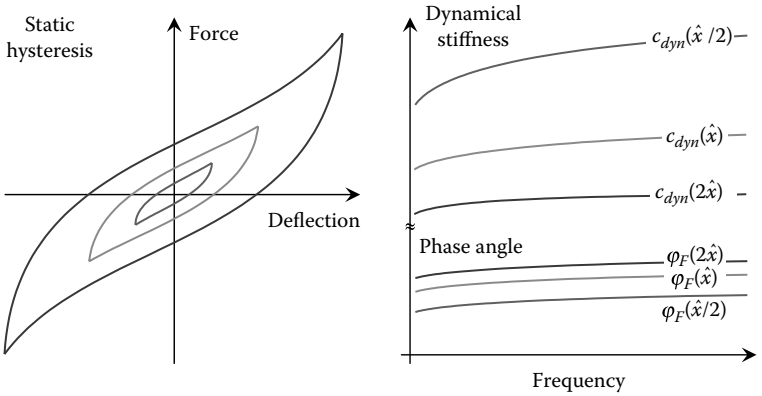

FIGURE 28.18 Quasi-static and dynamic behavior of a typical rubber mount component.

components show pronounced hysteresis effects, and under dynamic load they stiffen, as illustrated in Figure 28.18. The phase and loss angles are mostly small, however, and only increase slightly with the frequency.

In order to model the nonlinear component properties of rubber mounts, multicomponent models are often used which synthesize the observed effects by means of appropriately configured elements. In this process, a nonlinear spring element simulates the basic stiffness, as illustrated in Figure 28.19. The hysteresis effects can be modeled by means of a type of hysteresis generator, that is, a force element explicitly generating the typical curve shapes depending on the preceding movements. Besides these static approaches, Maxwell elements and, if required, a normal damping element are added in order to model the dynamic stiffening under increasing frequency.

The modeling of a rubber mount dynamics with Maxwell and damping elements proves problematic in practice as, with increasing approximation quality, the risk of generating negative loss angles at high frequencies increases. This type can be avoided by means of appropriate restrictions; their very existence shows, however, that shape functions do not ideally suit the system properties.

To avoid these difficulties in principle, an alternative concept has recently been suggested for modeling rubber stiffening on the basis of fractional derivatives [42]. The core idea is that almost all constant phase angles and the amplitudes of rubber hardening, which increase degressively with the frequency, correspond to a dynamic behavior that lies somewhere between the spring and damper. Fractional derivatives allow us to formulate such characteristics.

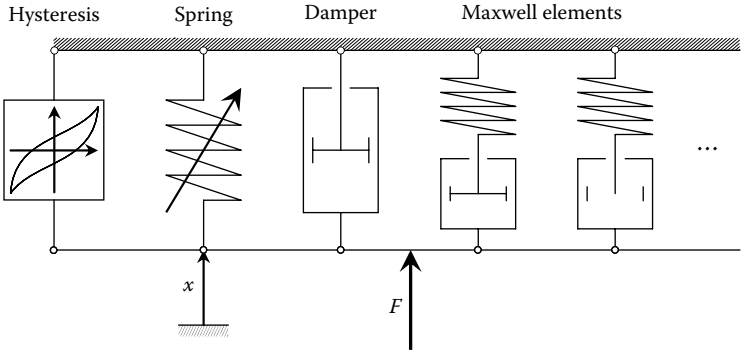

FIGURE 28.19 Synthesis model for a chassis rubber mount.

The fractional derivative $D^{\alpha}\{x(t)\}$ is defined in analogy to the known integer derivative of a time function $x(t)$:

$$y(t) = D^{\alpha}\left\{x(t)\right\} \equiv \overset{(\alpha)}{x}(t) = \frac{d^{\alpha}}{dt^{\alpha}}x(t); \quad \alpha \in \Re \tag{28.17}$$

The signal behavior of the α-times-differentiated signal $y(t)$ therefore results in the frequency domain from the following expression:

$$Y(\omega) = (j\omega)^{\alpha}X(\omega) = \omega^{\alpha}\left(\cos\frac{\alpha\pi}{2} + j\sin\frac{\alpha\pi}{2}\right)X(\omega) \tag{28.18}$$

The phase or loss angle is therefore constant at $\alpha\pi/2$. For signal x available at discrete time steps $\Delta t(x_k = x(k\Delta t))$, the calculation of the fractional derivative y can be reduced to a difference quotient evaluation:

$$y_k = D^{\alpha}\left\{x(t)\right\} = \lim_{n\to\infty}\sum_{l=0}^{n-1} a_l x_{k-l}; \quad a_l = \frac{\Delta t^{-\alpha}}{\Gamma(-\alpha)}\frac{\Gamma(l-\alpha)}{\Gamma(l+1)} \tag{28.19}$$

Herein, $\Gamma(n+1) = n!$ is the so-called gamma function, a continuous expansion of the factorial. In practice, the series expansion must be truncated at a predefined ordinal number n. This results in certain deviations from the continuous approach (28.18) at low frequencies, but should be acceptable for most applications as the coefficients a_l converge with increasing l quickly toward zero.

The frequency response of the discrete fractional model system finally results as follows:

$$F^{n}_{x>y}(\omega) = \frac{Y}{X} = \sum_{k=0}^{n-1}(\cos k\omega\Delta t - j\sin k\omega\Delta t)a_k \tag{28.20}$$

Figure 28.20 shows the transfer behavior of a standardized discrete fractional model (time step width $\Delta t = 3$ ms, system orders $n = 10$ and $n = 100$) in comparison to an exact, continuous approach at a derivative step of $\alpha = 0.15$. This corresponds to a loss angle of 13.5°. This shows clearly that this approach fits in well with the rubber-typical, almost-constant phase responses and with the amplitudes which increase degressively with increasing frequency. The deviations from the continuous approach at small frequencies are essentially determined by the absolute filter length, that is, product $n\Delta t$. The differences are insignificant, however, as only the deviations from the real mount frequency responses are decisive for the quality of the mount modeling.

In addition, there is a series of longitudinal rotary bearings, for example, in shock absorber struts or shock absorbers, which normally result in deflection-dependent bending stiffness values and in quite complex load–friction interactions [4,43,47]. This phenomenon cannot be discussed in detailed here, however.

In general, the elastokinematic design of a chassis is based on the fact that the geometrical position of the wheel (location and angle) changes under the influence of the wheel forces and can be adjusted in a targeted way. Effects of this type can be used, for example, to improve the vehicle behavior while cornering, as illustrated in Figure 28.21.

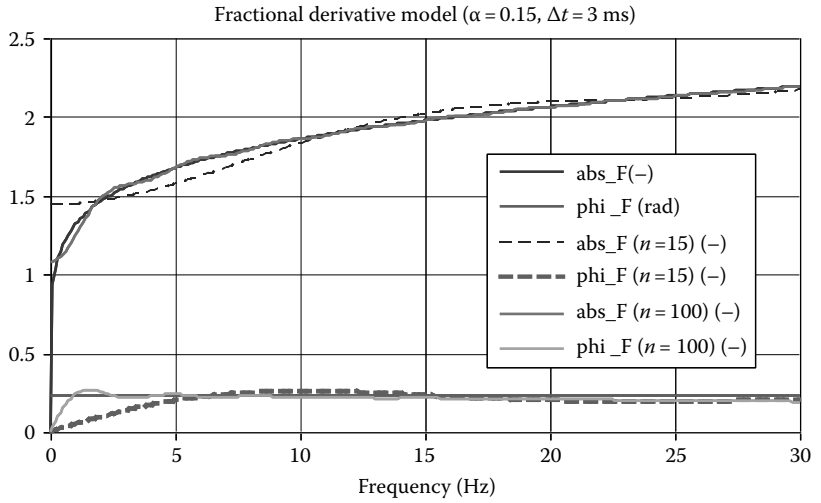

FIGURE 28.20 Frequency response of a rubber mount model on the basis of fractional derivatives.

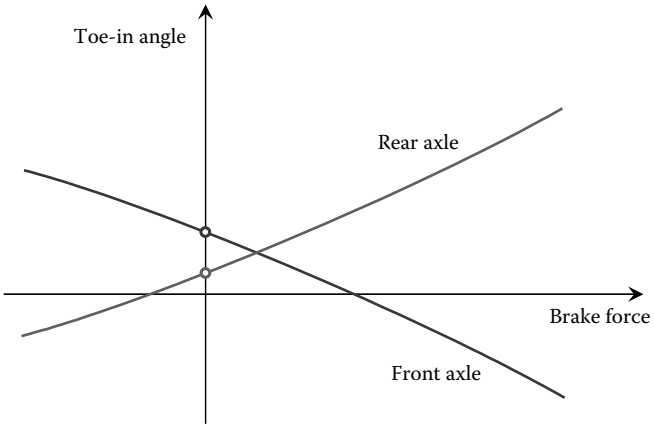

FIGURE 28.21 Elastokinematic optimization of the vehicle steering tendency during braking while cornering.

28.4.2 Elastokinematic Adjustment

Vehicle braking leads to displacement of the wheel loads toward the front. Consequently, the front wheels generate somewhat higher lateral forces—at a given slip angle. The lateral forces at the rear axle decrease accordingly. This is further reinforced by the additional stress due to the longitudinal force. This would result in the vehicle turning strongly toward the inside of the corner.

To avoid irritations for the driver, attempts are made to ensure that the vehicle behavior changes only a little or not at all during braking. This can be achieved by means, among other, of the measures shown in Figure 28.21. Here, the front axle goes into toe-out during braking, the crucial outer wheel therefore reduces its slip angle, and the disturbing increase in the lateral force is avoided. Vice versa, an additional side slip angle is generated elastokinematically at the rear axle counteracting the wheel-load-induced reduction in the lateral force or compensating it. Altogether, the resulting vehicle behavior is largely neutral to brake applications while cornering. (In contrast, the toe-in changes during μ-split braking should be adjusted in the opposite direction in order to improve vehicle directional stability.)

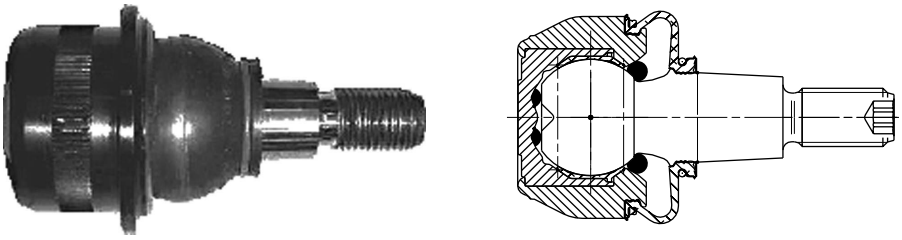

FIGURE 28.22 Chassis ball joint (cross section).

As the force transfer mechanisms are generally different for drive and brake forces and steering torques in the axle, noticeable improvements in the vehicle behavior can be achieved at least in the case of multilink suspensions, but within certain limits also for simpler axle concepts, by means of targeted force control interventions. The functionally relevant components for the elastokinematic design are the chassis mounts and—to a certain extent—the larger elasticities of the axle components themselves. In addition, chassis mounts fulfill a number of decoupling and isolating functions as they provide for a more resilient wheel–vehicle connection and therefore help suppress the transmission of disturbing excitations. However, synthetically introduced elasticity always promotes the restraint and natural vibration potential of the chassis. During chassis adjustment, a sustainable compromise must therefore be worked out between global control and isolating properties and the self-excitation tendencies of the chassis.

From a modeling point of view, probably the most simple and clear chassis mounts are ball joints, typically installed close to the wheel (refer to Figure 28.22). These joints generally demonstrate a comparable stiffness in all directions in space. The stiffness values reach around 10 kN/mm or more. Compared to other axle components, these are therefore quasi-rigid connections. The damping effect is correspondingly small or even negligible. Due to lifetime requirements, ball joints must be strongly pretensioned internally. This means that rotating movements are always associated with larger friction torques of some newton meters. To be able to correctly simulate the influence of the mount phenomenologically, especially with clearly differentiated adhesion and sliding states, some special integrator settings must be determined even for modern MBS systems.

28.5 SUSPENSION SYSTEMS

Suspension systems in vehicles have a number of different functions; they

- Carry the load of the vehicle body
- Compensate road irregularities and torsion effects
- Dampen and smooth road and vehicle dynamics–induced vibrations
- Ensure that the wheel travel limitations are sufficient

so that these functions can be fulfilled in practically all possible driving situations without damage to the vehicle or chassis.

Depending on the chassis design, spring–damper systems are either focused on separate components such as in multilink or double wishbone axles, or integrated into the wheel suspension system, for example, in McPherson or shock absorber strut independent suspensions. The latter generally results in a reduced installation space and weight, although it usually requires more elaborate detail solutions in order to suppress the mutual interferences of the design elements in a restricted space, for example, sophisticated strut top mounts that separate the vertical spring, damper, and lateral force transfer paths.

28.5.1 Steel-Spring Suspension and Suspension Characteristics

With regard to modeling, the body springs, that is, the supporting springs and stabilizer bars, are comparatively straightforward components. For their simulation with good approximation, it is sufficient to know the partly nonlinear spring characteristic. For individual wheel suspensions, the wheel jounce or distance of the spring mount points form the model input value for the suspension model; in the case of rigid axles, on the other hand, both wheel jounce values of an axle contribute to the spring deflection. For the stabilizer bar displacement, the difference in the jounce values between the left-hand and right-hand vehicle side is decisive; they generate a counteracting force couple that primarily counteracts roll movements.

For more precise analyses of the wheel suspension or axle dynamics, it is sometimes necessary to explicitly model the kinematics and design details of the spring and/or stabilizer bar construction and their mounts. For example, the internal vibration modes of a coil spring play a role with regard to the tire comfort. In the same way, the stabilizer bar mounting and, in the case of complex stabilizer shapes, maybe also their force transfer perpendicular to the actual effective direction, can improve, but also impair, the wheel suspension and steering properties.

The contribution of suspension spring components to the wheel suspension movements is especially obvious in the case of leaf springs guiding rigid axles. They are often used in commercial vehicles, in particular, because of their extraordinary robustness. The calculation of the kinematics and elastokinematics is particularly time consuming in this case, as many effects that can otherwise be separated are strongly coupled. An example is the support of the brake forces by the leaf springs, which results in axle pitching and jounce effects during braking and, therefore, among others, couples the brake control adjustment with the chassis design.

28.5.2 Air Suspension and Air Suspension Modeling

In contrast to steel spring suspensions, air suspensions and hydropneumatic arrangements generally require more detailed consideration of the relevant media and interconnections. In both cases, the actual suspension effect is achieved by means of compression of a gaseous medium. In the case of air springs, the operating pressure level usually amounts to some 10 bar, while hydropneumatic systems commonly reach operating pressures of 50–80 bar. Since typically simple, low-molecular gases are used, the pressure changes can be determined on the basis of the ideal gas equations. For slow, isothermal processes and fast, adiabatic volume changes $\dot{V}$, the edge case models apply (adiabatic exponent κ):

$$\dot{p}_{isotherm} = -\frac{p}{V}\dot{V}; \quad \dot{p}_{isotrop} = -\kappa\frac{p}{V}\dot{V} \tag{28.21}$$

In practice, the system always exchanges thermal energy with the environment. This results in a delayed pressure change:

$$\dot{p} + \omega_g p = -\kappa\frac{p}{V}\dot{V} + \omega_g\frac{p_0 V_0}{V}; \quad p_0 = p(T_u); \quad V_0 = V(T_u) \tag{28.22}$$

The heat transfer effects of the system are summarized in the limit frequency constant ω_g, p_0 represents the system reference pressure at ambient temperature T_u, and V_0 is the corresponding system volume. Depending on the system size and surface design, limit frequencies ω_g indicating delay times up to several seconds can occur—the latter predominantly in commercial vehicle air suspension systems. (This makes the technical analysis and assessment of air suspension systems more difficult, especially on laboratory rigs, as the thermal conditions must be precisely determined and checked.)

Besides comfort improvements mainly based on very low spring rates, gas-operated suspensions also have the advantage that the spring rate adjusts itself to the wheel load and therefore the vehicle load. The reduction in the natural system frequency with increasing load, which can normally be observed, is therefore avoided and in some cases even overcompensated.

Air suspension chassis also allow the spring rates to be adjusted to the vehicle operating requirements—by means of an appropriate design of the bellows characteristics. Similar results can be attained in the case of hydropneumatic suspensions by using several accumulators, whereby design possibilities are quite limited. Hydropneumatic chassis are of greater interest as a basis for active suspensions as they can be installed in a small space at reasonable cost and as they can easily be activated. At present, some tire comfort compromises due to problematic high-pressure sealing properties still exist which need to be overcome.

28.5.3 Dampers and Damper Modeling

Vehicle dampers are more complex with regard to modeling, as due to their design they respond very differently, depending on stress amplitude and frequency. Figure 28.23 shows the design of a single-tube damper that represents the most simple damper design. The nonlinear restrictor valves $\Delta p(s)$ installed in the damper piston determine the actual damper characteristic $F_d(\dot{x})$:

$$F_d = A_k p_k - A_s p_s; \quad p_k - p_s = \begin{cases} \Delta p_{Druck}(s) & \text{für } \dot{x} \geq 0, \\ \Delta p_{Zug}(s) & \text{für } \dot{x} \leq 0; \end{cases} \quad s = (A_k - A_s)\dot{x} \tag{28.23}$$

In order to be able to absorb the volume of the damper piston rod during compression, a small pressure chamber V_G is arranged on the damper floor. The gas contained therein is precompressed, usually at pressures p_G of 10–30 bar, so as to keep the rod side at positive pressures at all times. The precompression pressure is associated with a damper base force that is always positive:

$$F_G = (A_k - A_s)p_G \tag{28.24}$$

Due to the coupling with the gas volume, the piston pressure $p_k \cong p_G$ roughly corresponds to the gas pressure. The piston pressure fluctuations are relatively small, that is, the damper force spread occurs on the rod side.

As dampers are required to remain functional over a relatively long lifetime, high-performance seals and guides are used. In combination with the pressure preload, this means, however, that dampers will tend to "harden" at small excitation amplitudes. The force response of the damper then includes a pronounced elastic content; the phase turns from 90° into the direction of 0°.

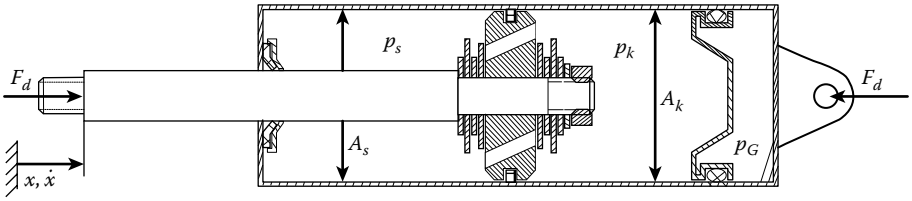

FIGURE 28.23 Design of a single-tube gas pressure shock absorber.

As the seals have a certain longitudinal elasticity (longitudinal stiffness c_D), the hardening effect can be modeled elegantly using spring-friction elements:

$$F_R = \min\left(\max\left(c_D \int \dot{x}dt;\quad -F_R^{\max}\right); F_R^{\max}\right) \tag{28.25}$$

Besides the external seal, the damper piston seal and the dividing piston contribute to the friction and hardening effects. In this process, the maximum friction force $F_R^{\max}$ is influenced by the current damper pressures p_s, p_k. In the event of higher-frequency damper stresses, the compressibility β of the damper medium has to be taken into account as well:

$$\beta = -\frac{\partial V}{V \partial p} \approx \frac{3 - 8 \times 10^{-5}}{\text{bar}}. \tag{28.26}$$

Typically, the effective compressibility β_{eff} is somewhat higher, as the damper body and sealing elements contribute additional elasticity. Examples of the consequences of the hardening and dynamic effects are shown in Figure 28.24.

In the event of very severe, fast damper excitations, the damper pressure on the rod side can briefly drop to steam pressure level. This results in local oil cavitation. Small steam bubbles emerge and collapse again. During normal driving operation, the damper design ensures that this operating state does not occur. During the so-called rough road testing, that is, during extreme durability tests on irregular tracks, it is hardly possible to avoid cavitation effects. To model the major effects, it is sufficient to adopt an additional pressure chamber at steam pressure level that fills dynamically when the steam pressure level is reached—and empties itself once the rod side pressure p_s increases again.

For the modeling of double-tube dampers, the same basic elements can be used again. However, the dividing piston is eliminated, and instead additional valve elements are to be added.

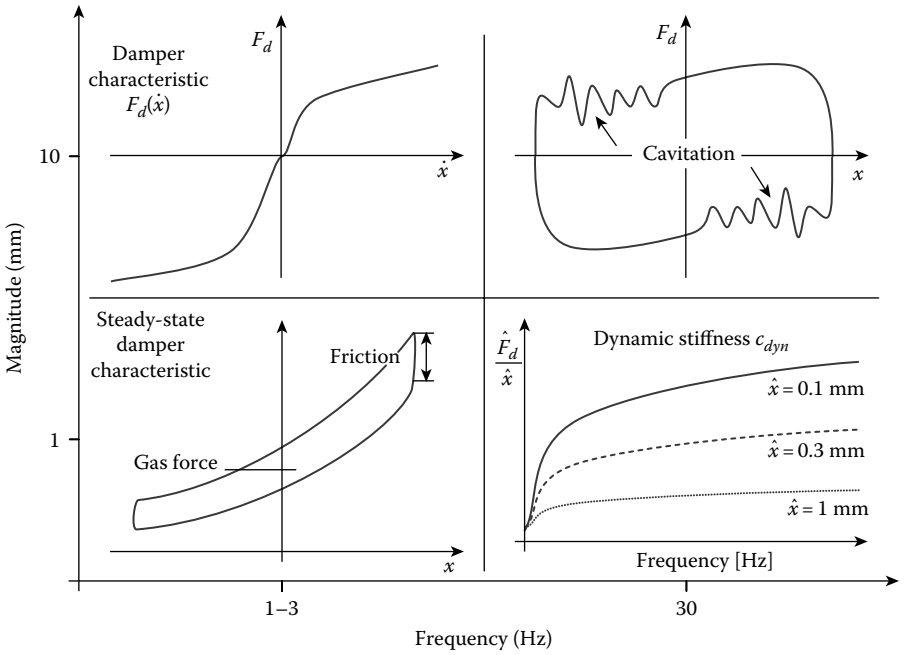

FIGURE 28.24 Aspects of damper characteristics in relevant operating ranges.

28.5.4 Variable Damper Systems

In the case of variable damper systems, bypass channels are usually added in order to allow the exchange of media between the rod and piston side by means of a switchable or continuously adjustable control valve. The basic damping is then normally increased strongly; control interventions therefore result in a reduction in the damping forces.

The related damper controls are mostly intended to adjust the damper hardness to the relevant driving situation. Fast control concepts influencing individual wheel movements have not so far been implemented in production vehicles, as on the one hand the required cycle rates result in high requirements with regard to computer capacity and signal processing, and on the other hand also damper speed measurements with very fine resolution would be necessary in order to make targeted use of the control intervention via the damping constant. Variable damping concepts influencing the force or differential pressure would resolve the sensor problem, but has not been so far realized robustly with the present technology.

Due to the inevitable hardening effects, dampers are normally connected to the chassis using rubber mounts. Their characteristics are adjusted such that the mounts react very softly to small deflections and therefore mask the friction effects. In the event of larger damper forces, however, high mount stiffness values occur so that the damping effect can impact on the chassis without major losses and act to reduce the body energy. All in all, a very low damping of smaller wheel vibrations of some 1–2 mm is therefore tolerated which does not noticeably reduce the ride comfort.

For commercial vehicles and some passenger cars, piston position–dependent dampers are sometimes used in order to be able to adjust the damping intensity depending on the load or in order to ensure by intelligent interconnection of bypass channels that the damper fills a pressure buffer during wheel movement, thus keeping the vehicle at its target level.

28.5.5 Push and Pull Stops

Due to the centering and longitudinal guides already in existence, the wheel movement stops are often integrated into the shock absorbers. The rebound buffers are usually straightforward progressive steel springs which "catch" the wheel elastically on lifting from the road before the mechanical spring travel limiters are reached. In contrast, the jounce buffers must be capable of absorbing sudden load peaks between the wheel and vehicle body in a limited installation space without endangering the body structure. Polymer foam stops fulfill this function quite efficiently as they counteract the jounce movement with high, progressively increasing forces. During the final rebound, they reach a much lower force level, however. This means that the mount directly reduces a significant amount of the kinetic energy. In modeling, these hysteresis effects can be approximated in a similar way as with rubber mounts (refer to Section 28.4).

28.5.6 Active Suspension Systems

Besides the conventional suspension systems described, a series of active suspension concepts have been developed over the last few years which are intended to resolve or at least attenuate the classic design conflicts between comfort and safety-oriented vehicle adjustments [45]. In principle, a distinction can be drawn between systems intervening on axles and individual wheel concepts.

The former activate the stabilizer bar, that is, they allow the imposition of stabilizer torsions generated by actuators or the generation of synthetic stabilizer forces. The main benefit of these systems is to influence the roll movements of the vehicle in a targeted way. (This is also where the internationally used designation ARS—active roll stabilization system—originates.) In most cases, the roll movements are simply suppressed by actuator elements up to the performance limits of the systems. The result is a vehicle which feels more stable and easier to control. Driving is

made much easier as the driver is actually no longer required to correct the vehicle roll by using his or her own orientation. However, this also means that these systems can be used to shape or to shadow vehicle roll properties that can be seen as a major and impressive vehicle stability indicator for normal drivers.

Technical realizations of active stabilization systems are based either on angular or torque actuators which are integrated either into the stabilizer itself or into hydraulic cylinders instead of the otherwise customary pendulum supports for stabilizer-wheel movement coupling. The latter are technologically more elegant, but require a certain minimum installation space. The modeling of the actuators is very specific to the system. In connection with pendulum support actuators, in particular, hydraulic diagonal coupling of the axles has been under discussion, in particular, with the aim of improving off-road performance. In individual cases, it will therefore be necessary to create very detailed models of the hydraulics networks to be able to optimize the layout and to assess and optimize the always very complex dynamic effects due to the normally rather long hydraulic connection lines.

Active suspensions controlling individual wheels fully include ARS systems as far as the range of functions regarding control of roll movements and wheel loads is concerned. They also allow for both vehicle level and vehicle pitch motions to be influenced in a targeted way. Figure 28.25 shows the two major design types: active hydro-pneumatic (AHP) and active body control (ABC) system.

In the ABC system, a hydraulic cylinder is arranged in series with a stiffer suspension spring. This allows the suspension level to be changed quickly and in a targeted way, sometimes against the shock absorber forces. Due to the series arrangement of suspension spring and actuator, ABC systems require a comparatively high installation space. The suspension spring, on the other hand, ensures that the overall comfort can reach the level of sophisticated conventional spring–damper systems. Depending on the system design, control limit frequencies of 3–8 Hz are reached, that is, the body motions can be controlled fully and confidently.

Active hydropneumatic systems are, in contrast, much more straightforward and space saving. Instead of the conventional spring–damper unit, a simple hydraulic cylinder is used that does not require significantly more space than a shock absorber. The basic suspension is taken over by a gas pressure accumulator. Damper valves are integrated in the connecting line which is kept as short as possible. The system is activated—in analogy with ABC or ARS systems—by controllable valves in combination with a high-performance pressure supply. The only, but decisive, disadvantage of AHP systems is the fact that friction effects in the load-bearing hydraulic cylinder give rise to a loss of comfort, which so far has ruled out its wider use in sophisticated vehicles.

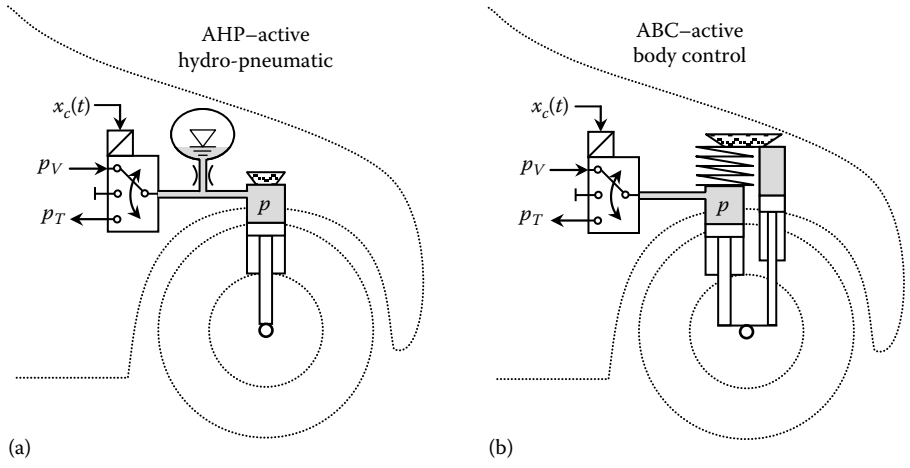

FIGURE 28.25 Types of active suspensions controlling individual wheels: AHP system (a) and ABC system (b).

The statements already made with regard to ARS systems equally apply to the modeling of active suspensions: Only on the basis of relatively elaborate detailed hydraulic system modeling can the dynamic transfer properties of the network be understood, interactions detected, and weak points or resonances be eliminated by targeted measures. For AHP and ABC systems, even more so than in the case of simpler ARS controls, the productive interaction between hydraulics, chassis mechanics, and control is decisive for good vehicle dynamics and comfort properties.

28.6 STEERING SYSTEMS

From the perspective of the driver, the steering system is supposedly the most important control intervention and also one of the most important sources of information about driving conditions.

28.6.1 Power Steering Systems

In order to keep the forces required to control the vehicle as small as possible, but at the same time allow sufficient design leeway for the optimization of the chassis in different velocity ranges, vehicles are today (almost) exclusively equipped with power steering systems. This means that the steering linkage, the connection between the steering wheel and axle steering, includes a reduction gear and at least one force-sensitive element as well as a hydraulic or electromechanical actuator.

Figure 28.26 shows a diagram of the most common steering design in use today, a hydraulic rack-and-pinion steering system. Figure 28.27 illustrates components of a vehicle power steering system. It becomes evident that many more than the basic elements described at the beginning are required for the design of a steering system.

Due to their high peak power, power steering systems require an efficient pressure supply. For this purpose, flow-controlled vane pumps are generally used with a delivery rate of up to 15 L/min and peak pressures of up to 150 bar. In smaller vehicles, it is possible to drive the power steering pumps by means of electric motors, thus avoiding a series of packaging and interaction problems.

Figure 28.28 illustrates the major hydraulic components of a vehicle power steering system. A torsion bar rotation, that is, the mechanical displacement of the torque-measuring element effects

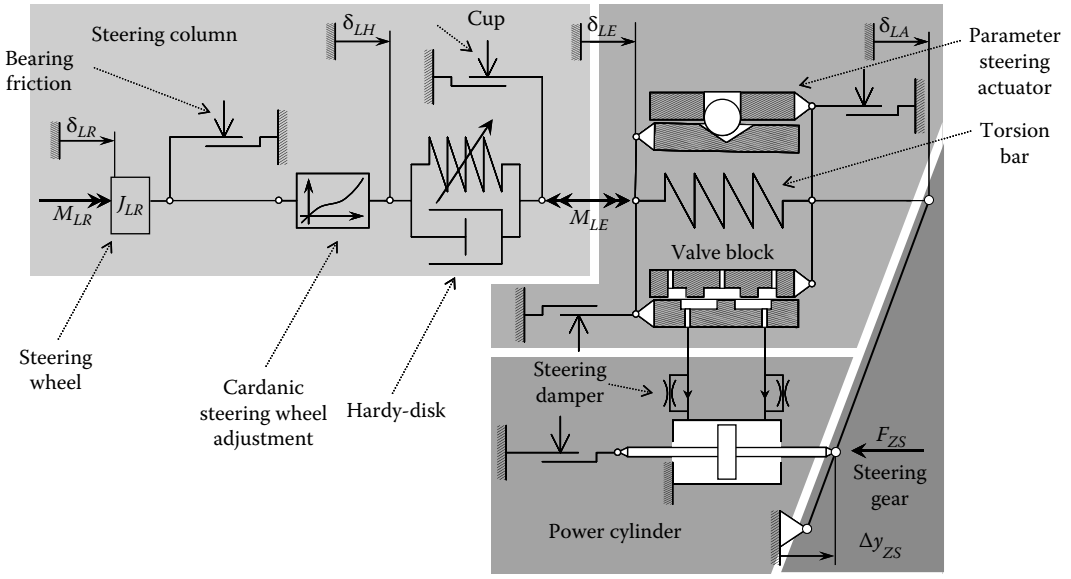

FIGURE 28.26 Mechanical function diagram of a vehicle power steering system, in analogy with a servo-hydraulic rack-and-pinion steering system.

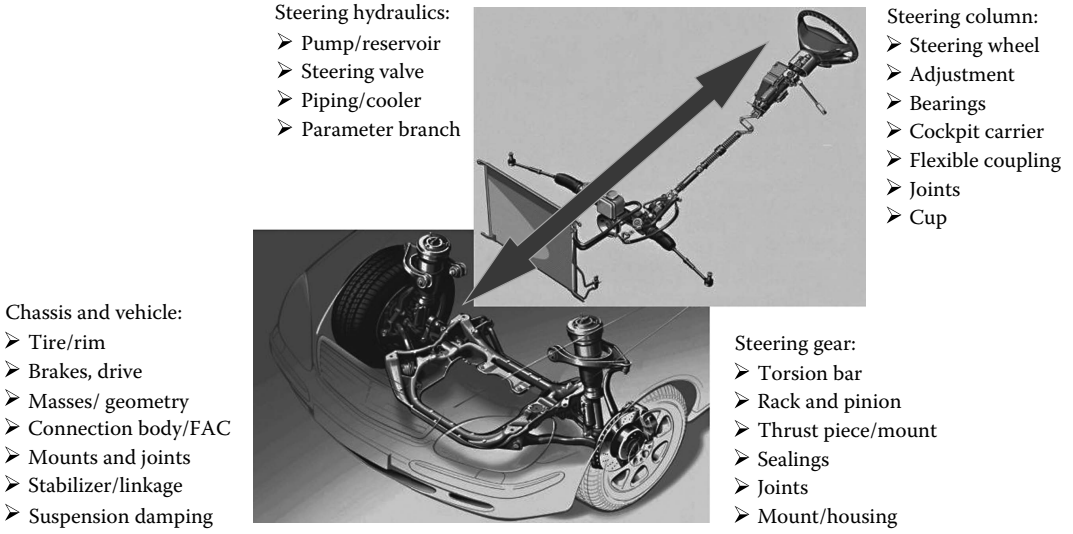

FIGURE 28.27 Hydraulic power steering system of a luxury passenger car (Mercedes S-Class, 2002): major components and parameters influencing the steering behavior.

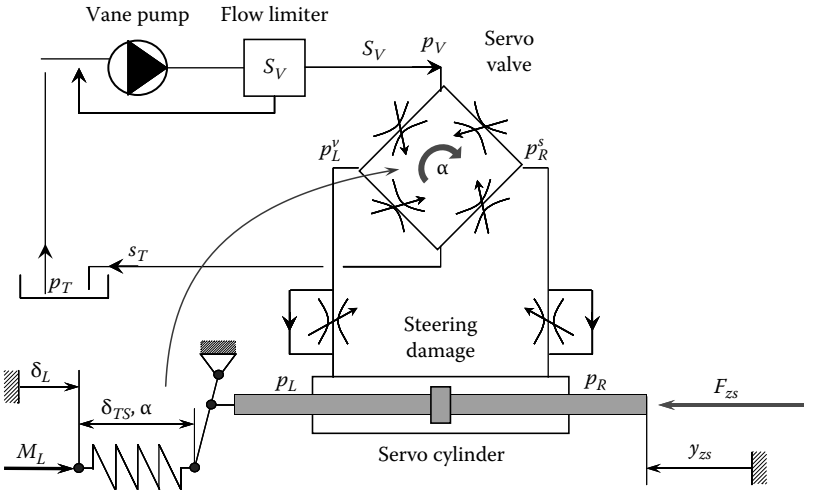

FIGURE 28.28 Basic hydraulics components of a vehicle power steering system (without parameter steering branch/function).

the displacement of the servo valves. These are arranged in a bridge design within the valve block so that valves facing each other diagonally are actuated simultaneously. At a (approximately) constant supply flow rate, the bridge asymmetry results in a pressure difference between cylinder surfaces and therefore to the steering-assisting power. To suppress road and chassis disturbances effectively, unidirectional steering damping valves are installed at the cylinder outlets. These oppose any disturbing excitations directly with matching damping forces. In practice, the damping effect must be restricted, however, in order not to impair quick steering movements by the driver. (For example, during emergency maneuvers, steering wheel rates of up to several hundred degrees per second may be required.)

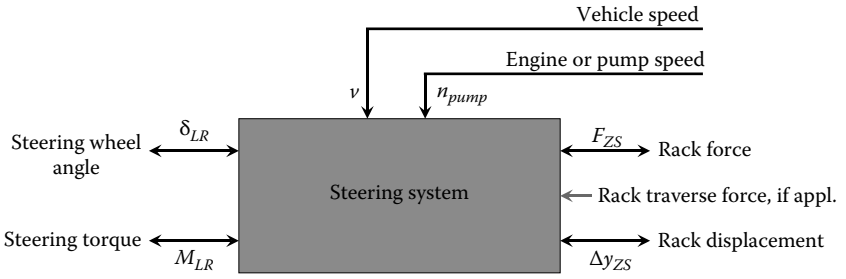

FIGURE 28.29 System limits of a vehicle steering system: four-pole characteristics with primary interaction parameters–steering wheel angle, steering wheel torque, lateral rack displacement, and rack force.

28.6.2 Transfer Characteristics

The steering wheel angle δ_L is probably the primary steering input variable in most driving situations; the steering wheel torque M_L therefore becomes a response or output variable. On transversely inclined roads or under crosswinds, the driver interventions point more toward some type of torque control, and the same applies to sudden interfering road surface excitations [58].

The interaction between the steering system and axle proves similarly complementary: By means of the transverse displacement of the rack y_{zs} relative to the vehicle (or relative to the front axle carrier), the steering imposes the wheel steer angle δ_R on the axle. On closer examination, however, it appears that the steer angles are created from an equilibrium of forces and torques around the chassis steering axles. A further contribution is made by the tie rod forces which are directly related to the transverse rack force F_{zs} of the steering. This also means that no unambiguous input–output behavior can be observed at the interface between the steering and chassis. The steering must therefore be understood and described as a general dynamic four-pole, as illustrated in Figure 28.29.

28.6.3 Steering Models for Vehicle Behavior Analysis

It is expedient to determine the quasi-stationary steering characteristics first for vehicle dynamics and vehicle behavior analyses in order to model the transfer properties for the relevant operating point adequately. Models of this category take into account

- The inertias of the steering wheel and steering column (the inertias of the rack and tie rods are normally added to the degrees of freedom of the axle steering)
- The steering ratio/ratio variations above the steering angle due to inclined joint positions, gearing nonuniformities, or also design gear ratio spreads
- The inner elasticity, damping, and friction of the steering column
- The power assistance, which is normally dependent on the traveling speed

For simple servo valve geometries, the resulting servo forces ΔF_{servo} can be determined directly from the valve resistance values. When friction effects are neglected, a steering torque M_L at a given steering ratio r_L generates a rack force F_{zs} of

$$F_{zs} = \left[\frac{1}{r_L} + \frac{\Delta F_{servo}^{\max}}{M_L^{\max}} \left(\frac{1 - \left(M_L^{\lim} / M_L^{\max} \right)^2}{1 - \left(\min(M_L; M_L^{\lim}) / M_L^{\max} \right)^2} \right)^2 \right] M_L \tag{28.27}$$

whereby ΔF_{servo}^{max} is the maximum servo force, M_L^{max} the related steering wheel torque, and M_L^{lim} the remaining design parameter for the servo characteristic. M_L^{max} is generally hardly smaller than M_L^{lim}. The servo characteristics are therefore very flat around the zero position which reinforces the steering feel during straight-line driving. Vice versa, high steering assistance forces are generated for larger steering torques, for example, during parking. All in all, a very strong nonlinear system characteristic results.

A further problem field in steering analysis and modeling is friction. Friction arises at different locations, among others in the steering column, in the servo valve block; between pinion, rack, and thrust piece; and on the seals and guides of the hydraulic cylinder actuator. Altogether, friction forces of up to 150 N are required, for example, to move the rack with free steering wheel. The various friction points always have design causes, but friction is also used in a targeted way in order to optimize the disturbance transfer behavior of the steering system.

With regard to modeling, several problems result at once: On the one hand, the distributed, sequential friction points in the steering system hardly allow the assignation of the overall effects to the responsible components without splitting up the steering system itself. On the other hand, some of the friction effects are directional, that is, different friction forces are generated for control and disturbance excitations. In addition, some of the friction effects directly depend on the hydraulic pressure—and thereby on the overall system state. (Unfortunately, this similarly applies to electromechanical steering systems.)

28.6.4 Detailed Steering System Models for Axle Dynamics Analysis

Due to these premises, detailed steering models for axle dynamics and vibration analyses are normally sophisticated mechanics–hydraulics compound models with some control extensions, for example, for the representation of parameter steering functions.

The mechanics include, among others, the steering column up to the entry of the steering gear as 1D torsion mechanics or as 3D mechanics model. Steering gears and the steering axle coupling are formulated as 3D mechanics models, in particular, in order to be able to model the effects of the steering mounting in different operational states adequately.

The steering hydraulics must take into account the following components at least:

- Power steering pump
- Flow control and pressure limiter
- Servo valve bridge circuit
- Expansion hoses
- Steering damper valves
- Servo actuator (hydraulic cylinder)

In addition, the modeling of the hydraulic parameter steering components should be considered. This is highly dependent on the manufacturer, however, and cannot therefore be discussed here with general validity. In principle, the parameter or map-controlled steering systems are always identical: A relatively small part of the flow is branched off at pump pressure level p_V; this is accumulated by means of a series of restrictor valves and a relatively slow control valve. The resulting control pressure is used to generate an internal steering torque to reinforce the torsion bar rotation. The required steering torque at low speeds and during parking is thereby reduced (refer to Figure 28.26).

Detailed steering system models are used for the optimization of the steering dynamics and improved adjustment of the disturbance transfer behavior, that is, to avoid steering shimmy, nervous steering, or steering kickback. All adjustment work in this sector is finally targeted at making the tire–road–steering system robust against disturbance excitations while at the same time safeguarding the primary control characteristics (direct, taut steering sensation, freedom from play, etc.).

Looking at the steering kickback phenomenon, that is, excessive steering wheel reactions when driving over bumps while cornering, it becomes clear that a justifiable distribution of the requirements

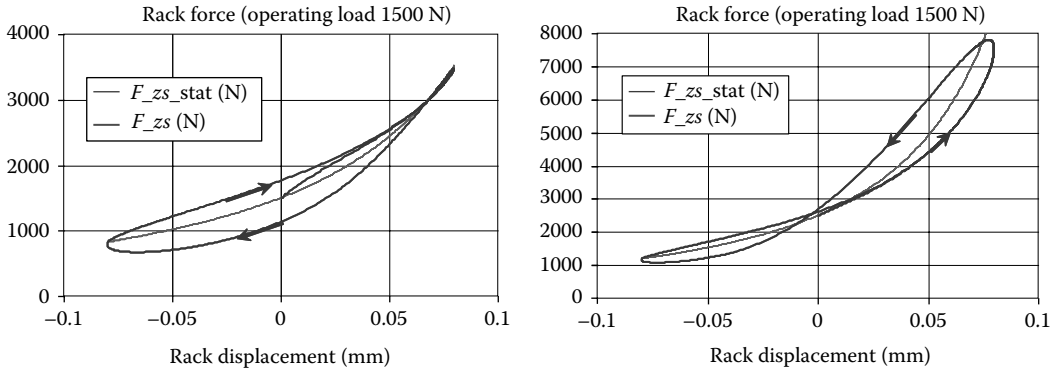

FIGURE 28.30 Disturbance behavior of a power steering system during cornering with high transverse force level, illustrated by a harmonic rack excitation at a frequency of 15 Hz; disturbance force amplitudes of 1.5 kN are absorbed and damped, while disturbance amplitudes of 2.5 kN result in an exciting steering response.

between the steering and chassis must be found or worked out: In this load case, the excitations from the road surface directly generate vertical and transverse axle vibrations resulting in tie rod force fluctuations and therefore steering disturbances. In the event of smaller force excitations or slower force changes, the steering has a damping effect and reduces the exciting energy quickly and efficiently. If the excitation exceeds a certain force or dynamic level, however, the steering system will at first have an exciting effect, as illustrated in Figure 28.30. As, due to the principle involved, this effect can occur in any hydraulic power steering system, the problem is solved conceptually in that the steering, on the one hand, has to cope with a defined dynamic force level by damping and not exciting, and in that the tire–chassis compound on the other hand ensures, in driving situations relevant to bump steering, that this steering limit force and disturbance force level are not exceeded.

28.6.5 Active Steering Systems

In addition to the conventional steering design, different types of active steering systems (torque and superimposed angle steering systems) have been discussed or are in use for some years. A large part of the conventional steering design is normally adopted or retained in these steering systems. The additional functions are realized by means of specific actuators in the steering linkage, as illustrated in Figure 28.31.

Active torque steering systems allow the additional imposition of synthetic steering torques ΔM_L and steering forces ΔF_S, either by appropriately controlling already existing steering actuators or by integrating additional torque actuators (e.g., electric motors) into the steering column. This allows advanced safety functions to be realized, which will, for example, suppress excessive steering movements in critical driving situations. On the other hand, minor chassis weak points such as insufficient steering return can be suppressed. Steering torque actuators also form the basis for a number of comfort functions—from straight-line running assistance via crosswind suppression thru to controlled track guidance based on track recognition sensors.

The force and torque input ensure that the steering intervention assistance should be accepted, given that the interventions are largely not perceivable by the driver and, above all, that the geometrical and dynamic aspects of vehicle perception hardly change as a result of the intervention.

The so-called superimposed steering systems, in contrast, feature additional steering angles. The actuators are arranged in the steering column, either close to the steering wheel or within the power steering between the valve block and gear unit (refer to Figure 28.31).

The primary purpose of superimposed steering systems is to improve vehicle behavior at very low and very high speeds without impairing the middle speed sector, which experience shows to be important. The background to the design problem is the concept-related (stationary) yaw

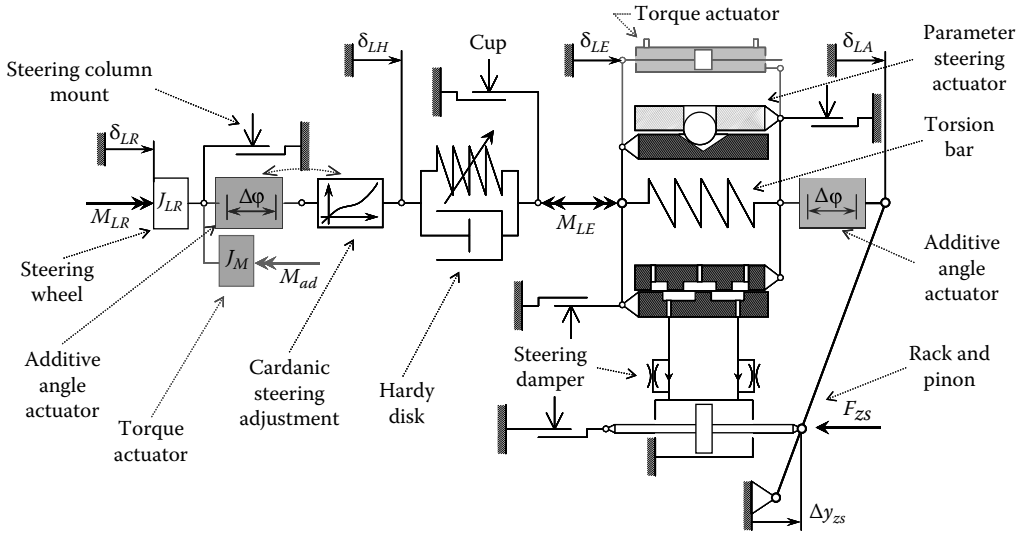

FIGURE 28.31 Structural implementation of superimposed torque (top right) and superimposed angle steering interventions (bottom).

amplification $K_{\dot{\psi}}$ and the transfer of steering angle changes into yaw motions. The yaw velocity $\dot{\psi}$ describes the rotation of the vehicle around its vertical axis:

$$K_{\dot{\psi}} = \left.\frac{\partial\dot{\psi}}{\partial\delta_L}\right|_{stationary} = \frac{v}{l_l + EGv^2}; \quad EG = \frac{m}{l_l}\left(\frac{l_h}{c_v} - \frac{l_v}{c_h}\right) \tag{28.28}$$

To ensure drivability in all speed ranges, the self-steering gradient EG must be set to values between 0.15 and 0.45 Grad/m/s^2. At a given vehicle mass m and geometry (wheelbase l_l, distance from center of gravity – front axle l_v, $l_h = l_l - l_v$), EG is fixed by design by means of the cornering stiffness values c_v and c_h of the front and rear axle. The resulting characteristic for the yaw amplification is illustrated in Figure 28.32.

Conventional vehicles therefore require much larger steering angles at smaller speeds than is desirable. At high speeds, attempts to reduce the sensitivity of the vehicle to rapid steering angle changes to such an extent that completely relaxed and smooth driving is supported are only moderately successful on the other hand. Superimposed steering systems offer the opportunity here, as illustrated in Figure 28.32,

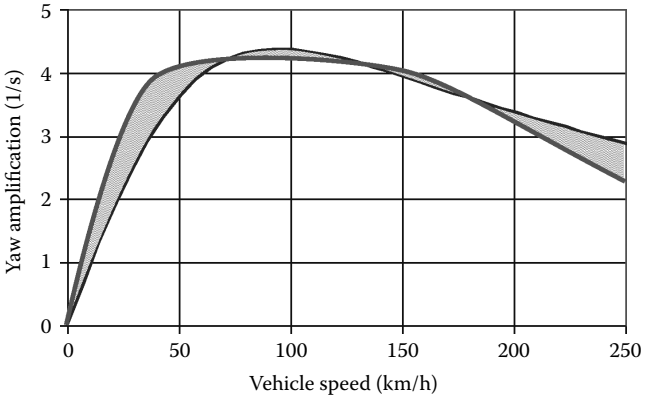

FIGURE 28.32 Yaw amplification for a conventional vehicle (black) and optimized yaw amplification characteristic (grey) on the basis of superimposed steering systems.

to increase the steering ratio significantly at low speeds and at the same time to realize a noticeably more indirect steering system at higher speeds. As long as the superimposed interventions are effected slowly and synchronous to the driver's steering movements, no acceptance problems are to be expected, as was shown in the case of superimposed torque steering systems [61,62]. (It will be hard to convince drivers of rapid superimposed steering interventions, on the other hand, which are not coordinated with the driver; this only seems feasible in the context of safety functions which are rarely activated.)

By combining torque and angle superimposition actuators, the functionality of a steer-by-wire system is recreated. In this case, the steering interventions can be controlled quasi independently of the driver, for example, in order to ensure vehicle stability even under the most adverse conditions or in order to offer the driver different—or also invariant—vehicle characteristics depending on the requirements in particular situations.

29.1 COMFORT AND SAFETY CRITERIA

The assessment of dynamical vehicle properties is related to the three essential motions:

- Longitudinal motion (driving and braking)
- Lateral motion (guidance and steering)
- Vertical motion (suspension and damping)

These three motions of a vehicle will be considered decoupled for the sake of simplicity so that the assessment criteria can be formulated separately for each motion. Of course, coupled criteria can be developed if necessary. But then, one has to compete with the subjective impression during driving tests. Thus, the question of a mathematical formulation of assessment criteria is difficult and can often be answered empirically only (see Chapter 37). Sometimes an interdisciplinary approach is helpful taking into account ergonomical knowledge.

The criteria to assess the longitudinal motion are known as *vehicle performance*. It comprises maximum speed, resistance of motion, and vehicle acceleration. These criteria are self-explaining to some extent (see also Chapter 27). However, it should be mentioned that the exact measurement of the vehicle performance in driving tests is a nontrivial problem (see Chapter 7).

The essential criterion for the lateral motion is the *driving stability*. The vehicle should safely follow a trajectory prescribed by the steering systems. Thus, a stability problem is given, which can be solved by applying the well-developed methods of system dynamics (see Chapter 5).

* Author Karl Popp passed away unexpectedly on 24 April 2005. This Chapter was respectfully revised by Werner Schiehlen.

For the vertical motion, the criteria *ride comfort and safety* are essential. The wheel suspension should absorb the disturbances coming from the road irregularities so that a comfortable ride becomes possible. At the same time, the weight of the vehicle should be transferred to the road without wheel vibrations, so that large lateral/longitudinal forces in the contact area remain in order to guarantee safety.

Besides the vehicle motions, the static and dynamic forces acting on the vehicle parts are important criteria, because the *lifetime* of the vehicle components depends strongly on the loads (see Chapters 9 and 10). These loads can be calculated in advance by model-based numerical simulations. In the following sections, the aforementioned criteria, driving stability, ride comfort, and safety, will be considered in detail. Scalar measures are introduced to simplify the assessment.

29.1.1 Driving Stability

The lateral motion generally can be described by homogeneous linear or nonlinear state equations,

$$\dot{\boldsymbol{x}}(t) = \boldsymbol{A}\boldsymbol{x}(t) \tag{29.1}$$

or

$$\dot{\boldsymbol{x}}(t) = \boldsymbol{a}(\boldsymbol{x}, t)\,, \boldsymbol{x}(t_0) = \boldsymbol{x}_0. \tag{29.2}$$

Thus, the driving stability can be defined as stability of motion in the sense of Lyapunov, which means:

The equilibrium state $\boldsymbol{x}(t) = \boldsymbol{0}$ of the dynamical system (29.2) with $\boldsymbol{a}(\boldsymbol{0}, t) = \boldsymbol{0}$ is called stable in the sense of Lyapunov, if for each t_0 and all $\varepsilon > 0$, there exists a positive number $\delta = \delta(\varepsilon, t_0) > 0$, such that for an arbitrary initial state $\boldsymbol{x}_0$ with

$$\| \boldsymbol{x}_0 \| < \delta \tag{29.3}$$

it follows a disturbed motion with

$$\| \boldsymbol{x}(t) \| < \varepsilon, t \geq t_0. \tag{29.4}$$

Here, $\|\boldsymbol{x}\|$ means any norm of the vector $\boldsymbol{x}$. Often, the Euclidian norm $\| \boldsymbol{x} \| = \sqrt{\boldsymbol{x}^{\mathrm{T}}\boldsymbol{x}}$ is chosen. Furthermore, if

$$\lim_{t \to \infty} \boldsymbol{x}(t) = 0, \tag{29.5}$$

holds, then the system is called asymptotically stable. On the other hand, the equilibrium state $x(t) = 0$ is called unstable, if it is not stable.

Example 29.1

Stability behavior of a second-order system.

For a system with one degree-of-freedom or two state variables x_1, x_2 that are combined in the state vector $\boldsymbol{x}$, $\boldsymbol{x} = [x_1\ x_2]^{\mathrm{T}}$, the trajectories shall be visualized in the phase plane (see Chapter 5) in case of an asymptotically stable, a stable, and an unstable equilibrium position, respectively.

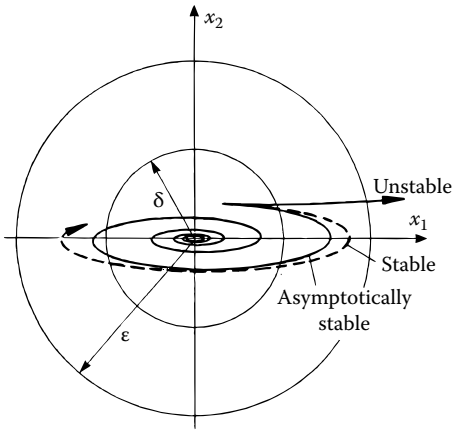

FIGURE 29.1 Solutions of a second-order system plotted in the phase plane.

Solution:

For a second-order system, the solution can be visualized completely in the phase plane (see Chapter 5) (see Figure 29.1). At first, the neighborhood ε of the equilibrium state, that is the origin of the coordinates, will be chosen. Then the neighborhood δ will be determined in such a way that the stable and asymptotically stable trajectories remain completely within the ε–neighborhood. This means that the δ–neighborhood should possibly be very small. Here, the Euclidian norm

$$|| \boldsymbol{x} || = \sqrt{x_1^2 + x_2^2} \tag{29.6}$$

has been applied, resulting in circles around the origin in the phase plane.

The definition of stability in the sense of Lyapunov holds also for linear systems (29.1). This definition, however, allows the assessment of stability only if the solution of the system is known. Thus, stability criteria that do not require the explicit solution of the system are of special interest. Such stability criteria are especially well developed for linear systems [1].

29.1.2 Ride Comfort

Ride comfort (see Chapter 36) is based on the subjective human perception. Numerous experimental investigations in ergonomics have shown that the *human perception* of vibrations depends on the acceleration,

$$K = K(a), \tag{29.7}$$

where

K is a nondimensional *perception measure*

a is the absolute value of the acceleration in horizontal or vertical direction, respectively, see Figure 29.2

Furthermore, the position of the human body (sitting, standing, or lying) is of importance. In ergonomics, the vibration tests have been performed using deterministic, especially harmonic, excitations. In vehicles, however, the human body usually is exposed to random vibrations. Therefore, in the following, the different types of excitations will be investigated separately.

29.1.2.1 Deterministic Excitation

For a rough qualitative assessment of ride comfort during a deterministic excitation,

$$K \sim a_{\max} \tag{29.8}$$

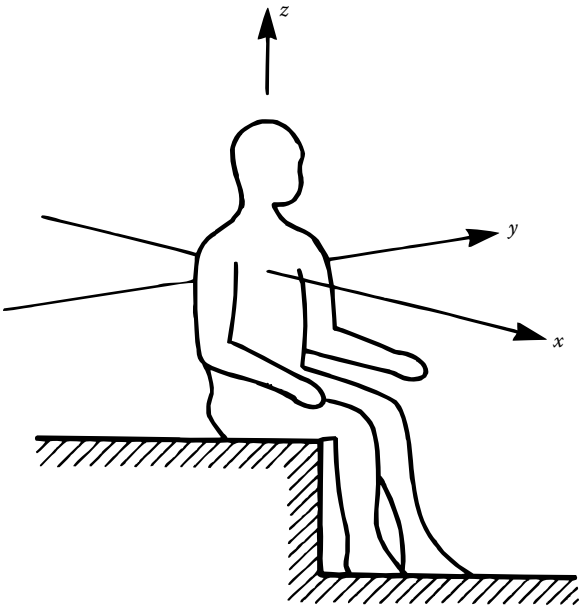

FIGURE 29.2 Directions of vibrations acting on a seated person.

is assumed, that is, the maximum acceleration value prevails upon the perception measure. As a thumb rule, $a_{\max} \leq 0.5$ m/s^2 results in good ride comfort. More refined relations between K and a are given in the international or national standards that are based on extensive ergonomical investigations (see ISO-Standard 2631 [2] or VDI-Standard 2057 [3]).

For harmonic excitations, the aforementioned standards give a precise relation that suits well for vehicle dynamics. Starting from the harmonic acceleration

$$a(t) = A\sin\omega t, \quad \omega = 2\pi f, \tag{29.9}$$

with frequency f [Hz], the root mean square (rms) value a_{rms} of the acceleration can be determined,

$$a_{\text{rms}} = \sqrt{\frac{1}{T}\int_0^T a^2(t)\,\mathrm{d}t} = \frac{A}{\sqrt{2}}\ [\text{m/s}^2], \tag{29.10}$$

where the unit m/s^2 has to be used. Then the perception measure K reads

$$\begin{aligned} K &= 10\,a_{\text{rms}}\sqrt{f}, && 1 \leq f \leq 4 \\ K &= 20\,a_{\text{rms}}, && 4 \leq f \leq 8, \\ K &= 160\ a_{\text{rms}} f^{-1}, && 8 \leq f \leq 80, \end{aligned} \tag{29.11}$$

for vertical excitation, and

$$\begin{aligned} K &= 28\,a_{\text{rms}}, && 1 \leq f \leq 2, \\ K &= 56\,a_{\text{rms}} f^{-1}, && 2 \leq f \leq 80. \end{aligned} \tag{29.12}$$

for horizontal excitation.

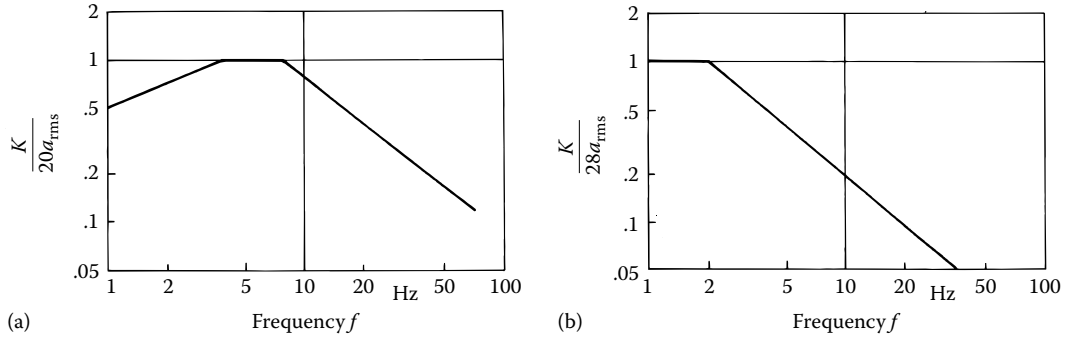

FIGURE 29.3 Frequency response functions of human perception for (a) vertical and (b) horizontal direction.

Equations 29.11 and 29.12 can be interpreted as experimentally determined frequency response functions (FRFs) of the human perception; they are depicted in Figure 29.3. From Figure 29.3a, one can observe that a vertical excitation between 4 and 8 Hz is perceived as very unpleasant, because resonance of the human stomach occurs in this range. The perception K is a nondimensional measure characterizing the subjective impression of test persons related to the criteria comfort, efficiency, and health respectively. Here, the exposure time plays an essential role. The standards ISO 2631 and VDI 2057 describe the relation between exposure time and the aforementioned limits (see Figure 29.4). The perception measure for road vehicles lies in the range

$$2 < K < 10. \tag{29.13}$$

Subclasses of the perception can be defined and the corresponding vibration levels can be described:

$$\begin{aligned} &C_1/C_2, \quad \text{noticeable,} \\ &D_1/D_2, \quad \text{strong noticeable, and} \\ &E_1/E_4, \quad \text{very strong noticeable.} \end{aligned} \tag{29.14}$$

Obviously, the description of perception shows some uncertainties, due to the subjective human nature.

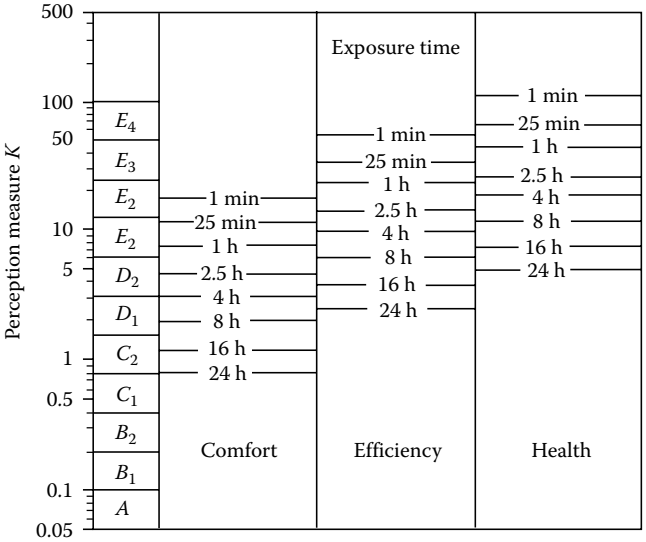

FIGURE 29.4 Human perception and exposure time of vibrations.

29.1.2.2 Stochastic Excitation

Experimental results for a stochastic excitation of test persons are very limited (see e.g., Chapter 22). However, they confirm the interpretation of the subjective human perception as a response to stochastic excitation also, in the sense of a mechanical system, and the possibility of describing it using the methods of linear system theory.

The rms value of a Gaussian process $a(t)$ is equivalent to its standard deviation σ_a,

$$a_{\mathrm{rms}} = \sigma_a = \sqrt{\int_0^\infty \Phi_a(\omega)\,\mathrm{d}\,\omega}, \tag{29.15}$$

where $\Phi_a(\omega)$ is the single-sided power spectral density (PSD) of the process under consideration. The standard deviation is a scalar parameter characterizing the stochastic process globally; however, it is frequency independent. Thus, the weighting of frequencies and the calculation of the rms value have to be interchanged, which is allowed for linear stochastic systems. This results in the variance $\sigma_{\bar{a}}^2$ of the weighted process $\bar{a}(t)$,

$$\sigma_{\bar{a}}^2 = \int_0^\infty \alpha^2 \,|\, F(\omega) \,|^2\, \Phi_a(\omega)\,\mathrm{d}\,\omega. \tag{29.16}$$

Here, α is a dimensional factor, $F(\omega)$ is the FRF of a weighting filter, and $\Phi_a(\omega)$ is the single-sided PSD of the acceleration process $a(t)$. The still unknown quantities of the frequency weighting in Equation 29.16 can be found by comparison with the results for deterministic excitation. For vertical excitation, the dimensional factor α reads

$$\alpha = 20\ \mathrm{s}^2/\mathrm{m}, \tag{29.17}$$

and the FRF is given by

$$\left|F(\omega)\right| = \frac{1}{20} K(a_{\mathrm{rms}}, f)\,,\ f = \frac{\omega}{2\pi}, \tag{29.18}$$

where the perception K according to Equation 29.11 has to be introduced.

The FRF (29.18) can be approximated well by a linear weighting filter or shape filter. This yields in frequency domain

$$\begin{aligned} F(\omega) &= \bar{\boldsymbol{h}}^{\mathrm{T}} (i\omega\, \boldsymbol{E} - \bar{\boldsymbol{F}})^{-1} \bar{\boldsymbol{g}} \\ &= \frac{b_0 + b_1(i\omega) + \cdots + b_r(i\omega)^r}{a_0 + a_1(i\omega) + \cdots + a_{s-1}(i\omega)^{s-1} + (i\omega)^s} \end{aligned} \tag{29.19}$$

Here, $\bar{\boldsymbol{h}}$ and $\bar{\boldsymbol{g}}$ are $s \times 1$-vectors and $\bar{\boldsymbol{F}}$ is a $s \times s$ matrix characterizing the shape filter. Furthermore, a_i, $i = 0(1)s-1$ and b_j, $j = 0(1)r < s$ are coefficients of the shape filter FRF. The following relation holds,

$$\bar{\boldsymbol{F}} = \begin{bmatrix} 0 & 1 & 0 & \cdots & 0 \\ 0 & 0 & 1 & \cdots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & 0 & & 1 \\ -a_0 & -a_1 & -a_2 & \cdots & -a_{s-1} \end{bmatrix}, \quad \bar{\boldsymbol{g}} = \begin{bmatrix} 0 \\ 0 \\ \vdots \\ 0 \\ 1 \end{bmatrix}, \bar{\boldsymbol{h}}^{\mathrm{T}} = [b_0\, b_1 \ldots b_r\, 0 \ldots 0], \tag{29.20}$$

that is, the system matrix $\bar{\boldsymbol{F}}$ can be chosen as Frobenius matrix.

In the time domain, the shape filter can be described equivalently by a differential equation,

$$\begin{aligned} \bar{a}(t) &= \alpha\, \bar{\boldsymbol{h}}^{\mathrm{T}} \bar{\boldsymbol{v}}(t), \quad \text{and} \\ \dot{\bar{\boldsymbol{v}}}(t) &= \bar{\boldsymbol{F}}\, \bar{\boldsymbol{v}}(t) + \boldsymbol{g} a(t). \end{aligned} \tag{29.21}$$

Here, $\bar{\boldsymbol{v}}$ is the $s \times 1$-state vector of the shape filter that is excited by the acceleration $a(t)$. The scalar product of the $s \times 1$-vectors $\bar{\boldsymbol{h}}$ and $\bar{\boldsymbol{v}}(t)$ results in the frequency weighted scalar acceleration $\bar{a}(t)$. The coefficients of the shape filter have to be determined in such a way that the given FRF (29.18) is approximated sufficiently well. This can always be achieved by choosing the order s of the filter large enough.

Example 29.2

Shape filter for the human perception.

A second-order shape filter shall be determined so that the FRF (29.11) for the human perception of vibration is approximated well.

Solution:

The shape filter of second order, $s = 2$, has the following form according to (29.20) and (29.21):

$$\bar{a} = \alpha [b_0 \; b_1] \begin{bmatrix} \bar{v}_1 \\ \bar{v}_2 \end{bmatrix}, \tag{29.22}$$

$$\begin{bmatrix} \dot{\bar{v}}_1 \\ \dot{\bar{v}}_2 \end{bmatrix} = \begin{bmatrix} 0 & 1 \\ -a_0 & -a_1 \end{bmatrix} \begin{bmatrix} \bar{v}_1 \\ \bar{v}_2 \end{bmatrix} + \begin{bmatrix} 0 \\ 1 \end{bmatrix} a(t). \tag{29.23}$$

Choosing the numbers

$$\begin{aligned} a_0 &= 1200\ \mathrm{s}^{-2}, \quad b_0 = 500\,\mathrm{s}^{-2}, \\ a_1 &= 50\ \mathrm{s}^{-1}, \quad b_1 = 50\,\mathrm{s}^{-1}, \\ \alpha &= 20\ \mathrm{s}^2\ \mathrm{m}^{-1} \end{aligned}$$

in case of vertical excitation results in the FRF depicted in Figure 29.5. It can be seen that already a second-order shape filter approximates the standard ISO 2631 surprisingly well. The deviations remain completely within the tolerances allowed by the standard.

Similarly, a second-order shape filter regarding the frequency weighting (29.12) for the horizontal excitation can be determined using the numbers

$$\begin{aligned} a_0 &= 75\ \mathrm{s}^{-2}, \quad b_0 = 31.25\,\mathrm{s}^{-2}, \\ a_1 &= 12.5\,\mathrm{s}^{-1}, \quad b_1 = 12.5\,\mathrm{s}^{-1}, \\ \alpha &= 28\ \mathrm{s}^2\ \mathrm{m}^{-1}. \end{aligned}$$

Thus, the computation of the perception quantity K results simply in

$$K = \sigma_{\bar{a}}, \tag{29.24}$$

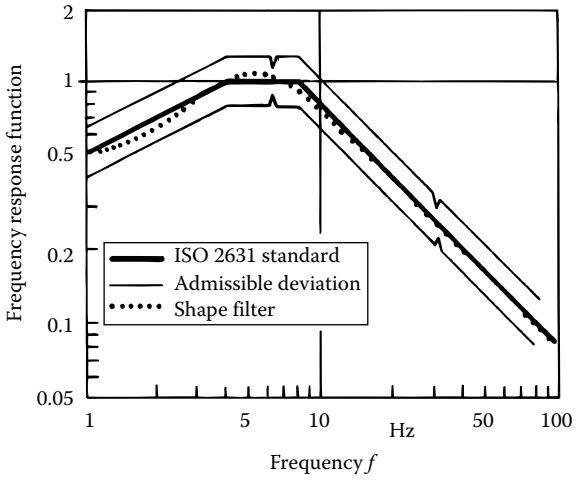

FIGURE 29.5 Shape filter FRF of human perception in the vertical direction.

which includes the frequency weighting automatically. Using the *K*-value from Equation 29.26 again, the allowed exposure time for the criteria comfort, efficiency, and health follows from Figure 29.4.

29.1.3 Ride Safety

Ride safety is related to the longitudinal braking forces and the lateral guidance forces of a vehicle. The tangential contact forces between tire and road are influenced essentially by the normal forces in the contact area. Hence, the remaining minimum wheel load is a criterion for ride safety.

The total wheel load f_{Wheel} can be divided into a static load f_{Stat} due to the vehicle weight and a dynamic load f_{Dyn} generated by vehicle vibrations,

$$f_{\text{Wheel}}(t) = f_{\text{Stat}} + f_{\text{Dyn}}(t), \tag{29.25}$$

as visualized in Figure 29.6. The remaining minimum total wheel load reads

$$f_{\text{Wheel, min}} = f_{\text{Stat}} - f_{\text{Dyn, max}}. \tag{29.26}$$

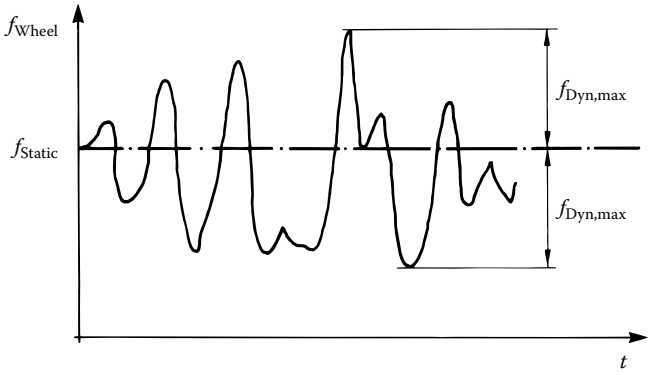

FIGURE 29.6 Static and dynamic wheel loads.

This defines the *safety margin R*,

$$R = \frac{f_{\text{Stat}} - f_{\text{Dyn, max}}}{f_{\text{Stat}}}, \tag{29.27}$$

a scalar quantity varying in the range of $0 \leq R \leq 1$. The safety margin for a vehicle in standstill is $R = 1$; it can drop down to $R = 0$ for a fast-moving vehicle on a rough road.

For roads with a randomly disturbed surface, the dynamic wheel load variations can be determined from numerical simulations. For an assessment of the ride safety, the standard deviation σ_f of the vertical wheel load variations can be used.

This yields

$$R = \frac{f_{\text{Stat}} - \sigma_f}{f_{\text{Stat}}}, \tag{29.28}$$

where R has to be considered as a statistical quantity.

The computation of dynamical wheel load variations, that is, f_{Dyn} or σ_f, is based on the state and input quantities of the global vehicle guideway system. Depending on the tire model, the relative displacements and velocities also have to be known. Hence, the following general expressions can be given,

$$f_{\text{Dyn}} = \boldsymbol{b}^{\text{T}} \boldsymbol{x} \tag{29.29}$$

or

$$\sigma_f^2 = \boldsymbol{b}^{\text{T}} \boldsymbol{P}_x \boldsymbol{b}, \quad \boldsymbol{P}_x = E\{\boldsymbol{x}\,\boldsymbol{x}^{\text{T}}\} \tag{29.30}$$

where $\boldsymbol{b}$ denotes a $n \times 1$ vector of coefficients; $\boldsymbol{x}(t)$, the $n \times 1$-state vector; and $\boldsymbol{P}_x$ the corresponding $n \times n$-covariance matrix.

29.2 MODELING OF RANDOM VEHICLE EXCITATION

Vehicles on rigid guideways are subject to perturbations due to various reasons which have to be added to the vehicle models [4]. Generally, individual obstacles and the guideway unevenness can be distinguished. The obstacles comprise steps (rail joints curbstone edges) and cleats (potholes and bumps) that can be described mathematically by step and impulse functions, primarily resulting in free vibrations of the vehicle. The guideway unevenness causes forced vibrations of the vehicle. The unevenness is a permanent and, therefore, very important source of excitation. In the past, it has been assumed sometimes to be sinusoidal and, thus, it was treated deterministically as well. Nowadays, the unevenness is regarded as random [5], and stochastic methods are applied. In principle, the guideway unevenness could be measured locally with sufficient accuracy and reproducibility, and be treated deterministically. Nevertheless, the main focus in vehicle dynamics is the consideration of a variety of local unevenness representing globally roads or tracks. For this purpose, stochastic processes provide suitable mathematical methods. In the following, the guideway irregularities will at first be described as a *roughness profile* depending on a spacial coordinate. Then, with regard to vehicle speed, it will be transformed into time domain, resulting in a *random excitation process* acting on the vehicle and generating random vibration. The resulting system response is important to assess, for example, ride comfort and ride safety.

The investigation of road roughness profiles has been an ongoing process for decades [6–9]. Numerous measurements have shown that a mathematical description can be given in the form of

- Stationary, normal distributed, and ergodic random processes.

Prior to the description of roughness profiles and the corresponding excitation processes, a general introduction to random processes shall be given in order to explain the aforementioned properties (see also [10–12]).

29.2.1 Mathematical Description of Random Processes

Let us consider a special type of road, for example, the network of highways in a country, and let us assume that the roughness has been recorded by a large number of sectional profile measurements $\zeta^{(r)}(x)$, $r = 1, 2, \ldots$, that are put together in a diagram one above the other (see Figure 29.7a). The independent variable x denotes the distance from an arbitrary chosen starting point in each section. The single roughness profiles are different from each other, $\zeta^{(r)}(x) \neq \zeta^{(s)}(x)$ for $r \neq s$. The complete set of measurement records, however, builds a random process $\zeta(x)$ that represents the highway roughness. Each single record $\zeta^{(r)}(x)$ is called a *realization or sample function* of the process. The ensemble of roughness values $\zeta_j = \zeta(x_j)$ for a definite distance $x = x_j$, $j = 1, 2, \ldots$, builds a random *variable*. It can statistically be evaluated resulting in the *probability density function* $p(\zeta)$ (Figure 29.7b). From $p(\zeta)$ follows the *probability* Pr that the random variable ζ_j lies within a certain interval $[a, b]$,

$$\Pr(a \le \zeta_j \le b) = \int_a^b p(\zeta_j)\,\mathrm{d}\zeta_j, 0 \le \Pr \le 1. \tag{29.31}$$

If the interval grows to infinite, then the roughness value ζ_j lies in it for sure, that is, the probability is Pr = 1,

$$\int_{-\infty}^{\infty} p(\zeta_j)\,\mathrm{d}\zeta_j = 1. \tag{29.32}$$

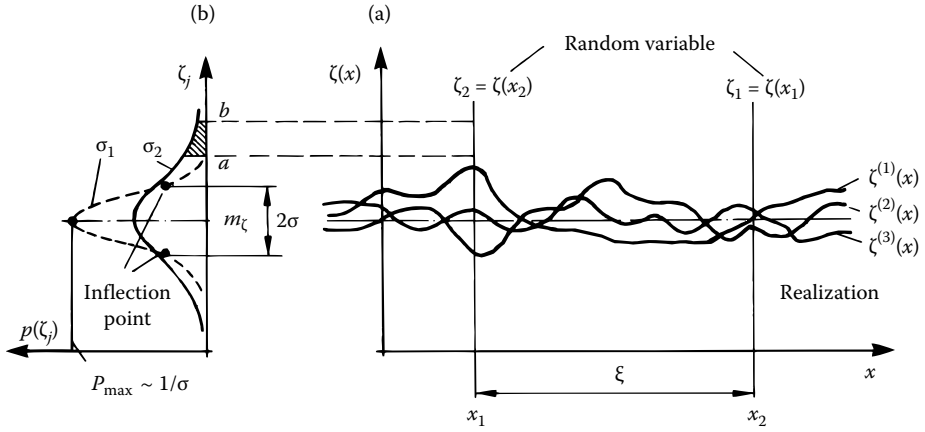

FIGURE 29.7 Roughness profiles as a random process, (a) realization $\zeta(r)(x)$ and random variable ζ_j, (b) probability density function $p(\zeta_j)$.

The *moments* of the probability density function are called mathematical expectation $E\{\cdot\}$; they characterize the random variable. The most important ones are the first-order moment called mean $m_\zeta(x_j)$ or *expected value* and the second-order moment called *mean square value* $m_{\zeta^2}(x_j)$.

For $j = 1$, it follows

$$m_\zeta(x_1) = E\left\{\zeta(x_1)\right\} \equiv \int_{-\infty}^{\infty} \zeta_1 p(\zeta_1)\,\mathrm{d}\zeta_1, \tag{29.33}$$

$$m_{\zeta^2}(x_1) = E\left\{\zeta^2(x_1)\right\} \equiv \int_{-\infty}^{\infty} \zeta_1^2 p(\zeta_1)\,\mathrm{d}\zeta_1. \tag{29.34}$$

The square root of (29.34) is called *root mean square* value or *rms* value. An important statistical parameter is the variance $P_\zeta(x_1) \equiv \sigma_\zeta^2(x_1)$ or the square of the standard deviation $\sigma_\zeta(x_1)$. It is the ensemble average of the square of the deviation from the mean, the so-called central second moment,

$$P_\zeta(x_1) \equiv \sigma_\zeta^2(x_1) = E\left\{\left[\zeta(x_1) - m_\zeta(x_1)\right]^2\right\} = E\left\{\zeta^2(x_1)\right\} - m_\zeta^2(x_1). \tag{29.35}$$

The mathematical exception $E\{\cdot\}$ is a linear operation, where $E\{c\} = c$ for $c = \text{const}$. This property has been used in Equation 29.35. First- and second-order moments are well known from the determination of the center of mass and the moment of inertia. For readers not familiar with the concept of mean and variance, the *mechanical mass analogy* may be helpful. A rod or wire is imagined with infinite length that has a variable mass density ρ (mass per unit length) identical to the probability density $p(x)$ in the probability distribution. According to Equation 29.32, the total mass of the rod is normalized to unity. The mean value (29.33) corresponds to the coordinate of the center of mass and the mean square value (29.34) can be interpreted as moment of inertia related to the origin. The variances (29.35), however, correspond to the moment of inertia related to the center of mass. Thus, the relation $\sigma_\zeta^2 = E\{\zeta^2\} - m_\zeta^2$ in Equation 29.35 can be interpreted as the parallel axes theorem. The first two moments contain information about the distribution of the corresponding quantities, that is, probability or mass, respectively.

Let us consider two random variables $\zeta_1 = \zeta(x_1)$ and $\zeta_2 = \zeta(x_2)$ of the random process ζ. From the statistical relationship between these variables, insight is gained into the random process itself. This is achieved by the (auto) *correlation* $R_\zeta(x_1, x_2)$ or the (auto) *covariance* $P_\zeta(x_1, x_2)$, where, in the latter, the central second moments are used,

$$R_\zeta(x_1, x_2) = E\left\{\left[\zeta(x_1)\zeta(x_2)\right]\right\} = \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} \zeta_1\zeta_2 p(\zeta_1, \zeta_2)\,\mathrm{d}\zeta_1\,\mathrm{d}\zeta_2, \tag{29.36}$$

$$\begin{aligned} P(x_1, x_2) &= E\left\{\left[\zeta(x_1) - m_\zeta(x_1)\right]\left[\zeta(x_2) - m_\zeta(x_2)\right]\right\} \\ &= E\left\{\zeta(x_1)\zeta(x_2)\right\} - m_\zeta(x_1)m_\zeta(x_2). \end{aligned} \tag{29.37}$$

Here, $p(\zeta_1, \zeta_2)$ denotes the second-order probability density function. The prefix "auto" refers to the fact that both random variables belong to the same random process. Otherwise, that is, if the two random variables belong to different random processes, the prefix "cross" will be used. In the limit

case $x_1 = x_2$ of equal correlation positions, the correlation (29.36) becomes equal to the mean square value (29.34) and the covariance (29.37) becomes identical to the variance (29.35).

After these prerequisites, the properties stationarity, normal or Gaussian distribution, and ergodicity shall be explained and described mathematically.

A random process is called *stationary* (or homogeneous) if its statistical properties are invariant under a shift of the origin of the x axis. Thus, all first-order probability density functions are equal, $p(\zeta_1) = p(\zeta_2) = p(\zeta)$, and the second-order probability density function $p(\zeta_1, \zeta_2)$ only depends on the distance $\xi = x_1 - x_2$, known as correlation width. As a consequence, all random variables and, thus, the whole process have the same mean and the same mean square value, respectively. A stationary random process can always be centralized, so that its mean value becomes zero. Thus, for stationary processes, it follows from Equations 29.33 through 29.37

$$m_\zeta(x) = \text{const} = 0, \tag{29.38}$$

$$R_\zeta(x_1, x_2) = P_\zeta(x_1, x_2) = R_\zeta(\xi = x_1 - x_2), \tag{29.39}$$

$$m_{\zeta^2}(x) = \sigma_\zeta^2(x) = R_\zeta(\xi = 0) = \text{const}. \tag{29.40}$$

For centered processes, correlation and covariance are identical. According to Equation 29.39, the correlation depends on the correlation width ξ only; thus, it is called *correlation function* and characterizes the entire random process.

A random process is called *normal distributed* or a *Gaussian process* if for every value x_j, the corresponding random variable $\zeta_j = \zeta(x_j)$ has a probability density function

$$p(\zeta_j) = \frac{1}{\sigma_j\sqrt{2\pi}} \exp\left[\frac{(\zeta_j - m_j)^2}{2\sigma_j^2}\right], \tag{29.41}$$

where $m_j = m_\zeta(x_j)$ and $\sigma_j = \sigma_\zeta(x_j)$. A normal distributed process can uniquely be defined by its mean and variance, that is, by its first two moments. The higher order moments can be expressed by these two quantities. For stationary, normal distributed processes, Equation 29.41 can be simplified using Equations 29.38 and 29.40. The graph of the probability density function (29.41) has the well-known bell shape (see Figure 29.7b). This curve shows a maximum value of $p_{\max} = 1/\left(\sigma_j\sqrt{2\pi}\right)$ at $\zeta_j = m_j$ and is symmetrical with respect to $\zeta_j = m_j$, with points of inflection at $\zeta_j = m_j \pm \sigma_j = \pm\zeta^*$, where $p(\pm\zeta^*) = p_{\max}/\sqrt{e}$ holds. Small values of the standard deviation σ_j mean that the quantity ζ_j is concentrated around m_j. From Equation 29.31, the probability can be calculated, so that the normal distributed random variable ζ_j lies in the interval of length $2k\,\sigma_j, k = 1, 2, \ldots$, around the mean m_j. These intervals are called confidential intervals or $k\sigma$ limits, $k = 1, 2, \ldots$:

$$\begin{aligned}
k = 1: \quad & \Pr(m - \sigma \le \zeta \le m + \sigma) = \Pr\left(|\zeta - m| \le \sigma\right) = 0.6827, \\
k = 2: \quad & \Pr\left(|\zeta - m| \le 2\sigma\right) = 0.9545, \\
k = 3: \quad & \Pr\left(|\zeta - m| \le 3\sigma\right) = 0.9973, \\
k = 3: \quad & \Pr\left(|\zeta - m| \le 4\sigma\right) = 0.99994.
\end{aligned} \tag{29.42}$$

Here, the index j has been dropped. The probability that a Gaussian random variable lies outside, for example, the 2σ limit is only $\Pr = 0,0455 \mathrel{\hat{=}} 4,55\%$.

A stationary random process is called *ergodic* if the ensemble averages of the random variables $\zeta_j = \zeta(x_j)$ is equal to the corresponding spacial (or temporal) averages taken along the coordinate x (or t) of any sufficiently long representative sample function $\zeta^{(r)}(x)$. This means in short

- Ensemble average is equal to sample average

For ergodic processes, it follows:

$$m_\zeta = \lim_{X\to\infty} \frac{1}{2X} \int_X^X \zeta^{(r)}(x)\,\mathrm{d}x, \tag{29.43}$$

$$R_\zeta(\xi) = \lim_{X\to\infty} \frac{1}{2X} \int_{-X}^{X} \zeta^{(r)}(x)\,\zeta^{(r)}(x-\xi)\mathrm{d}x, \tag{29.44}$$

$$m_{\zeta^2} = R_\zeta(\xi = 0) = \lim_{X\to\infty} \frac{1}{2X} \int_{-X}^{X} \left[\zeta^{(r)}(x)\right]^2 \mathrm{d}x, \tag{29.45}$$

$$P_\zeta(\xi) = \lim_{X\to\infty} \frac{1}{2X} \int_{-X}^{X} \left[\zeta^{(r)}(x) - m_\zeta\right]\left[\zeta^{(r)}(x-\xi) - m_\zeta\right]\mathrm{d}x, \tag{29.46}$$

$$\sigma_\zeta^2 = P_\zeta(\xi = 0) = \lim_{X\to\infty} \frac{1}{2X} \int_{-X}^{X} \left[\zeta^{(r)}(x) - m_\zeta\right]^2 \mathrm{d}x. \tag{29.47}$$

Often, it is difficult to decide if a stationary random process is ergodic or not. In the present case of guideway irregularities, ergodicity is at least plausible if one considers the generation of Figure 29.7: With respect to the information that can be gained, it is equivalent to analyzing a single very long measurement record (sample function) of, for example, highway surface irregularities or if one takes the ensemble of pieces of this record and performs a statistical analysis. In general, the averaging of sample functions is less time consuming than the ensemble averaging. However, in practical applications, neither an infinitely large ensemble nor a sample function of infinite length is given. So, both procedures result in approximations for the averages only.

In the following, always centered random processes with mean $m_\zeta = 0$ are assumed. Thus, there is no difference between mean square and variance or between correlation function and covariance function.

In technical applications, stationary processes are often characterized by their PSD or shortly spectral density $S_\zeta(\Omega)$. It can be gained from the correlation function $R_\zeta(\xi)$, by a Fourier transform,

$$S_\zeta(\Omega) = \frac{1}{2\pi} \int_{-\infty}^{\infty} R_\zeta(\xi)\,\mathrm{e}^{-i\Omega\xi}\,\mathrm{d}\xi, \tag{29.48}$$

$$R_\zeta(\xi) = \int_{-\infty}^{\infty} S_\zeta(\Omega)\,\mathrm{e}^{i\Omega\xi}\,\mathrm{d}\Omega, \tag{29.49}$$

$$m_\zeta = 0 : P_\zeta = \sigma_\zeta^2 = R_\zeta(\xi = 0) = \int_{-\infty}^{\infty} S_\zeta(\Omega)\mathrm{d}\Omega. \tag{29.50}$$

Here, Ω with unit rad/m denotes a spacial circular frequency (wave number) that is connected to the wave length λ and the spacial frequency F by $\Omega = 2\pi/\lambda = 2\pi F$. Equations 29.48 and 29.49 are also known as Wiener–Chintschin relation; however, in literature, the factor $1/2\pi$ can also be found in front of the integral in Equation 29.49 or as factors $1/\sqrt{2\pi}$ in both equations. The benefit of the notation chosen here is clear from Equation 29.50, where the variance is equal to the spectral power. The random process ζ of guideway irregularities can equivalently be characterized by the correlation function $R_\zeta(\xi)$ in the spacial domain or by the spectral density $S_\zeta(\Omega)$ in the frequency domain. The variance σ_ζ^2 follows from $R_\zeta(\xi)$ for $\xi = 0$ or as an integral over the variance shares $S_\zeta(\Omega)\mathrm{d}\Omega$ related to the frequency Ω. Such a share can also be interpreted as variance after the process has passed a narrow band filter of bandwidth dΩ. Both functions $R_\zeta(\xi)$ and $S_\zeta(\Omega)$ are even functions,

$$R_\zeta(\xi) = R_\zeta(-\xi), \quad S_\zeta(\Omega) = S_\zeta(-\Omega). \tag{29.51}$$

This property allows an easy computation of the integrals in Equations 29.44 and 29.48 through 29.50, and leads to the introduction of the single-sided spectral density $\Phi_\zeta(\Omega)$ with nonnegative circular frequencies

$$\Phi_\zeta(\Omega) = \begin{cases} 2S(\Omega) & \Omega \geq 0 \\ \text{for} & . \\ 0 & \Omega < 0 \end{cases} \tag{29.52}$$

Correspondingly, $S(\Omega)$ is sometimes denoted as double-sided spectral density. Table 29.1 shows some often-used correlation functions $R_\zeta(\xi)$ and their corresponding single-sided spectral densities $\Phi_\zeta(\Omega)$.

Until now, only a scalar random process has been considered. If two scalar processes ζ_l, r are given, for example, the irregularities of the left and right track of an automobile, then the auto and cross-correlation functions and their corresponding spectra have to be distinguished. This is usually being done by double indices of the cross-correlation functions, where the Fourier transform is defined analogously to Equations 29.48 and 29.49,

$$S_{lr}(\Omega) = \frac{1}{2\pi} \int_{-\infty}^{\infty} R_{lr}(\xi)\, \mathrm{e}^{-i\Omega\xi}\, \mathrm{d}\,\xi \tag{29.53}$$

$$R_{lr}(\xi) = \int_{-\infty}^{\infty} S_{lr}(\Omega)\, \mathrm{e}^{i\Omega\xi}\, \mathrm{d}\,\Omega. \tag{29.54}$$

The cross-spectral densities are in general complex functions, where the following symmetries hold,

$$R_{lr}(\xi) = R_{rl}(-\xi), \quad S_{lr}(\Omega) = S_{rl}(-\Omega). \tag{29.55}$$

TABLE 29.1
Correlation Functions $R\zeta(\xi)$ and Corresponding Single-Sided Spectral Densities $\Phi_\zeta(\Omega)$ (All Constants Are Positive)

No.	Correlation Function $R(\xi) = \int_0^\infty \Phi(\Omega)\cos\Omega\xi d\Omega$	Single-Sided Spectral Density $\Phi(\Omega) = \frac{2}{\pi}\int_0^\infty R(\xi)\cos\Omega\xi d\xi$
I	$\sigma^2 e^{-\alpha\lvert\xi\rvert}$	$\frac{2\alpha\sigma^2}{\pi}\cdot\frac{1}{\Omega^2+\alpha^2}$
II	$\sigma^2 e^{-\alpha\lvert\xi\rvert}\cos\beta\xi$	$\frac{2\alpha\sigma^2}{\pi}\cdot\frac{\Omega^2+\alpha^2+\beta^2}{(\Omega^2-\alpha^2-\beta^2)^2+4\alpha^2\Omega^2}$
III	$\sigma^2 e^{-\alpha\lvert\xi\rvert}\left(\cos\beta\xi-\frac{\alpha}{\beta}\sin\beta\lvert\xi\rvert\right)$	$\frac{4\alpha\sigma^2}{\pi}\cdot\frac{\Omega^2}{(\Omega^2-\alpha^2-\beta^2)^2+4\alpha^2\Omega^2}$
IV	$\sigma^2 e^{-\alpha\lvert\xi\rvert}\left(\cos\beta\xi+\frac{\alpha}{\beta}\sin\beta\lvert\xi\rvert\right)$	$\frac{4\alpha\sigma^2}{\pi}\cdot\frac{\alpha^2+\beta^2}{(\Omega^2-\alpha^2-\beta^2)^2+4\alpha^2\Omega^2}$
	$\Omega_d = \sqrt{1-D^2}\cdot\Omega_0$	
V	$\sigma^2 e^{-D\Omega_0\lvert\xi\rvert}\left(\cos\Omega_d\xi+\frac{D\Omega_0}{\Omega_d}\sin\Omega_d\lvert\xi\rvert\right)$	$\frac{4D\Omega_0\sigma^2}{\pi}\cdot\frac{\Omega_0^2}{\left(\Omega^2-\Omega_0^2\right)^2+4D^2\Omega_0^2\Omega^2}$
VI	$\frac{\sigma^2}{\beta-\alpha}\left[\beta e^{-\alpha\lvert\xi\rvert}-\alpha e^{-\beta\lvert\xi\rvert}\right]$	$\frac{2\alpha\beta(\alpha+\beta)\sigma^2}{\pi}\cdot\frac{1}{(\Omega^2+\alpha^2)(\Omega^2+\beta^2)}$
VII	$\sigma^2 e^{-\alpha\xi^2}$	$\frac{\sigma^2}{\sqrt{\pi\alpha}}\cdot e^{-\frac{\Omega^2}{4\alpha}}$
VIII	$\sigma^2 e^{-\alpha\xi^2}\cos\beta\xi$	$\frac{\sigma^2}{\sqrt{4\pi\alpha}}\left[e^{-\frac{(\Omega+\beta)^2}{4\alpha}}+e^{-\frac{(\Omega-\beta)^2}{4\alpha}}\right]$
Harmonic function		
IX	$\sigma^2\cos\beta\xi$	$\sigma^2\delta(\Omega-\beta)$
White noise		
X	$q_w\delta(\xi)$	$\frac{1}{\pi}q_w$
Band limited white noise		
XI	$q_w\frac{\sin\alpha\xi}{\pi\xi}$	$\frac{1}{\pi}q_w$ if $0 \le \Omega \le \alpha$ 0 else
Ideal band pass		
XII	$2q_w\frac{\sin\alpha\xi/2\cdot\cos\beta\xi}{\pi\xi}$	$\frac{1}{\pi}q_w$ if $0 \le \beta-\frac{\alpha}{2} \le \Omega \le \beta+\frac{\alpha}{2}$ 0 else

A normalized measure for the correlation between two processes is given by the coherence function $\gamma(\Omega)$,

$$\gamma^2(\Omega) = \frac{\left|S_{lr}(\Omega)\right|^2}{S_l(\Omega)S_r(\Omega)}, 0 \le \gamma \le 1. \tag{29.56}$$

For $\gamma \equiv 0$, both processes, for example, the irregularities of the left and right track, are completely uncorrelated, and for $\gamma \equiv 1$, they are completely correlated. In general, the correlation is frequency dependent, as can be seen from Equation 29.56.

If n scalar processes ζ_ν, $\nu = 1(1)n$, are given, then it is suitable to combine them to a $n \times 1$-vector process $\boldsymbol{\zeta}$. The mean m_ζ is then replaced by the $n \times 1$-mean vector $\boldsymbol{m}_\zeta$ and the variance P_ζ by the $n \times n$-covariance matrix $\boldsymbol{P}_\zeta$,

$$\boldsymbol{m}_\zeta(x) = E\left\{\boldsymbol{\zeta}(x)\right\},$$

$$\boldsymbol{P}_\zeta(x) = E\left\{\left[\boldsymbol{\zeta}(x) - \boldsymbol{m}_\zeta(x)\right]\left[\boldsymbol{\zeta}(x) - \boldsymbol{m}_\zeta(x)\right]^{\mathrm{T}}\right\} = \boldsymbol{P}_\zeta^{\mathrm{T}}(x). \tag{29.57}$$

The variances of the single scalar processes appear as diagonal elements of the matrix $\boldsymbol{P}_\zeta$. It is clear that the variances are very important quantities to characterize the considered stationary, normal distributed, and ergodic processes. The variances can be interpreted in different ways as follows:

- Central second-order moment of a random variable, (29.35) and (29.57)
- Mean square of a centered sample function, (29.47)
- Spectral power of a centered process, (29.50)
- Square of the standard deviation of the probability density function, and, thus, defining the Gaussian bell-shaped distribution (29.41) and the size of the confidence intervals (29.42)

Example 29.3

White and coloured noise.

The correlation functions no. X, I, and IV of Table 29.1 should be taken to derive and interpret the corresponding PSDs.

Solution:

First, the Fourier transform for the single-sided PSD $\Phi(\Omega)$ will be derived. Introducing Euler's formula $\exp(\pm i\Omega\xi) = \cos\Omega\xi \pm i\sin\Omega t$ into Equations 29.48 and 29.49, and splitting the range of integration yields for Equation 29.48

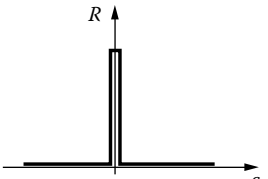
$$S(\Omega) = \frac{1}{2\pi}\left[\int_{-\infty}^{0} R(\xi)(\cos\Omega\xi - i\sin\Omega\xi)\,\mathrm{d}\xi + \int_{0}^{\infty} R(\xi)(\cos\Omega\xi - i\sin\Omega\xi)\,\mathrm{d}\xi\right]. \tag{29.58}$$

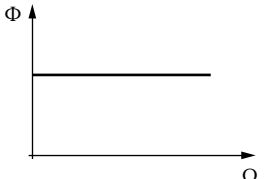
Using $\xi = -\bar{\xi}$ in the first integral, where $\bar{\xi}$ is a new variable, and regarding $R(\xi) = R(-\xi) = R(\bar{\xi})$ according to (29.51) results in

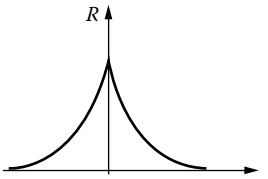
$$2S(\Omega) = \frac{1}{\pi}\left[\int_{0}^{\infty} R(\bar{\xi})(\cos\Omega\bar{\xi} + i\sin\Omega\bar{\xi})\,\mathrm{d}\bar{\xi} + \int_{0}^{\infty} R(\xi)(\cos\Omega\xi - i\sin\Omega\xi)\,\mathrm{d}\xi\right]. \tag{29.59}$$

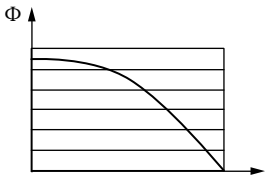
Putting the right-hand side together and regarding $2S(\Omega) = \Phi(\Omega)$, it follows

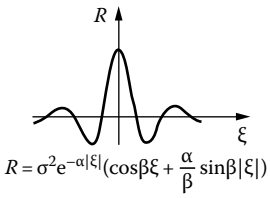
$$\Phi(\Omega) = \frac{2}{\pi}\int_0^\infty R(\xi)\cos\Omega\xi\,d\xi. \tag{29.60}$$

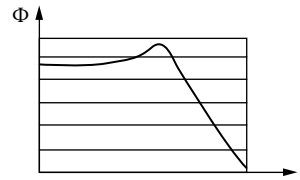












The inverse transform follows in the same manner,

$$R(\xi) = \int_0^\infty \Phi(\Omega)\cos\Omega\xi\,d\Omega. \tag{29.61}$$

Introducing the three correlation functions from Table 29.1 into Equation 29.61 yields the following results that are visualized in Table 29.2.

(1) Correlation function no. $X, R(\xi) = q_w\delta(\xi)$:

TABLE 29.2
Comparison of Correlation Function $R_\xi(\xi)$ and Spectral Density $\Phi_\xi(\Omega)$ of White and Colored Noise

Denomination	Correlation Function $R(\xi)$	Spectral Density $\Phi(\Omega)$ (Double Logarithmic Scale)
White noise	 $R = q_w\delta(\xi)$	 $\Phi = \frac{1}{\pi} q_w$
Colored noise I	 $R = \sigma^2 e^{-\alpha\lvert\xi\rvert}$	 $\Phi = \frac{2\alpha\sigma^2}{\pi} \times \frac{1}{\alpha^2 + \Omega^2}$
Colored noise IV	 $R = \sigma^2 e^{-\alpha\lvert\xi\rvert}(\cos\beta\xi + \frac{\alpha}{\beta}\sin\beta\lvert\xi\rvert)$	 $\Phi = \frac{4\alpha\sigma^2}{\pi} \times \frac{\alpha^2 + \beta^2}{(\alpha^2 - \beta^2 + \Omega^2)^2 + 4\alpha^2\beta^2}$

The evaluation of Equation 29.61 yields

$$\frac{2}{\pi}\Phi(\Omega) = \int_0^\infty q_w \delta(\xi)\cos\Omega\xi \mathrm{d}\xi = \frac{q_w}{\pi} = \text{const.} \tag{29.62}$$

For the computation of the integral in Equation 29.62, it has to be considered that the lower limit of the integral coincides with the coordinate where the Dirac distribution $\delta(\xi)$ is nonzero, thus, not the entire integrand but only one half of it is filtered out by the integration. The same results follow, if the transform (29.48) is applied, where $S(\Omega) = \Phi(\Omega)/2$ has to be introduced. As a consequence, the random process no. X that is completely uncorrelated for $\xi \neq 0$ has a constant PSD for all frequencies. Such a process is called white noise $w(x)$, because it contains a constant spectrum like white light. However, this noise process has an infinite variance,

$$P_w = \sigma_w^2 = R_w(\xi = 0) = \int_0^\infty \Phi(\Omega)\mathrm{d}\Omega = \infty. \tag{29.63}$$

This shows that white noise is a mathematical idealization and does not occur in nature. However, it is a useful limit case of real noise and it can mathematically be handled easily; thus, it is applied very often. Stationary Gaussian white noise with zero mean, $m_w = 0$, and intensity q_w will be denoted by

$$w(x) \sim N(0, q_w). \tag{29.64}$$

(2) Correlation function no. I, $R(\xi) = \sigma^2 \mathrm{e}^{-\alpha|\xi|}, \alpha > 0$:

The solution requires the evaluation of Equation 29.60,

$$\Phi(\Omega) = \frac{2\sigma^2}{\pi}\int_0^\infty \mathrm{e}^{-\alpha\xi}\cos\Omega\xi\,\mathrm{d}\xi = \frac{2\sigma^2}{\pi}\left[\frac{\mathrm{e}^{-\alpha\xi}}{\Omega^2+\alpha^2}(-\alpha\cos\Omega\xi + \Omega\sin\Omega\xi)\right]_{\xi=0}^{\xi=\infty},$$

$$\Phi(\Omega) = \frac{2\sigma^2}{\pi}\frac{\alpha}{\Omega^2+\alpha^2}. \tag{29.65}$$

Here, the computation is very simple, since $|\xi| = \xi$ for $\xi \geq 0$ holds and the right-hand side of Equation 29.65 vanishes at the upper limit. The result is a coloured noise process with a maximum PSD of $\Phi_{max} = 2\sigma^2/(\pi\alpha)$ at the spacial frequency $\Omega = 0$, and it follows an asymptotic behavior $\Omega \sim 1/\Omega^2$ for $\Omega \to \infty$. Here, the variance $\sigma^2 = R(\xi = 0)$ is finite. The correlation decreases with increasing distance ξ monotonically. Table 29.2 shows clearly the differences to a white noise process.

(3) Correlation function no. IV, $R(\xi) = \sigma^2 \mathrm{e}^{-\alpha|\xi|}\left(\cos\beta\xi + \frac{\alpha}{\beta}\sin\beta|\xi|\right), \alpha > 0$:

In this case, the solution is analogous to (29.59) regarding trigonometrical transformations for products of harmonic functions,

$$\Phi(\Omega) = \frac{2\sigma^2}{\pi}\int_0^\infty \mathrm{e}^{-\alpha\xi}\left(\cos\beta\xi + \frac{\alpha}{\beta}\sin\beta\xi\right)\cos\Omega\xi\,\mathrm{d}\xi$$

$$= \frac{2\sigma^2}{\pi}\int_0^\infty \left\{\mathrm{e}^{-\alpha\xi}\frac{1}{2}\left[\cos(\beta+\Omega)\xi + \cos(\beta-\Omega)\xi\right] + \mathrm{e}^{-\alpha\xi}\frac{\alpha}{2\beta}\left[\sin(\beta+\Omega)\xi + \sin(\beta-\Omega)\xi\right]\right\}\mathrm{d}\xi$$

$$\begin{aligned}\Phi(\Omega) &= \left\{ e^{-\alpha\xi}\left[\frac{1}{\alpha^2+(\beta+\Omega)^2}\left(-\alpha\cos(\beta+\Omega)\xi+(\beta+\Omega)\sin(\beta+\Omega)\xi\right)\right.\right.\\ &+\frac{1}{\alpha^2+(\beta-\Omega)^2}\left(-\alpha\cos(\beta-\Omega)\xi+(\beta-\Omega)\sin(\beta-\Omega)\xi\right)\\ &+\frac{\alpha}{\beta\left(\alpha^2+(\beta+\Omega)^2\right)}\left(-\alpha\sin(\beta+\Omega)\xi-(\beta+\Omega)\cos(\beta+\Omega)\xi\right)\\ &\left.\left.+\frac{\alpha}{\beta\left(\alpha^2+(\beta-\Omega)^2\right)}(-\alpha\sin(\beta-\Omega)\xi-(\beta-\Omega)\cos(\beta-\Omega)\xi)\right]\right\}_{\xi=0}^{\xi=\infty}\\ &=\frac{\sigma^2}{\pi}\left[\frac{\alpha}{\alpha^2+(\beta+\Omega)^2}+\frac{\alpha}{\alpha^2+(\beta-\Omega)^2}\right.\\ &\left.+\frac{\alpha}{\beta}\left(\frac{\beta+\Omega}{\alpha^2+(\beta+\Omega)^2}+\frac{\beta-\Omega}{\alpha^2+(\beta-\Omega)^2}\right)\right]\\ &=\frac{4\alpha\sigma^2}{\pi}\frac{\alpha^2+\beta^2}{N}. \end{aligned} \tag{29.66}$$

In the last expression, the denominator can be expressed in a different manner,

$$\begin{aligned}N &= \left[\alpha^2+(\beta+\Omega)^2\right]\left[\alpha^2+(\beta-\Omega)^2\right]\\ &=\left(\Omega^2-(\alpha^2-\beta^2)^2\right)+4\alpha^2\Omega^2=(\Omega^2+\alpha^2-\beta^2)^2+4\alpha^2\beta^2. \end{aligned} \tag{29.67}$$

Again, the result is a colored noise process with the following maximum PSD Φ_{max},

$$\Phi_{max}=\begin{cases}\dfrac{\alpha\sigma^2}{\pi} & \dfrac{\alpha^2+\beta^2}{\alpha^2\beta^2} \quad \text{at} \quad \Omega=\sqrt{\beta^2-\alpha^2} \quad \text{for} \quad \beta\geq\alpha\\ \dfrac{\alpha\sigma^2}{\pi} & \dfrac{4}{\alpha^2+\beta^2} \quad \text{at} \quad \Omega=0 \quad \text{for} \quad \beta\leq\alpha\end{cases}. \tag{29.68}$$

It results in asymptotic behavior $\Phi \sim 1/\Omega^4$ for $\Omega \to \infty$. The variance $\sigma^2 = R(\xi = 0)$ is finite. Here, the correlation decreases with increasing distance ξ in an oscillating manner around zero, Table 29.2.

29.2.2 Models of Road Roughness Profiles

The evaluation and preparation of numerous measurement data of road roughness profiles show a tendency toward standardization. A simple but often-used road roughness model reads

$$\Phi_\zeta(\Omega)=\Phi_0\left(\frac{\Omega_0}{\Omega}\right)^w, \quad 0<\Omega_I\leq\Omega\leq\Omega_\Pi<\infty, \tag{29.69}$$

where the frequency range is bounded. Here, Ω_0[rad/m] denotes a standardized spacial circular frequency (wave number), $\Phi_0 = \Phi_\zeta(\Omega_0)$[m^2/(rad/m)] characterizes the roughness at Ω_0 and can be

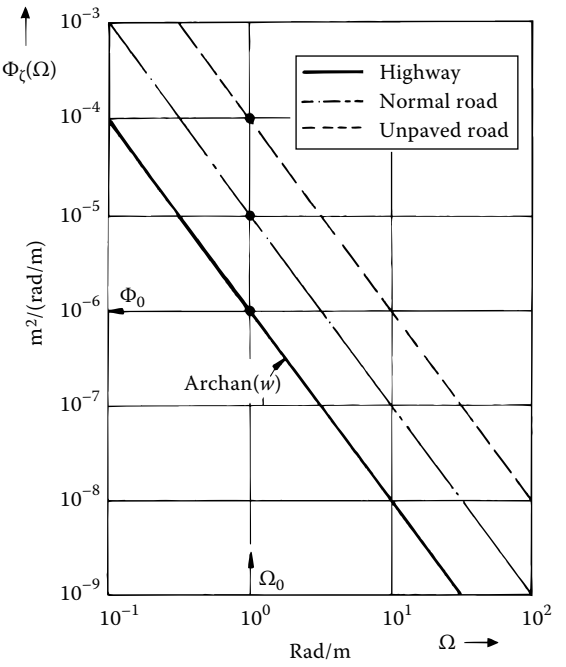


FIGURE 29.8 Simple road roughness models with approximate values of the roughness level $\Phi_0 = \Phi(\Omega_o)$, $\Omega_0 = 1$ rad/m.

considered as roughness level, and w is called waviness and characterizes whether the road contains long wave lengths (w large) or short wave lengths (w small) with pronounced spectral densities. For the wavelength λ, the relation $\lambda = 2\pi/\Omega$ holds. The waviness w of road profiles lies in the range $1.75 \le w \le 2.25$ with $w \approx 2$ as an average value. Equation 29.69 is usually plotted in a Ω, Φ–diagram with double logarithmic scale and results in decreasing straight lines with slopes ($-w$) (Figure 29.8).

A similar but more complicated model reads, [13],

$$\Phi_\zeta(\Omega) = \begin{cases} \Phi_0 \left(\dfrac{\Omega_0}{\Omega} \right)^{w_1} & 0 < \Omega_\mathrm{I} \le \Omega \le \Omega_0, \\ & \text{for} \\ \Phi_0 \left(\dfrac{\Omega_0}{\Omega} \right)^{w_2} & \Omega_0 \le \Omega \le \Omega_\mathrm{II} < \infty, \end{cases} \tag{29.70}$$

where different values w_1, w_2, $w_1 < w_2$, of the waviness occur in the two frequency ranges.

The road roughness models (29.68) and (29.70) are approximations to measured PSD in a distinct frequency range $0 < \Omega_\mathrm{I} \le \Omega \le \Omega_\mathrm{II} < \infty$. In the limit case $\Omega \to 0$, both models result in infinite values of the PSD, $\Phi_\zeta(0) \to \infty$, and, thus, in infinite variances, $P_\zeta \to \infty$. To avoid this unrealistic case, extended road roughness models have been suggested that hold in the entire frequency range. These models are colored noise processes characterized by the PSD

$$\mathrm{I}: \quad \Phi_{\zeta_\mathrm{I}}(\Omega) = \frac{2\alpha\sigma^2}{\pi} \frac{1}{\alpha^2 + \Omega^2}, \tag{29.71}$$

$$0 \le \Omega < \infty,$$

$$\text{II}: \Phi_{\zeta\text{II}}(\Omega) = \frac{2\alpha\sigma^2}{\pi} \frac{\Omega^2 + \alpha^2 + \beta^2}{(\Omega^2 - \alpha^2 - \beta^2)^2 + 4\alpha^2\Omega^2}, \tag{29.72}$$

where α, β, and σ^2 are positive constants. The corresponding correlation functions can be calculated using

$$R_\zeta(\xi) = \int_0^\infty \Phi_\zeta(\Omega) \cos\Omega_\xi \, \mathrm{d}\Omega, \tag{29.73}$$

Inserting (29.71) and (29.72) into (29.73) results in

$$\text{I}: \; R_{\zeta\text{I}}(\xi) = \sigma^2 \, \mathrm{e}^{-\alpha|\xi|}, \tag{29.74}$$

$$\text{II}: \quad R_{\zeta\text{II}}(\xi) = \sigma^2 \, \mathrm{e}^{-\alpha|\xi|} \cos\beta\xi, \tag{29.75}$$

see also Table 29.2, where $\sigma^2 = R_\zeta(\xi = 0)$ denotes the finite variance of the road roughness profile. For $\Omega \to \infty$, both PSDs (29.71) and (29.72) decay according to $\Phi \sim 1/\Omega^2$. Thus, they approximate measured road roughness profiles very well.

29.2.3 Models of Vehicle Excitation

From the models of the road roughness profiles $\zeta(x)$ shown in Section 29.2, corresponding models of the vehicle excitation $\zeta(t)$ in the time domain can be derived. Here, permanent road contact is assumed and, in a first step, only one contact point is considered. The transformation from space to time domain, $\zeta(x) \to \zeta(t)$, is performed considering the vehicle speed $v(t)$,

$$\mathrm{d}\, x(t) = v(t)\mathrm{d}t, \quad x(t) = x(t_0) + \int_{t_0}^{t} v(\tau)\, \mathrm{d}\,\tau. \tag{29.76}$$

From the road roughness profiles that are stationary in space domain, it generally follows non-stationary vehicle excitation processes in the time domain if the vehicle speed $v(t)$ is time varying [14,15]. This case will not be considered here. Throughout, we assume a constant vehicle speed, $v = \text{const}$, resulting in stationary vehicle excitation processes. For $t_0 = 0$ and $x(t_0) = 0$ from (29.76), it follows

$$x(t) \; = vt, \quad \xi = v\tau, \quad \omega = v\Omega, \quad v = \text{const}. \tag{29.77}$$

Here, τ means the correlation time corresponding to the correlation width ξ and ω with unit rad/s denotes the temporal circular frequency. Since the variances $R_\zeta(0)$ of road profiles $\zeta(x)$ and vehicle excitations $\zeta(t)$ must be equal, Equation 29.73 yields $\Phi_\zeta(\omega)\mathrm{d}\omega = \Phi_\zeta(\Omega)\, \mathrm{d}\Omega$ that results in (29.77) in the PSD $\Phi_\zeta(\omega)$ [m^2/(rad/s)] of the vehicle excitation

$$\Phi_\zeta(\omega) = \frac{1}{v} \Phi_\zeta\left(\Omega = \frac{\omega}{v}\right). \tag{29.78}$$

For example, from the road roughness model (29.69) with the average waviness $w = 2$, it follows

$$\tilde{\Phi}_\zeta(\omega) = \frac{1}{v}\tilde{\Phi}_0\left(\frac{v\Omega_0}{\omega}\right)^2 = v\,\tilde{\Phi}_0\left(\frac{\Omega_0}{\omega}\right)^2. \tag{29.79}$$

Until now, we considered stochastic excitation processes $\zeta(t)$ of the vehicle displacements only. But the differentiated processes $\dot{\zeta}(t)$ and $\ddot{\zeta}(t)$ of vehicle velocity and vehicle acceleration, respectively, can also be regarded. The corresponding PSDs read, [11],

$$\Phi_{\dot{\zeta}}(\omega) = \omega^2\Phi_\zeta(\omega), \quad \Phi_{\ddot{\zeta}}(\omega) = \omega^4\Phi_\zeta(\omega). \tag{29.80}$$

Equation 29.80 applied to (29.79), for example, yields a white noise process for the vehicle excitation velocity $\dot{\zeta}(t)$ characterized by the PSD

$$\tilde{\Phi}_{\dot{\zeta}}(\omega) = \omega^2 v\,\tilde{\Phi}_0\left(\frac{\Omega_0}{\omega}\right)^2 = v\,\tilde{\Phi}_0\Omega_0^2 = \text{const}. \tag{29.81}$$

The corresponding correlation function reads

$$R_{\dot{\zeta}}(\tau) = q_{\dot{\zeta}}\delta(\tau), \quad q_{\dot{\zeta}} = \pi v\,\tilde{\Phi}_0\Omega_0^2, \tag{29.82}$$

where $q_{\dot{\zeta}}$ denotes the noise intensity of $\dot{\zeta}(t)$ and $\delta(\tau)$ is the Dirac distribution. Assuming the waviness $w = 4$ from Equation 29.69, similarly, a white noise process for the vehicle excitation acceleration $\ddot{\zeta}(t)$ follows,

$$\tilde{\tilde{\Phi}}_{\ddot{\zeta}}(\omega) = \omega^4 v\tilde{\tilde{\Phi}}_0\left(\frac{\Omega_0}{\omega}\right)^4 = v\,\tilde{\tilde{\Phi}}_0\Omega_0^4 = \text{const}, \tag{29.83}$$

$$R_{\ddot{\zeta}}(\omega) = q_{\ddot{\zeta}}\delta(\tau), \quad q_{\ddot{\zeta}} = \pi v\,\tilde{\tilde{\Phi}}_0\Omega_0^4. \tag{29.84}$$

The white noise processes are characterized by infinite variances and, thus, they are not realistic. On the other hand, assuming vehicle excitations like (29.81)–(29.84), the effort for the computation of vehicle random vibrations can be reduced considerably. Therefore, the white noise velocity excitation of road vehicles is of importance as a technical approximation.

More realistic models of vehicle excitations $\zeta(t)$ are based on Equations 29.71 through 29.75, that is, they are stationary Gaussian colored noise processes. These processes can be generated as a steady-state solution of a system of linear time-invariant ordinary differential equations (ODEs) that are excited by white noise $w(t)$. These ODEs change—graphically speaking—the shape of the PSD or corresponding correlation function; thus, they are called shape filters (Figure 29.9).

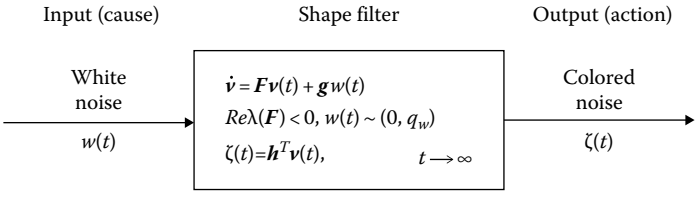

FIGURE 29.9 Visualization of a shape filter.

Generally holds, if a stationary, ergodic Gaussian process excites a system of linear time-invariant ODEs, then the properties stationarity, normal distribution, and ergodicity will be transferred from the system input to the system output. The shape filter eqs. read

$$\zeta(t) = \boldsymbol{h}^{\mathrm{T}}\boldsymbol{v}(t), \tag{29.85}$$

$$\dot{\boldsymbol{v}}(t) = \boldsymbol{F}\boldsymbol{v}(t) + \boldsymbol{g}w(t), \mathrm{Re}\,\lambda(F) < 0, w(t) \sim N(0, q_w). \tag{29.86}$$

In steady state, the colored noise process $\zeta(t)$ results by the superposition of the state variables $v_i(t)$, $i = 1(1)m$, that are combined to the $m \times 1$-state vector v, (29.85). This state vector v is solution of a system of ODEs that are combined to the shape filter state equation (29.86), where the system matrix F is asymptotically stable and the excitation is given by white noise $w(t)$ with zero mean and intensity q_w. The quantities $\boldsymbol{F}$, $\boldsymbol{g}$, and $\boldsymbol{h}$ characterize the shape filter completely. For the models (29.71)–(29.75), these quantities read

$$\mathrm{I}: \quad F = -\alpha v, \quad \boldsymbol{g} = g, \quad \boldsymbol{h} = 1, \quad (g^2 q_w = 2\alpha v \sigma^2), \tag{29.87}$$

$$\mathrm{II}: \quad F = \begin{bmatrix} 0 & 1 \\ -(\alpha^2 + \beta^2)v^2 & -2\alpha v \end{bmatrix}, \quad \boldsymbol{g} = g\begin{bmatrix} 0 \\ 1 \end{bmatrix}, \quad \boldsymbol{h} = \begin{bmatrix} v\sqrt{\alpha^2 + \beta^2} \\ 1 \end{bmatrix}, \quad (g^2 q_w = 2\alpha v \sigma^2). \tag{29.88}$$

Since the product $g^2 q_w$ of the shape filter quantities follows from a product of model parameters, there is a possibility of choice. If we put $g = 1$, for example, then for both shape filters, the intensity q_w of the white noise excitation reads $q_w = 2\,\alpha\, v\, \sigma^2$. This shows that the intensity of the vehicle excitation grows proportional to the vehicle speed v.

In general, the shape filter quantities should be determined directly from measured PSDs $\Phi_\zeta(\Omega)$ rather than from analytical approximations such as those shown here. However, in this case, the order m of the filter has to be chosen. For $m = 2$, this procedure is extensively described in [16].

Until now, only vehicle excitations caused by a single contact point have been considered resulting in a scalar stochastic excitation process. However, real multiaxle vehicles have multiple road contacts. For $i = 1(1)q$ axles and $k = 1(1)s$ tracks, there are $q{\cdot}s$ contact points resulting in correspondingly many scalar excitation processes that can be combined to a $(q{\cdot}s) \times 1 -$ vector process ζ of vehicle excitation.

In case of subsequent contact points in a single track, the excitation processes $\zeta_i(t)$, $i = 1(1)q$ can be gained from the excitation process $\zeta_1(t) \equiv \zeta(t)$ of the first contact point by a time shift t_i

$$\zeta_i(t) = \zeta(t - t_i), \quad t_i = \frac{l_i}{v}, \quad 0 = t_1 < t_2 < \cdots < t_q, \quad i = 1(1)q, \tag{29.89}$$

where

l_i denotes the distance between the first and the ith axle

v is the const is the vehicle speed

Further details can be found in [17].

In case of parallel tracks, the statistical relationship between the parallel-acting excitation processes have to be regarded. Measurements of correlation functions are reported in [9]. A corresponding shape filter is given by [14].

A typical vector process characterizing the excitation of a four-wheel vehicle reads ($f \triangleq$ front, $r \triangleq$ rear, $l \triangleq$ left, $r \triangleq$ right),

$$\boldsymbol{\zeta}(t,T) = \begin{bmatrix} \zeta_{lf}(t) \\ \zeta_{rf}(t) \\ \zeta_{lr}(t) \\ \zeta_{rr}(t) \end{bmatrix} = \begin{bmatrix} \zeta_{l}(t) \\ \zeta_{r}(t) \\ \zeta_{l}(t-T) \\ \zeta_{r}(t-T) \end{bmatrix}, \quad T \equiv t_2 = \frac{l_2}{v}, \tag{29.90}$$

where the delay time T follows from the axle distance l_2 and the vehicle speed v.

29.3 COMPUTATION OF THE RANDOM VEHICLE RESPONSE

The entire vehicle system modelled by the equation of motion (see Chapter 2) and excited by road roughness can be described by the non linear state equation

$$\dot{\boldsymbol{x}}(t) = \boldsymbol{a}(\boldsymbol{x}, \boldsymbol{w}, t), \tag{29.91}$$

where
- $\boldsymbol{x}$ is the state vector
- $\boldsymbol{w}$ characterizes the excitation
- $\boldsymbol{a}$ denotes a nonlinear vector function

In the following, we will assume that Equation 29.91 can be linearized resulting in the linear state equation

$$\dot{\boldsymbol{x}}(t) = \boldsymbol{A}(t)\,\boldsymbol{x}(t) + \boldsymbol{B}(t)\,\boldsymbol{w}(t), \tag{29.92}$$

where, in many cases, the state matrix $\boldsymbol{A}$ and the input matrix $\boldsymbol{B}$ are time invariant. The state equation serves immediately as the basis of evaluation of the driving stability (Section 29.1.1). However, in case of ride comfort evaluation, a special shape filter has to be considered. The input of this shape filter is the acceleration $a(t)$ at the seat position, which is composed of the states and excitation quantities of the entire vehicle system,

$$a(t) = \boldsymbol{c}^{\mathrm{T}}\boldsymbol{x}(t) + \boldsymbol{d}^{\mathrm{T}}\boldsymbol{w}(t), \tag{29.93}$$

where
- c is a weighting vector of the states
- d a weighting vector of the excitations

Thus, the state Equation 29.92 extended by the shape filter Equation 29.2 reads

$$\underbrace{\begin{bmatrix} \dot{\boldsymbol{x}} \\ \dot{\bar{\boldsymbol{v}}} \end{bmatrix}}_{\dot{\tilde{\boldsymbol{x}}}} = \underbrace{\begin{bmatrix} \boldsymbol{A} & \boldsymbol{0} \\ \boldsymbol{g}\boldsymbol{c}^{\mathrm{T}} & \bar{\boldsymbol{F}} \end{bmatrix}}_{\tilde{\boldsymbol{A}}} \underbrace{\begin{bmatrix} \boldsymbol{x} \\ \bar{\boldsymbol{v}} \end{bmatrix}}_{\tilde{\boldsymbol{x}}} + \underbrace{\begin{bmatrix} \boldsymbol{B} \\ \boldsymbol{g}\boldsymbol{d}^{\mathrm{T}} \end{bmatrix}}_{\tilde{\boldsymbol{B}}} \boldsymbol{w}, \tag{29.94}$$

$$\dot{\tilde{\boldsymbol{x}}} = \tilde{\boldsymbol{A}}\tilde{\boldsymbol{x}} + \tilde{\boldsymbol{B}}\boldsymbol{w}.$$

The extended system (29.94) has exactly the same structure as the vehicle system (29.92), so that we can consider system (29.92) subsequently without loss of generality. The required computational methods can be subdivided into numerical and analytical methods that will be described in the following sections.

29.3.1 Numerical Simulation

The given set of linear or nonlinear differential Equations 29.91 and 29.92 can be analyzed by numerical integration (see Chapters 2, 3, and 5). For random excitations, a single realization is sufficient due to ergodicity. In case of nonlinear systems, the random response in general is not normally distributed any more. Even so, in many cases, one computes the first two moments only for evaluation purposes. However, the effort of numerical simulations is always large due to the complex vehicle system models. Thus, a proper choice of the integration methods is very important. Unfortunately, it is not possible to give general recommendations, since on the one hand new integration methods will be developed in numerical mathematics, and on the other hand, the performance of computers is still increasing. Often, the users apply the integration methods at hand and perform test runs for comparison.

Example 29.4

Simulation of vertical motions of vehicles.

Different integration methods shall be applied to the simulation of the vertical motion of the front and rear axle of a nonlinear 16-DOF-vehicle model under a ramp excitation. Furthermore, a five-DOF-vehicle model is considered as a test example of a random excitation.

Solution:

The ramp is crossed first by the front axle and then by the rear axle; this results in a time delay in the corresponding vibration responses (Figure 29.10).
Similar to Rill [18], the following integration methods shall be compared:

- Single-step methods
  (Runge–Kutta–Fehlberg procedure of orders 5 and 6 [RKF5, RKF6]),
- Predictor-corrector multistep method
  (Shampine–Gordon procedure [SGDE]),
- Extrapolation method
  (Stoer–Bulirsch procedure [SB]).

The results of the large-vehicle model are shown in Figure 29.11. It can be seen that the Shampine–Gordon procedure [19] leads to the best results with respect to computing time and accuracy.

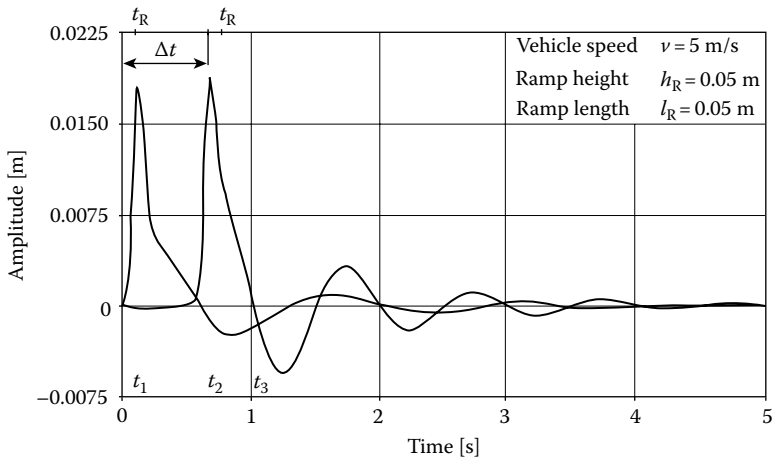

FIGURE 29.10 Vertical motion of the front and rear wheels of a nonlinear 16-DOF-vehicle model with ramp excitation.

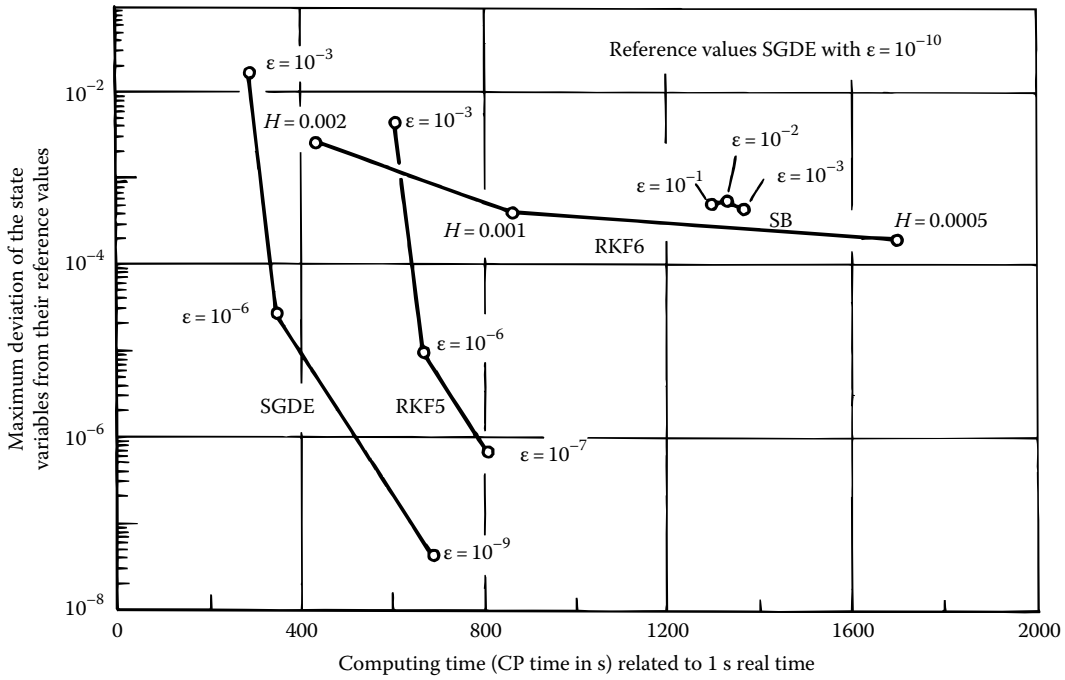

FIGURE 29.11 Comparison of integration methods for a 16-DOF-vehicle model with ramp excitation (error bound ε, step size H).

The random excitation of the small-vehicle model is generated by a random superposition of harmonic functions characterizing the road roughness profile (Figure 29.12).

The vertical motion of the front axle, see Figure 29.13, follows the road profile; however, the high-frequency components of the excitation are suppressed. Nevertheless, the integration procedure must take into account the high frequencies. Applying the procedures mentioned earlier lead to the results shown in Figure 29.14. Here, the simple Runge–Kutta–Fehlberg procedures are superior due to the fast evaluation of the right-hand side of the differential equations.

The numerical integration procedures result in time histories that have to be evaluated in order to assess ride comfort and safety. In case of random excitation, the computation of the performance criteria requires time averages that can be gained directly from spectral density or covariance analysis.

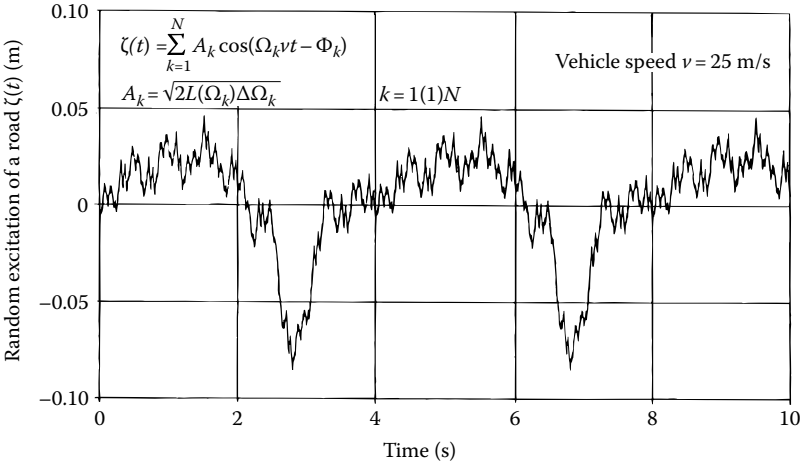

FIGURE 29.12 Realization of a random road excitation process.

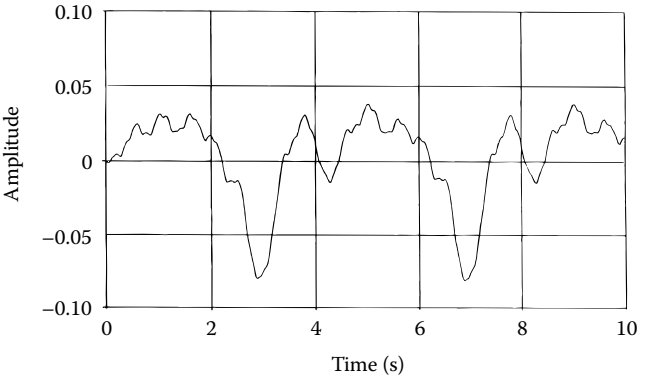

FIGURE 29.13 Vertical motion of the front wheel of a nonlinear five-DOF-vehicle model with random excitation.

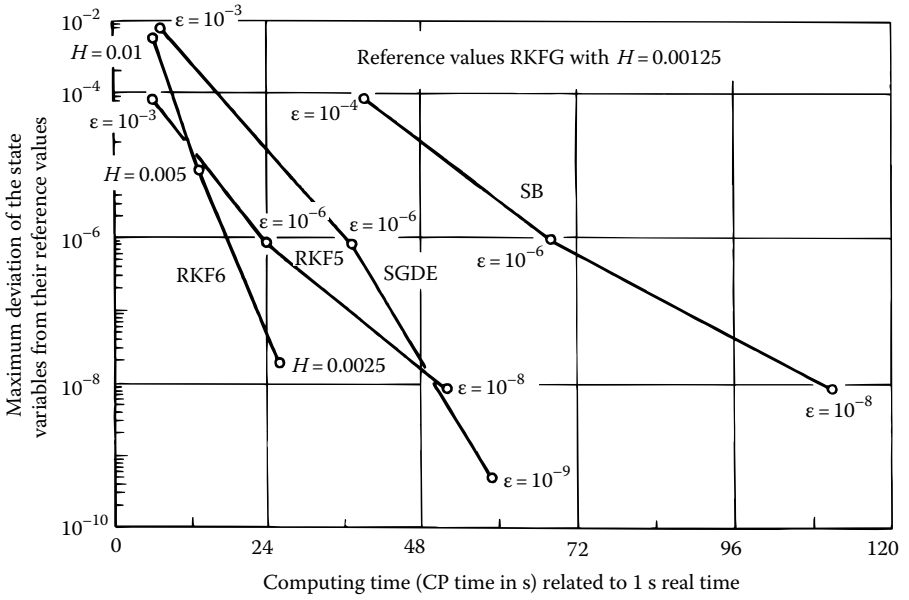

FIGURE 29.14 Comparison of integration methods for a five-DOF-vehicle model with random excitation (error bound ε, step size H).

29.3.2 Spectral Density Analysis

The investigation of random vibrations can be performed in the frequency domain using spectral analysis or in the time domain applying covariance analysis.

Assuming that $x(t) = 0$ is an asymptotically stable equilibrium position, then from $E\{\boldsymbol{w}(t)\} = \mathbf{0}$, it follows $E\{\boldsymbol{x}(t)\} = \mathbf{0}$, that is, the mean value of the state vector vanishes in the steady state. Thus, the essential goal is to calculate the characterizing variances, for example, the variance $\sigma_{\bar{a}}^2 = E\left\{\bar{a}^2(t)\right\}$ of the frequency weighted acceleration $\bar{a}(t)$.

First, we calculate the PSD that is a characteristic quantity of a random process in the frequency domain. In particular, for linear systems, the PSD of the input and output processes are related to each other by its FRFs. However, one should keep in mind that the ride comfort and safety criteria depend primarily on variances and not on PSDs.

The $n \times n$-PSD-matrix $\boldsymbol{S}_x(\omega)$ of the entire vehicle system described by the state Equation 29.92, where $\boldsymbol{A}$ = const and $\boldsymbol{B}$ = const has been assumed, follows from the white noise process $\boldsymbol{w}(t) \sim (\boldsymbol{0}, \boldsymbol{Q}_W)$ as

$$\boldsymbol{S}_x(\omega) = (i\omega\boldsymbol{E} - \boldsymbol{A})^{-1}\boldsymbol{B}\,\boldsymbol{Q}_W\boldsymbol{B}^{\mathrm{T}}(-i\omega\boldsymbol{E} - \boldsymbol{A})^{-\mathrm{T}}. \tag{29.95}$$

Thus, the PSD-matrix $\boldsymbol{S}_x(\omega)$ is gained from the input intensity matrix $\boldsymbol{Q}_W$ by matrix multiplications with the FRF-matrix $\boldsymbol{F}_x = (i\omega\boldsymbol{E} - \boldsymbol{A})^{-1}$. Since the state vector $x(t)$ and the system matrix A often can be partitioned, it is possible to obtain intermediate results for the PSD matrices of the road excitation, the suspension system, and the chassis, respectively. This reduces possibly the numerical amount considerably.

The scalar PSD $S_a(\omega)$ of the scalar acceleration $a(t)$, given by Equation 29.93, reads

$$S_a(\omega) = (\boldsymbol{c}^{\mathrm{T}}\boldsymbol{F}_x(\omega)\boldsymbol{B} + \boldsymbol{d}^{\mathrm{T}})\,\boldsymbol{Q}_W\left(\boldsymbol{B}^{\mathrm{T}}\boldsymbol{F}_x^{\mathrm{T}}(-\omega)\,\boldsymbol{c} + \boldsymbol{d}\right), \tag{29.96}$$

where the $n \times n$-FRF-matrix $\boldsymbol{F}_x$ has been used again. Equation 29.95 shows that the PSD is a quadratic expression, that is, the PSD of a sum of quantities leads to additional terms in the result. Using the PSD $S_a(\omega)$, Equation 29.95, the frequency weighting due to Equation 29.16 can be performed very easily; it yields

$$S_{\bar{a}}(\omega) = \alpha^2 \left|F(\omega)\right|^2 S_a\,. \tag{29.97}$$

The variance follows from the PSD by integration over an infinite interval,

$$\sigma_{\bar{a}}^2 = \int_{-\infty}^{\infty} S_{\bar{a}}(\omega)\,\mathrm{d}\,\omega = \int_{0}^{\infty} \Phi_{\bar{a}}(\omega)\,\mathrm{d}\,\omega. \tag{29.98}$$

For comparison with Equation 29.16 in Equation 29.98, the single-sided PSD $\Phi_{\bar{a}}(\omega)$ with $\Phi_{\bar{a}}(\omega) = 2S_{\bar{a}}(\omega)$ has been introduced.

The numerical computation of the PSD (29.98) is generally not difficult. However, one has to deal with complex matrices, many approximation points, and a very large integration interval; this can lead to numerical errors and considerable computation times. The integration (29.98) can be avoided by applying the covariance analysis as shown in the next section.

Special care is required in the spectral analysis of multiaxle vehicles. The excitation at different axles is given by an excitation function with time delay,

$$\begin{aligned} \boldsymbol{B}\boldsymbol{w}(t) &= \sum_{i=1}^{m} \boldsymbol{B}_i\zeta_i(t), \\ \zeta_i(t) &= \zeta(t - t_i), \quad 0 = t_1 < t_2 < \cdots < t_m, \\ t_i &= \frac{l_i}{v}, \quad i = 1, \ldots, m, \end{aligned} \tag{29.99}$$

where

l_i denotes the distance between the front axle and the ith axle

v is the const is the vehicle speed

The PSD matrix of a two-axle vehicle under random excitation reads

$$\boldsymbol{S}_x(\omega) = (i\omega\boldsymbol{E} - \boldsymbol{A})^{-1}\Big[\, B_1\boldsymbol{S}_\zeta B_1^{\mathrm{T}} + \boldsymbol{B}_2\boldsymbol{S}_\zeta\boldsymbol{B}_2^{\mathrm{T}} + \mathrm{e}^{i\omega(t_1-t_2)}\,\boldsymbol{B}_2\boldsymbol{S}_\zeta\boldsymbol{B}_1^{\mathrm{T}} + \mathrm{e}^{i\omega(t_2-t_1)}\,\boldsymbol{B}_1\boldsymbol{S}_\zeta\boldsymbol{B}_2^{\mathrm{T}}\Big](-i\omega\boldsymbol{E} - \boldsymbol{A})^{-\mathrm{T}}. \tag{29.100}$$

In the frequency domain, the time delay $(t_2 - t_1)$ results in additional terms, weighted by the exponential function.

29.3.3 Covariance Analysis

In contrast to spectral analysis, the covariance analysis directly yields the variances that are required for the assessment of ride comfort and safety. The covariance matrix of the entire vehicle system follows from an algebraic equation, the so-called Lyapunov matrix equation, and no integrations are required. An essential prerequisite of the covariance analysis is a white noise input process. This can always be provided by modeling the random vehicle excitation by means of a shape filter.

The Lyapunov matrix equation corresponding to the state Equation 29.92 of the entire vehicle system reads

$$\boldsymbol{A}\boldsymbol{P}_x + \boldsymbol{P}_x\boldsymbol{A}^{\mathrm{T}} + \boldsymbol{B}\boldsymbol{Q}_W\boldsymbol{B}^{\mathrm{T}} = 0, \tag{29.101}$$

where

$\boldsymbol{P}_x = E\,\{\boldsymbol{x}\,\boldsymbol{x}^{\mathrm{T}}\}$ denotes the symmetric $n \times n$-covariance matrix

$\boldsymbol{Q}_W$ is the $r \times r$-intensity matrix of the white noise input

An extensive derivation of Equation 29.101 can be found in [20]. Stable numerical procedures to solve the Lyapunov matrix equation are given in [21,22]. As a result, one gets the variances of all state variables of the system. However, the computation of the ride comfort requires the variance of the frequency weighted acceleration. Thus, the covariance analysis has to be applied to the extended system (29.94). The covariance matrix of the extended state vector $\tilde{\boldsymbol{x}}$ reads

$$\boldsymbol{P}_{\tilde{x}} = \begin{bmatrix} \boldsymbol{P}_x & \boldsymbol{P}_{x\bar{v}} \\ \boldsymbol{P}_{\bar{v}x} & \boldsymbol{P}_{\bar{v}} \end{bmatrix} \tag{29.102}$$

where $\boldsymbol{P}_{x\bar{v}} = \boldsymbol{P}_{\bar{v}x}^{\mathrm{T}}$ holds. The $s \times 1$-vector process $\bar{\boldsymbol{v}}(t)$ yields, according to (29.21), immediately the frequency weighted acceleration and its variance

$$\sigma_{\bar{a}}^2 = \alpha^2\,\bar{\boldsymbol{h}}^{\mathrm{T}}\boldsymbol{P}_{\bar{v}}\,\bar{\boldsymbol{h}}. \tag{29.103}$$

This is the relation corresponding to Equation 29.98. The investigation of multiaxle vehicles is also possible by the covariance analysis. The theory needed can be developed, as shown in [16]. In contrast to spectral analysis, the covariance analysis can also be applied to nonstationary and nonlinear problems without difficulties.

Example 29.5

Random vibrations of a single-axle vehicle.

A wheel guided in the vertical direction is excited by the road roughness and performs random vibration (Figure 29.15). The variance of the dynamic wheel load variations have to be investigated by applying covariance analysis. The road roughness is characterized by white velocity noise $\dot{\zeta}(t) \sim (0, q)$.

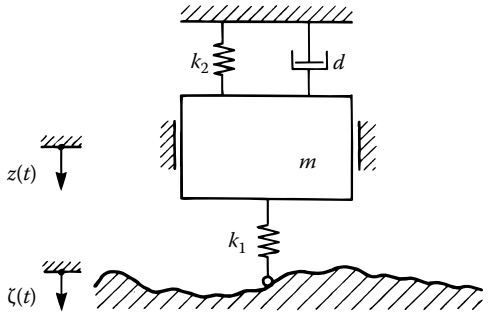

FIGURE 29.15 Single-axle vehicle model under random excitation.

Solution:

The equation of motion of the wheel reads

$$m\ddot{z} + d\dot{z} + (k_1 + k_2)z = k_1\zeta(t), \tag{29.104}$$

where $\zeta(t)$ is a scalar random process. The corresponding state equation has the form

$$\underbrace{\begin{bmatrix} \dot{z} \\ \ddot{z} \end{bmatrix}}_{\dot{\boldsymbol{x}}} = \underbrace{\begin{bmatrix} 0 & 1 \\ -\kappa_{12} & -\delta \end{bmatrix}}_{\boldsymbol{A}} \underbrace{\begin{bmatrix} z \\ \dot{z} \end{bmatrix}}_{\boldsymbol{x}} + \underbrace{\begin{bmatrix} 0 \\ \kappa_1 \end{bmatrix}}_{\boldsymbol{B}} \zeta(t), \tag{29.105}$$

$$\dot{\boldsymbol{x}} = \boldsymbol{A}\boldsymbol{x} + \boldsymbol{B}\boldsymbol{w}(t),$$

where the abbreviations $\delta = d/m$, $\kappa_{12} = (k_1 + k_2)/m$, $\kappa_1 = k_1/m$ have been used.

Since the random excitation is given by a white velocity noise process, it is recommendable to differentiate Equation 29.105 so that the process $\dot{\zeta}(t)$ appears directly as excitation. Then, the Lyapunov equation reads

$$\boldsymbol{A}\boldsymbol{P}_{\dot{x}} + \boldsymbol{P}_{\dot{x}}\boldsymbol{A}^{\mathrm{T}} + \boldsymbol{B}\boldsymbol{q}\boldsymbol{B}^{\mathrm{T}} = 0, \tag{29.106}$$

where the 2 × 2-covariance matrix of the first derivative $\dot{x}$ of the state vector has been introduced,

$$\boldsymbol{P}_{\dot{x}} = \begin{bmatrix} P_{11} & P_{12} \\ P_{12} & P_{22} \end{bmatrix} = \begin{bmatrix} P_{\dot{z}\dot{z}} & P_{\dot{z}\ddot{z}} \\ P_{\dot{z}\ddot{z}} & P_{\ddot{z}\ddot{z}} \end{bmatrix}. \tag{29.107}$$

The solution of Equation 29.106 yields the following matrices

$$\boldsymbol{A}\boldsymbol{P}_{\dot{x}} = \begin{bmatrix} P_{12} & P_{22} \\ -\kappa_{12}P_{12} - \delta P_{12} & -\kappa_{12}P_{12} - \delta P_{22} \end{bmatrix}, \tag{29.108}$$

$$\boldsymbol{B}\boldsymbol{q}\boldsymbol{B}^{\mathrm{T}} = \begin{bmatrix} 0 & 0 \\ 0 & \kappa_1^2 q \end{bmatrix}. \tag{29.109}$$

Due to the symmetry of the covariance matrix from Equation 29.106, it follows altogether three linear equations for the unknowns

$$\begin{bmatrix} 0 & 2 & 0 \\ -\kappa_{12} & -\delta & 1 \\ 0 & -2\kappa_{12} & -2\delta \end{bmatrix} \begin{bmatrix} P_{11} \\ P_{12} \\ P_{22} \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \\ \kappa_1^2 q \end{bmatrix} \tag{29.110}$$

with the solutions

$$P_{11} = \frac{k_1^2}{2d(k_1 + k_2)} q, \quad P_{12} = 0, \quad P_{22} = \frac{k_1^2}{2dm} q. \tag{29.111}$$

The weighting vector b of the dynamic wheel loads reads, according to Equation 29.104,

$$f_{Dyn} = k_1(z - \zeta) = \underbrace{[-d - m]}_{\boldsymbol{b}^T} \underbrace{\begin{bmatrix} \dot{z} \\ \ddot{z} \end{bmatrix}}_{\dot{x}}, \tag{29.112}$$

where $k_2 << k_1$ has been regarded. The variance σ_f^2 of the dynamic wheel load variation reads

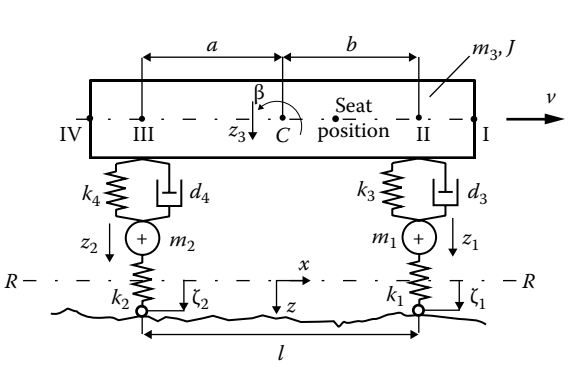
$$\sigma_f^2 = \boldsymbol{b}^T \boldsymbol{P}_{\dot{x}} \boldsymbol{b} = \left[\frac{k_1 d}{2} + \frac{k_1^2 m}{2d} \right] q. \tag{29.113}$$

It can be seen that σ_f^2 becomes a minimum if the viscous damping factor $D = d \Big/ \left(2\sqrt{k_1 m} \right) = 0.5$ is chosen. In this case of optimal damping, it follows $\sigma_f^2 = k_1 \sqrt{k_1 m} q$. This result shows that small wheel masses m and small tire stiffnesses k_1 are beneficial for the dynamic wheel load variations. However, there are design limits for these parameters (see Chapter 8).

The assumption $k_2 << k_1$ is necessary in this example, since an idealized white velocity noise process has been considered. In the general case of colored noise, this assumption is not required.

Example 29.6

Random vibrations of a two-axle vehicle.



The covariance analysis is demonstrated by the example shown in Figure 29.16. A two-axle vehicle with four degrees of freedom is excited by colored noise $\zeta(t)$ according to (29.79) or white noise (29.81) for the derivated process $\dot{\zeta}(t)$.

Small motions are assumed and the time lag $t_2 = l_2/v$ between the front and rear contact has to be taken into account.

Solution:

The generalized coordinates are summarized in the position vector $\boldsymbol{y}(t)$, $\boldsymbol{y}(t) = [y_1(t), y_2(t), y_3(t), \Phi(t)]^T$. Then, the equation of motion reads

$$\boldsymbol{M}\ddot{\boldsymbol{y}}(t) + \boldsymbol{D}\dot{\boldsymbol{y}}(t) + \boldsymbol{K}\boldsymbol{y}(t) = \boldsymbol{s}_1\zeta_1(t) + \boldsymbol{s}_2\zeta_2(t), \quad \zeta_1(t) = \zeta(t), \quad \zeta_2(t) = \zeta(t - t_2), \tag{29.114}$$

$m_1 = 100$ kg
$m_2 = 54$ kg
$m_3 = 1{,}247$ kg
$J = 1{,}945$ kgm^2
$k_1 = k_2 = 34{,}3350$ N/m
$k_3 = 47{,}382$ N/m
$k_4 = 51{,}208$ N/m
$d_3 = 3{,}198$ Ns/m
$d_4 = 3{,}434$ N/m
$a = 1.2$ m
$b = 1.3$ m
$l = 2.5$ m

FIGURE 29.16 Two-axle vehicle model under random excitation and system parameters.

where $\boldsymbol{M}$, $\boldsymbol{D}$, and $\boldsymbol{K}$ characterize inertia, damping, and stiffness matrix, respectively, and $\boldsymbol{s}_1$, $\boldsymbol{s}_2$ are the excitation input vectors, $\boldsymbol{M} = \mathbf{diag}[m_1, m_2, m_3, J]$, $\boldsymbol{s}_1 = [k_1 0\ 0\ 0]^T$, $\boldsymbol{s}_2 = [0\ k_2 0\ 0]^T$,

$$\boldsymbol{D} = \begin{bmatrix} d_3 & 0 & -d_3 & bd_3 \\ 0 & d_4 & -d_4 & -ad_4 \\ -d_3 & -d_4 & d_3 + d_4 & -bd_3 + ad_4 \\ bd_3 & -ad_4 & -bd_3 + ad_4 & b^2 d_3 + a^2 d_4 \end{bmatrix}, \tag{29.115}$$

$$\boldsymbol{K} = \begin{bmatrix} k_1 + k_3 & 0 & -k_3 & bk_3 \\ 0 & k_2 + k_4 & -k_4 & -ak_4 \\ -k_3 & -k_4 & k_3 + k_4 & -bk_3 + ak_4 \\ bk_3 & -ak_4 & -bk_3 + ak_4 & b^2 k_3 + a^2 k_4 \end{bmatrix}. \tag{29.116}$$

From (29.114), the vehicle state space representation can be obtained,

$$\dot{\boldsymbol{x}}(t) = \boldsymbol{A}\boldsymbol{x}(t) + \boldsymbol{b}_1\zeta_1(t) + \boldsymbol{b}_2\zeta_2(t) = \boldsymbol{A}\boldsymbol{x}(t) + \boldsymbol{B}\xi, \tag{29.117}$$

$$\boldsymbol{x}(t) = \begin{bmatrix} \boldsymbol{y}(t) \\ \dot{\boldsymbol{y}}(t) \end{bmatrix}, \quad \xi(t) = \begin{bmatrix} \zeta_1(t) \\ \zeta_2(t) \end{bmatrix}, \quad \boldsymbol{A} = \begin{bmatrix} \boldsymbol{0} & \boldsymbol{E} \\ -\boldsymbol{M}^{-1}\boldsymbol{K} & -\boldsymbol{M}^{-1}\boldsymbol{D} \end{bmatrix}, \quad \boldsymbol{b}_1 = \begin{bmatrix} \boldsymbol{0} \\ \boldsymbol{M}^{-1}\boldsymbol{s}_2 \end{bmatrix}$$

$$\boldsymbol{B} = [\boldsymbol{b}_1 \quad \boldsymbol{b}_2].$$

In order to use white noise vehicle excitation, $\dot{\zeta}(t) \equiv w(t)$, Equation 29.116 has to be differentiated,

$$\left[\dot{\boldsymbol{x}}(t)\right]^{\bullet} = \boldsymbol{A}\left[\dot{\boldsymbol{x}}(t)\right] + \boldsymbol{B}\boldsymbol{w}(t). \tag{29.118}$$

Here, the autocorrelation matrix of the white noise vector process w reads

$$\boldsymbol{R}_W(\tau) = E\left\{\boldsymbol{w}(t)\boldsymbol{w}^T(t-\tau)\right\} = q_\zeta \begin{bmatrix} \delta(\tau) & \delta(\tau + t_2) \\ \delta(\tau - t_2) & \delta(\tau) \end{bmatrix}. \tag{29.119}$$

Thus, the covariance matrix $\boldsymbol{P}_{\dot{x}}$ in the steady state follows from the algebraic Lyapunov equation

$$\boldsymbol{A}\boldsymbol{P}_{\dot{x}} + \boldsymbol{P}_{\dot{x}}\boldsymbol{A}^T + \boldsymbol{Q} = \boldsymbol{0}, \quad \mathrm{c}\,\boldsymbol{Q} = q_{\dot{\zeta}}\left[\boldsymbol{b}_1\boldsymbol{b}_1^T + \boldsymbol{b}_2\boldsymbol{b}_2^T + e^{At_2}\boldsymbol{b}_1\boldsymbol{b}_2^T + \boldsymbol{b}_2\boldsymbol{b}_1^T e^{\boldsymbol{A}^T t_2}\right]. \tag{29.120}$$

From $\boldsymbol{P}_{\dot{x}}$, the variances σ_a^2 of the car body acceleration $\ddot{y}_p(t)$ at any point P with coordinates $y_p(t) = \boldsymbol{a}^T\boldsymbol{y}(t)$ can immediately be calculated by

$$\sigma_a^2 = [\boldsymbol{0}^T\boldsymbol{a}^T]\ \boldsymbol{P}_{\dot{x}}\begin{bmatrix} \boldsymbol{0} \\ \boldsymbol{a} \end{bmatrix}. \tag{29.121}$$

A similar expression holds for the variances σ_F^2 of the wheel loads $F_i = k_i(\zeta_i - y_i)$, $i = 1, 2$, but here Equation 29.114 has to be used to eliminate the displacements. Figure 29.17 shows some numerical results, where a smooth road ($q_\zeta = 3{,}14{\cdot}10^{-6} \cdot \mathrm{vm}^2/s$ – solid line) and a rough road excitation ($q_\zeta = 24.7{\cdot}10^{-6} \cdot \mathrm{vm}^2/s$ – dashedline) is assumed. In Figure 29.17a), the standard deviation σ_F/F_o of the load

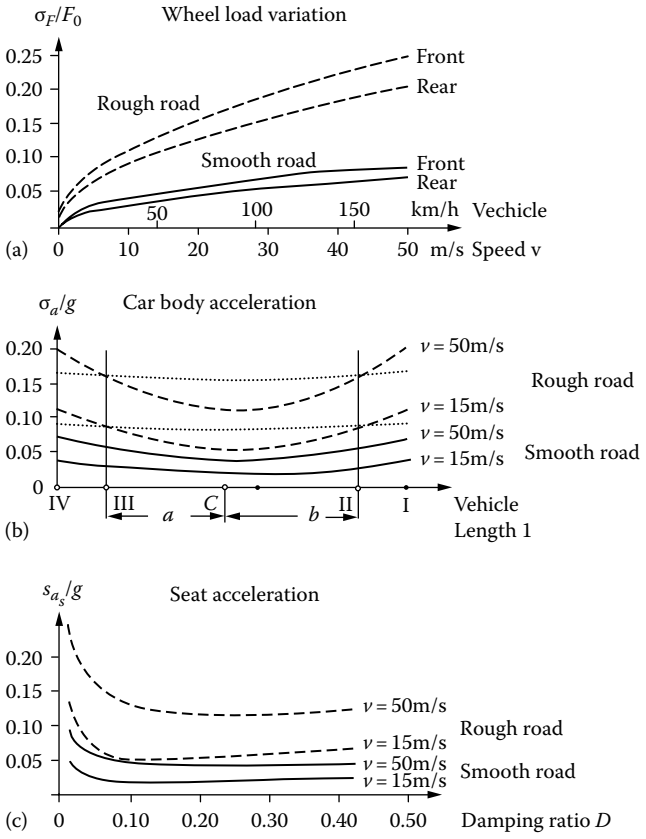


FIGURE 29.17 Random response variances, (a) wheel load variation depending on vehicle speed, (b) car body acceleration over vehicle length, (c) seat acceleration versus damping (— — rough road — — smooth road).

variation of the front and rear wheels is plotted against speed v, where F_o denotes the static weight. It increases with $\sqrt{v}$ since the excitation intensity is proportional to v. Even in the worst case (rough road, front wheel, maximum speed), the safety margin R according to Equation 29.28 takes the value $R = 1-\sigma_F/F_o \approx 0.75$, which indicates a safe ride. In Figure 29.17b, the standard deviation σ_a/g of the car body acceleration versus vehicle length is given, which clearly shows a minimum for the center of mass position at different speeds. Neglecting the time lag between the front and rear excitation (dotted line) can lead to incorrect results, especially near the seat position. The covariance analysis has an important application in optimization problems also. Figure 29.17c shows a simple example, where the influence of the nondimensional damping ratio $D = D_i \equiv d_i / \left(2\sqrt{k_i \bar{m}_i}\right)$, $i = 1,2,(\bar{m}_1 = m_3 a/l_1$, $\bar{m}_2 = m_3 b/l_1)$ on the standard deviation of the seat acceleration, σ_{a_s}/g, is studied. Best results are obtained in the range $0.1 \le D \le 0.25$. However, tradeoffs with the wheel load variation call for higher damping. For ride comfort evaluation, the perception measure K has to be calculated. A rough approximate estimation using the thumb rule $a_{max} \le 0.5$ m/s shows that the worst case (rough road, maximum speed, and maximum damping) certainly results in bad ride comfort. For further information on optimization methods of vehicle suspensions, see Chapter 8.

30.1 OVERVIEW OF CONTROL SYSTEMS OF CARS

In some driving situations, the driver may lose control over his car. For instance, such a situation may arise if the driver applies the brake pedal too hard and the wheels stop rotating and lock up. If the front wheels are locked, the driver will not be able to steer the car and the car will drift, while if the rear wheels are locked, the driver will not be able to keep the car from swerving. A similar situation may arise if the driver applies the accelerator pedal too much: the wheels spin with the same effect on the car as if the wheels were locked. However, even if neither the accelerator pedal nor the brake pedal is applied too much, the driver may still lose control over his car, for example, because of violent steering maneuvers.

In those situations, control systems help the driver to maintain control over his car. These control systems are the antilock brake system (ABS), which keeps the wheels from locking; the traction slip control system (TCS or ASR), which keeps the wheels from spinning; and the electronic stability program (ESP), which keeps the car from swerving and drifting. In the following sections, ABS and TCS will be explained as stand-alone systems. ESP includes the functions ABS and TCS which will be explained as parts of the hierarchical structure of ESP. For an overview of these systems, see [1–3].

30.1.1 Controllability of Cars

It is well known that if the wheels of a car lock or spin, then the resultant forces and the yaw moment on the car are independent of the slip angles of the tires. Thus, the loss of controllability of the car can be explained. However, it is not immediately clear why a car can become uncontrollable even if the wheels do neither lock nor spin (Figure 30.1).

FIGURE 30.1 Swerving car on dry asphalt, initial velocity 100 km/h, step steering wheel angle input 90°.

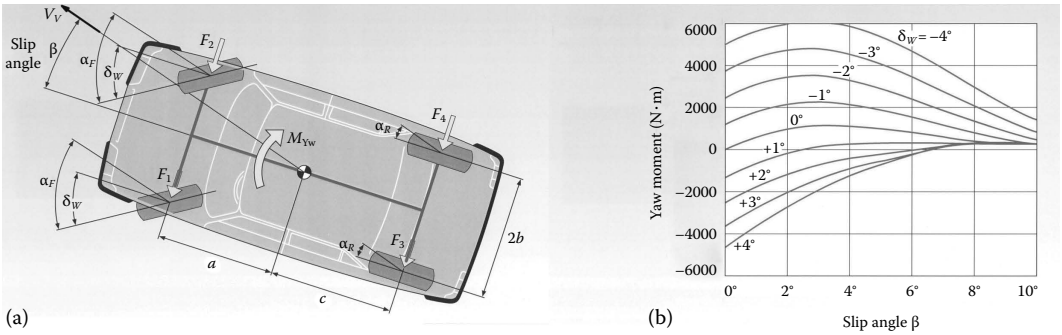

FIGURE 30.2 The beta method: (a) Top view of the car, (b) yaw moment on the car in dependence of the slip angle of the car for various steering wheel angles.

In order to explain this, Honda has developed a method [4] called the beta method, which shows the influence of the slip angle of the car on the yaw moment (Figure 30.2). For small slip angles, the yaw moment changes due to changes in the steering angle is much larger than for large slip angles. If for some reasons, the slip angle becomes large, then the influence of changing the steering angle on the yaw moment is small and may be so small that the slip angle cannot be reduced by steering and car swerve can hardly be avoided. This explains why average drivers that usually do not steer more than 90° at the steering wheel in either direction lose control if the slip angle of the car is large (larger than 6°).

Another explanation of why a car may become uncontrollable is given by Toyota (Figure 30.3) [5]. The figures show the trajectories of the car motion for combinations of slip angle and slip angle velocity at different steering angles. In the stable area, combinations of slip angle and slip angle velocity lead to a steady state of constant slip angle and zero slip angle velocity. If the steering angle is zero, then the steady state is a zero slip angle and a zero slip angle velocity. This means that eventually the car will move straight ahead, independent of the initial state (Figure 30.3a). In the unstable area, the steady state is not achieved and the car will not drive straight ahead, which, however, is the intention of the driver. If the steering angle is not zero, then the stability area is shrunk (Figure 30.3b), and if the steering angle is large enough (Figure 30.3c), there is even no stable state of the vehicle in motion.

Controlling the car in such situations may be extremely difficult for the driver. Here, ESP helps him with his task of keeping the car under control. Furthermore, the results show that even if ABS and TCS keep the wheels from locking and from spinning, respectively, it may still be difficult to control the car. Special control logic is used in these systems to improve the controllability of the car while keeping the wheels from locking and spinning, respectively. Furthermore, the systems must be tuned to each car to achieve optimum performance with regard to the car behavior. This shows the necessity of ESP to improve vehicle controllability for ABS and TCS situations also.

30.1.2 Basic Tire Properties

If a wheel is not steered and neither braked nor driven, then its rotational velocity, called the free rolling rotational velocity ω_{R0}, can be computed from the vehicle velocity v_v: $\omega_{R0} = v_v/R$ (Figure 30.4). The wheel radius R is computed by dividing the distance the wheel has traveled during one complete revolution by 2π. If the wheel is braked by a brake torque M_{BR}, then the rotational velocity ω_R will be smaller than the free rolling rotational velocity ω_{R0}. In the description of the control systems, the wheel velocity is used instead of the rotational velocity. The wheel velocity is defined as the product of the rotational wheel velocity and the wheel radius R. The free rolling wheel velocity is then $v_{WhlFre} = \omega_{R0} R$, while the wheel velocity is $v_{Whl} = \omega_R R$.

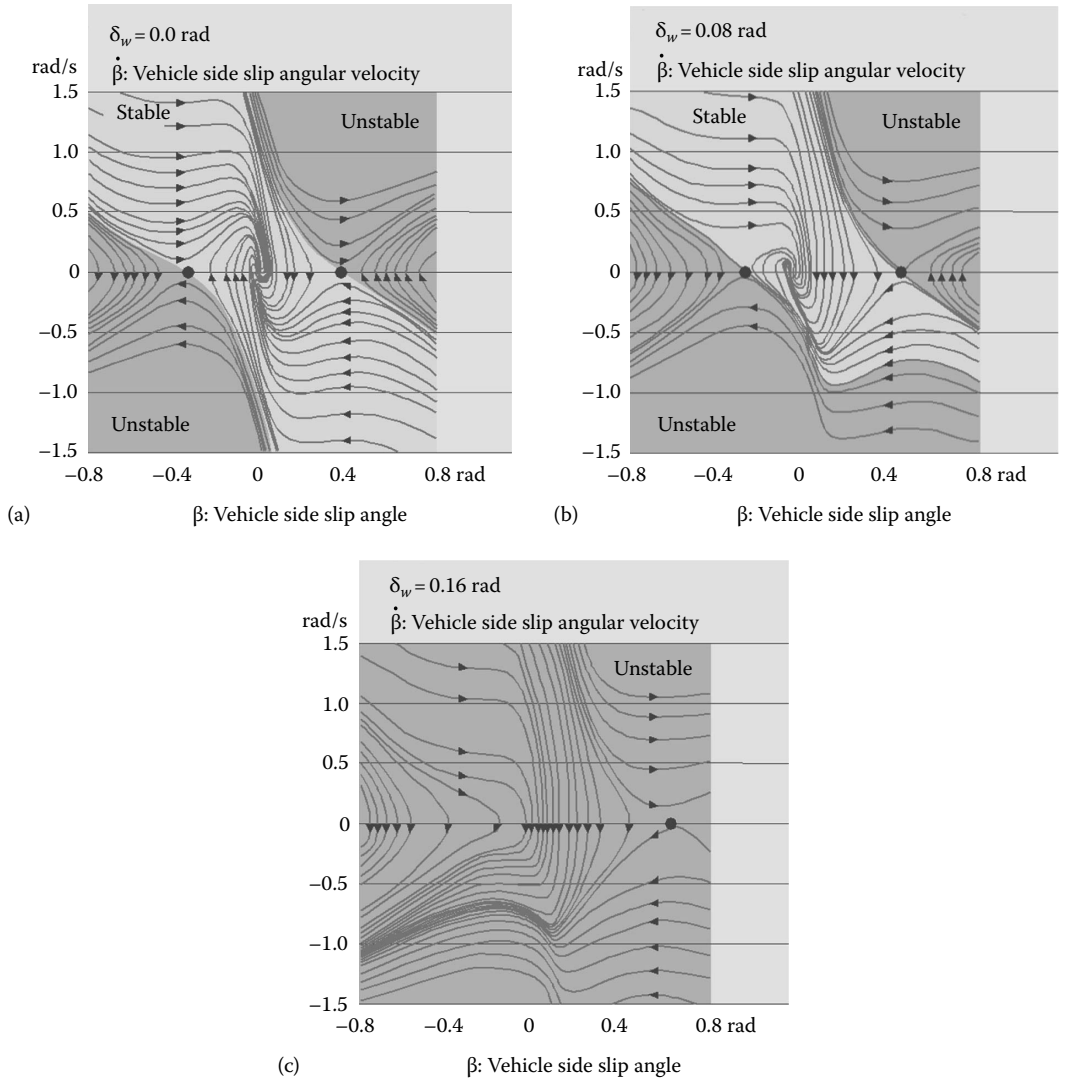

FIGURE 30.3 Phase plane plots of the car motion with stable and unstable regions depending on the steering wheel angle. (a) Steering wheel angle 0 rad, (b) Steering wheel angle 0.08 rad, (c) Steering wheel angle 0.16 rad.

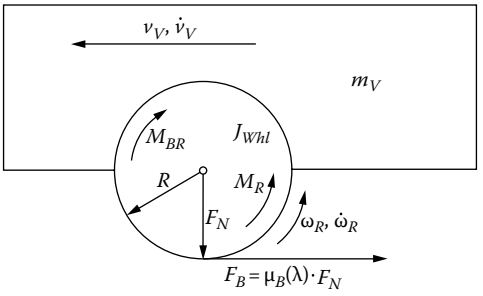

FIGURE 30.4 Simple physical model of a wheel attached to the vehicle body.

The difference between the free rolling and the braked wheel velocity is called the slip velocity. The slip velocity divided by the free rolling wheel velocity is called the wheel or tire slip λ. It is a dimensionless quantity whose value is one if the wheel is locked. Often, the slip is also expressed in percent, and the slip is 100% if the wheel locks.

$$\lambda = \frac{v_{WhlFre} - v_{Whl}}{v_{WhlFre}} \tag{30.1}$$

If a brake torque M_{BR} acts on the wheel, then a brake force F_B between the tire and the road results. If the normal force on the tire is F_N, then the brake coefficient of friction is $\mu_B = F_B/F_N$. The road torque on the wheel M_R is defined as the product of the brake force F_B and the wheel radius R: $M_R = \mu_B \cdot F_N \cdot R$. Between the brake slip and the brake coefficient of friction, a nonlinear relationship exists, called the μ-slip curve. Figure 30.5 shows a typical μ-slip curve, while Figure 30.6 shows some slip curves for various road surfaces. The curves usually exhibit a maximum, but for loose road surfaces

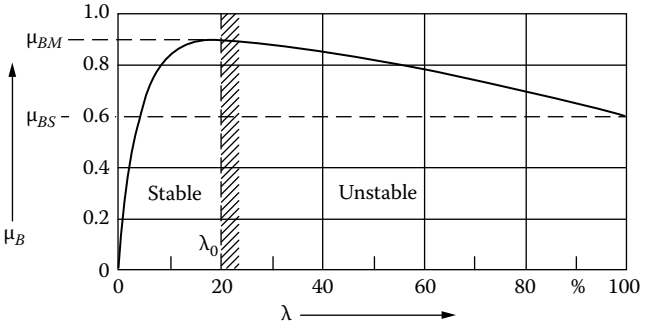

FIGURE 30.5 Typical μ-slip curve with μ_{BM} as the maximum value of the coefficient of friction and μ_{BS} as the value of the coefficient of friction of the skidding tire.

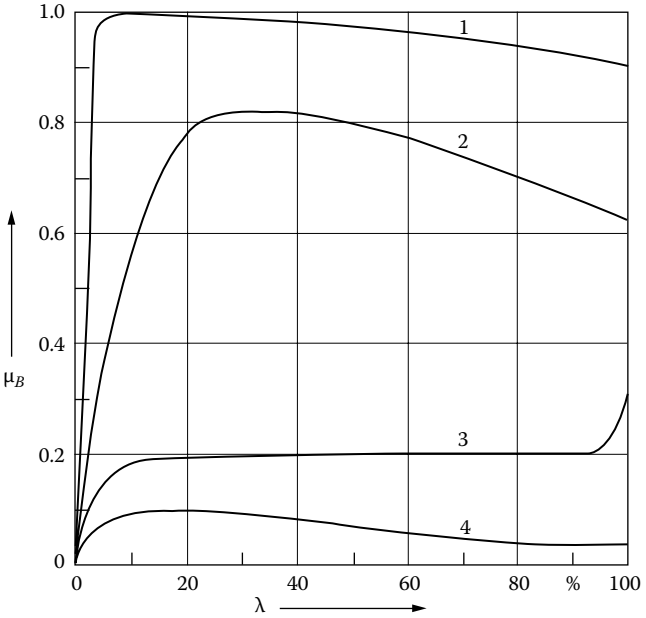

FIGURE 30.6 Typical μ-slip curves for some road surfaces: (1) dry asphalt, (2) wet asphalt, (3) packed snow, and (4) polished ice.

like snow and sand, the curve may not exhibit a maximum. The slip value at the maximum of the slip curve is often called λ_0. For values of the tire slip larger than λ_0, the μ-slip curve is unstable, since there is no stable equilibrium between the brake torque and the road torque: the tire slip will not be stable for a constant brake torque but will increase until the wheel locks.

If a free rolling wheel, whose longitudinal velocity is v_x, is pushed sideways, then the wheel will move also in the lateral direction and the resultant velocity of the wheel center is v_{VWhl} (Figure 30.7). The angle between the resulting wheel velocity and the wheel plane is called the slip angle α. Because the wheel is pushed sideways, the road acts with a force F_S in the opposite lateral direction on the wheel. The side force depends on the slip angle and on the normal force on the tire. Figure 30.8 shows the side force to be dependent on the slip angle for some wheel loads. Note that the maximum side force is not proportional to the normal force. The lateral coefficient of friction is the lateral force divided by the normal force on the wheel, $\mu_S = F_S/F_N$. The nonlinear relationship between the slip angle and the lateral coefficient of friction is called the μ-slip angle curve, which looks similar to that between the slip and the longitudinal coefficient of friction.

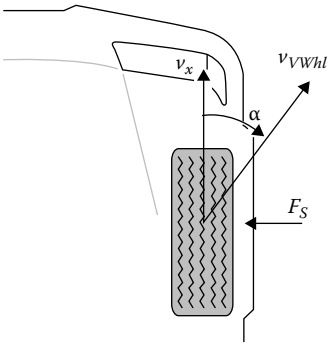

FIGURE 30.7 Definition of the slip angle and the side force on a wheel.

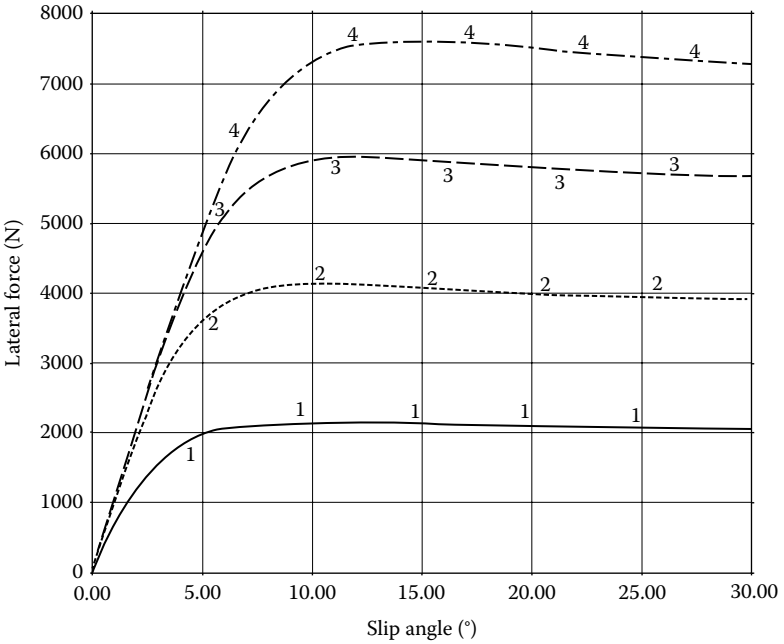

FIGURE 30.8 Lateral force on the wheel depending on the slip angle of the wheel for some wheel loads: (1) 2000 N, (2) 4000 N, (3) 6000 N, and (4) 8000 N.

The lateral coefficient of friction depends also on the tire slip: in general, if the tire slip is increased, then the lateral coefficient of friction drops if the slip angle is kept fixed (Figure 30.9). Furthermore, the μ-slip curve has different shapes for different slip angles. In general, μ_B decreases for a fixed slip value and λ_0 increases if the slip angle increases.

Often the relationship between the longitudinal and the lateral force on the wheel is shown as a map, in which curves of constant slip angle values and variable slip values are plotted (Figure 30.10). If the wheel locks, then the resultant force between the tire and the road has a direction opposite to

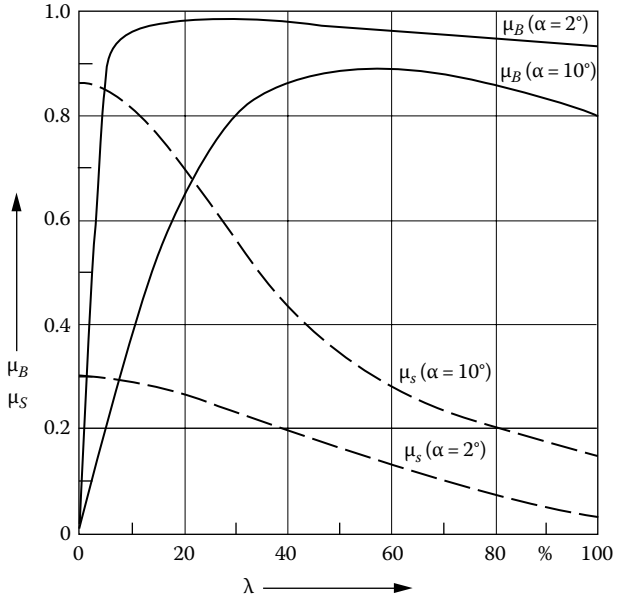

FIGURE 30.9 μ-slip curves for some fixed slip angles and the side force coefficient of friction for some fixed slip angles depending on the slip.

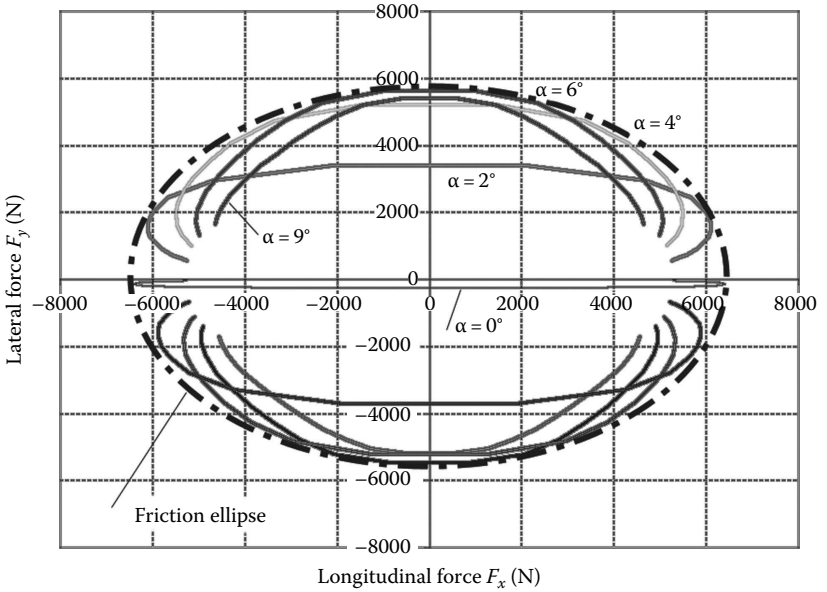

FIGURE 30.10 Map of the lateral and longitudinal forces for some fixed slip angles and the friction ellipse as the envelope of the map.

the velocity of the wheel: at those points in the map is $\tan \alpha = F_S/F_B$. For the control systems, the envelope of the map is approximated by an ellipse, which is called the friction ellipse.

30.1.3 The Antilock Brake System

The idea to keep the wheels from locking is very old and dates back to the beginning of the twentieth century. The first modern electronically controlled ABS was installed in a Mercedes car in 1978. An excellent description of the physics and the idea behind this system can be found in [6].

The first requirement of ABS is to keep the wheels from locking. However, the requirements can be formulated more specifically. The most important requirements are as follows:

1. The control of the brakes should secure a good controllability of the car by the driver on all roads, even if the road on one side of the car is more slippery than on the other side of the car (called split-μ braking).
2. In case of hydroplaning, stability and straight-line driving should be secured.
3. The coefficient of friction between the tires and the road should be maximally exploited during full braking.
4. The control function must be given at all car velocities down to zero.
5. The control performance must be tolerant of wear of the car and of the system, and also with respect to tire types and tire wear.
6. In the temperature range from −20°C to 120°C, the system must show full performance, while at lower temperatures the performance must not suddenly vanish.
7. Priorities during high-speed straight-line braking:
   a. Stopping distance
   b. Car stability
   c. Comfort (noise and brake pedal pulsation)
8. Priorities during high-speed handling:
   a. Car stability
   b. Stopping distance
   c. Comfort (noise and brake pedal pulsation)
9. Priorities during μ-split braking:
   a. Stopping distance
   b. Car stability
   c. Car steer ability (steering wheel rotational speed <90°/s)
   d. Car lateral displacement (<0.5 m relative to the middle of the track)
   e. Comfort (noise and brake pedal pulsation)
10. The system should be constantly monitored for proper performance. If a failure in a system component is recognized, which may reduce the system performance, then the system must switch off itself. The driver must be warned by a warning light on the display of the dashboard. If the system is switched off, then the base brake system must be fully functional.

In order to meet these requirements, the control system must limit the slip of the wheels such that the lateral stability margin at the front and at the rear axles is large enough for the driver to keep his car under control while at the same time minimizing the stopping distance.

For cost reasons, the car velocity is not measured; hence, the slip can neither be directly determined nor controlled. Instead, the stand-alone ABS is primarily designed as an optimizer of the brake force in the following way. If the slip is larger than the slip at the maximum brake force, λ_0, then the slip is unstable and the wheel will tend to lock, which is shown by a large deceleration of the wheel. And vice versa, it is assumed that if the deceleration of the wheel is large, then the slip is larger than λ_0 and the brake force is smaller than that at the maximum. In this situation, the brake pressure must be reduced in order to accelerate the wheel, increase its velocity, and thus reduce its

slip and increase its brake force. Furthermore, it is assumed that after the acceleration of the wheel has dropped to a small value, then the slip is smaller than λ_0 and the brake force is smaller than its maximum value. In this situation, the brake pressure must be increased in order to increase the slip and thus increase the brake force. The brake pressure control at the wheel is thus governed by the acceleration and deceleration of the wheel: ABS primarily controls the acceleration and deceleration of the wheel. At the slip value λ_0, the lateral stability margins of the tires already improve the controllability of the vehicle during full braking.

ABS reduces the brake pressures at the wheels from that induced by the driver such that the wheels do not lock. If the driver does not apply the brake pedal hard enough and the wheel does not tend to lock, then the control does not start. Therefore, the brake pressure at the wheels cannot be larger than that induced by the driver: ABS cannot actively increase the pressure at the wheels.

The simplified principle of the pressure control of ABS is shown in Figure 30.11. In phase 1, the brake pressure at the wheel p_{Whl} at the beginning of a braking maneuver is shown. Because of the brake torque, the wheel decelerates and so does the vehicle. If the wheel acceleration a_{Whl} drops below the threshold $-a$, then the brake pressure increase is interrupted. It is kept constant and not immediately reduced since horizontal axle motions can feign a wheel instability. This may happen in particular at the beginning of a braking maneuver, when the compliance of the wheel carrier plays a role. Only after the wheel velocity has also dropped below the curve λ_1, the pressure is reduced. The curve λ_1 lies at a certain threshold value below the curve of the reference velocity v_{Ref}.

It is assumed that during the wheel deceleration, if a_{Whl} reaches the value $-a$, the coefficient of friction has reached its maximum value. Since v_{Ref} should approximate the wheel velocity at which the coefficient of friction is maximal, the reference velocity is extrapolated from this wheel velocity. The slope of the extrapolation is variable, starts with the value of −0.3 g (which corresponds approximately to the coefficient of friction of packed snow), and is large during each pressure increase. Furthermore, the v_{Ref} is derived for each diagonal wheel pair, for example, for the front-left and the rear-right wheel; and at the rear axle, the reference velocities are tied together by some logic. It is important that the average slope of v_{Ref} is not too steep, while otherwise, the wheels may lock before the car has come to a stop.

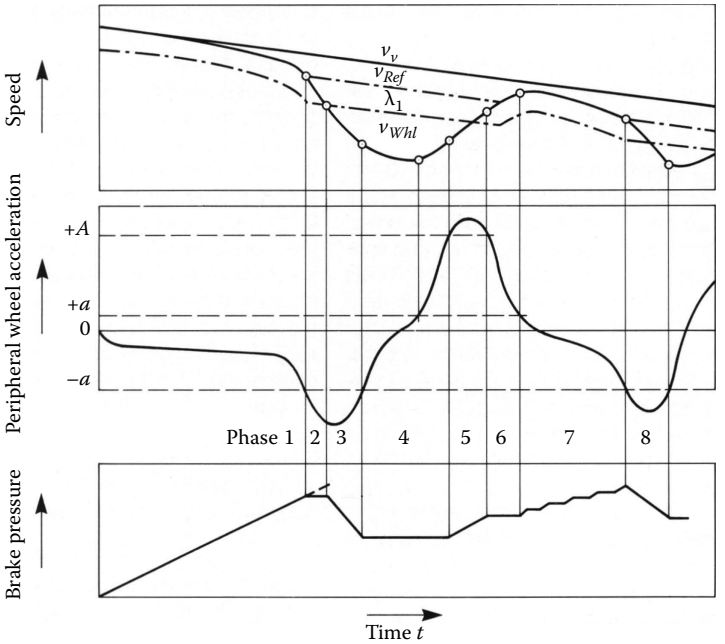

FIGURE 30.11 Typical initial part of the time plot of a stand-alone ABS braking control maneuver.

If the wheel deceleration diminishes and a_{Whl} increases above the threshold $-a$, the pressure reduction stops and the pressure is kept constant. During this phase (4), the wheel acceleration and velocity are observed. If the wheel velocity does not increase fast enough to become larger than the velocity λ_1, then the pressure is reduced in a stepwise manner. In phase 5, the acceleration of the wheel is so large that it exceeds the threshold $+A$. In this situation, it is assumed that the difference between the brake torque M_{BR} and the road torque M_R is very large. Therefore, the brake pressure is increased during this entire phase. After this phase 5, the brake pressure is kept constant and the wheel acceleration further observed.

If the wheel decelerates again, then a stable slip has established. Shortly before this happens, as the wheel acceleration drops below the threshold $+a$, the brake pressure is increased again—now in a stepwise manner. The first step is variable, while the following ones are fixed but increasing in magnitude. The value of the first step is chosen according to a learning scheme in order to get close to the maximum brake force. The idea behind following the stepwise manner, and thus a slow increase in the brake pressure, is to increase the slip level only slowly, such that the brake force stays at its maximum value for quite sometime. The pressure is increased stepwise until the wheel acceleration reaches the threshold $-a$ again. Now, the brake pressure is reduced immediately since it is assumed that the compliance of the wheel carrier has no influence on the wheel motion anymore. The control cycle is then repeated. Because of the logical nature of the control scheme with its many thresholds, it is often referred to as the ABS logic.

Since the wheel acceleration and deceleration depend only on the difference between the brake and the road torque and not on their magnitudes, the coefficient of friction of the road has little influence on the control performance. Therefore, ABS is adaptive to the road friction coefficient. The same is true for variations in the coefficient of friction of the brakes, for example, due to brake fading. The mean value of the slip can be modified by modifying the threshold values and by modifying the pressure steps. In general, for improved vehicle controllability, the modifications are chosen such that an average slip results, which is smaller than the slip value at the maximum of the μ-slip curve.

The control shown earlier aims at almost maximizing the brake force individually at each wheel. This type of control is called individual control. In some cases, individual control is not sufficient for the driver to keep his car under control. In particular, on split-μ roads (these are roads where on the one side of the car the coefficient of friction is smaller than on the other side of the car), special control features are required. These are "Select Low" control at the rear axle and "Yaw Moment Gradient Attenuation" (GMA) at the front axle. These special features will be discussed for a split-μ braking maneuver.

The braking maneuver on a split-μ road surface is shown in Figure 30.12. On the left side of the car, the coefficient of friction of the road surface is high ($\mu_B = 0.8$), while on the right side, it is very low ($\mu_B = 0.1$). For individual control, the brake forces on the left will be much higher than those on the right side. The result will be a large yaw moment on the car. The driver must balance this yaw moment by fast and heavy countersteering. In order to reduce the yaw moment and increase the stability margin at the rear axle of the car, the pressure on the left side of the rear axle is made equal to that on the right side (this is called the select low principle). Then the slip of the left rear wheel is very small and the side force reduction due to slip is also very small. Thus it is easier for the driver to control his car. This principle cannot be used at the front axle because then the higher coefficient of friction on the left side of the car would not be exploited at all and the stopping distance would be correspondingly long. Instead, at the front axle, a yaw moment is allowed; however, it is not allowed to increase very fast. This can be realized in several ways. One way is to start a stepwise brake pressure increase at the left wheel as soon as at the right wheel the deceleration threshold is reached (curve 3, Figure 30.13). The required steering effort is smaller (curve 7, Figure 30.13) than that for individual control (curves 2 and 6, Figure 30.13). Another way is shown in Figure 30.13 by curve 4. Because of this reduction in the gradient of the yaw moment, the driver has sufficient time to countersteer and keep his car stable on track.

If the car has a negative scrub radius, the countersteering effort of the driver is also reduced, since the wheels will automatically countersteer. However, both the GMA and the negative scrub radius

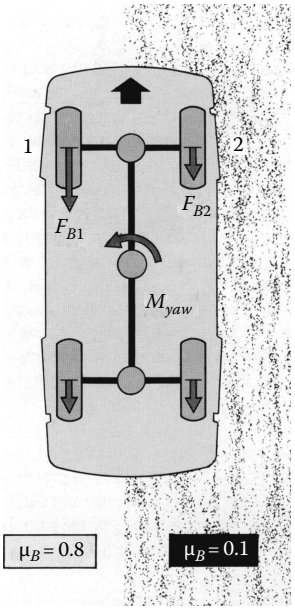

FIGURE 30.12 Brake forces F_{B1} and F_{B2} and yaw moment M_{yaw} on the vehicle during a stand-alone ABS braking control maneuver on a split-μ road surface.

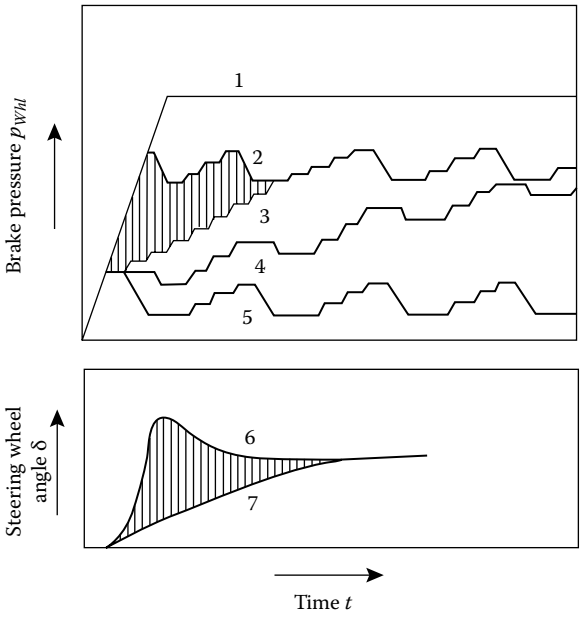

FIGURE 30.13 Influence of some yaw moment gradient reduction schemes on the required steering wheel angle effort. (1) Brake pressure induced by the driver, (2) individual wheel brake control, (3, 4) two possible reduced brake pressure gradient control schemes of the wheel on the high-μ surface, (5) brake control at the low-μ surface, (6) required steering wheel angle time history for individual control, (7) required steering wheel angle time history for reduced brake pressure gradient control.

have a negative effect on the stability of the car while braking in a turn. During cornering, the wheels on the outside of the turn have vertical forces which are larger than those on the inside of the turn, so that for individual control, the brake pressure at the wheels on the outside of the turn will be larger than those on the inside of the turn. "Braking while cornering" is therefore similar to "braking on split-μ." At the beginning of ABS control, the GMA feature will control the brake pressure to start with select low at the front and at the rear axle. This situation resembles partial braking in a turn from which it is known that the vehicle will tend to oversteer. The tendency disappears at the time that the wheels at the front axle are individually controlled (Figure 30.14). With a negative scrub radius, the car will also tend to oversteer during braking in a turn, since the front wheels will steer more into the turn. However, the situation is more severe, since the self-steering effect remains active during the entire maneuver. Therefore, the GMA feature must not be optimized for split-μ braking only, but a compromise must be found between vehicle controllability during braking on split-μ and while cornering.

On snow-covered roads, the μ-slip curve may not exhibit a maximum for slip values smaller than 100% (Figure 30.6). In this case and in general in all cases where the coefficient of friction continuously increases with the tire slip (e.g., deep snow, deep sand), the basic assumption of ABS (a maximum of the μ-slip curve exists for small slip values where the lateral stability margin is large) is violated. For these cases, ABS control may still eventually lead to locked wheels.

The hydraulic principle of pressure modulation for one wheel is shown in Figure 30.15. The components in the hydraulic block diagram are shown in the untriggered position, the inlet valve (EV) is then open, and the outlet valve (AV) is closed. If the driver applies the brake pedal, the brake fluid is pressed from the brake master cylinder (MC) through the open EV to the brake wheel cylinder (BC). If the EV is triggered, the brake pressure in the brake BC is kept constant. If the AV is triggered, then the brake fluid can escape from the brake BC to the low-pressure accumulator (Spk), and the pressure in the brake BC is reduced. If the motor (EM) is triggered, the recirculation pump (RFP) transports the brake fluid from the low-pressure accumulator back to the brake MC.

The block diagram of the hydraulic system for ABS is shown in Figure 30.16. Here, the EVs show an additional check valve. This check valve is required to release the brake fluid immediately from the brake BCs if the driver releases the brake pedal while the control is in operation. Furthermore,

a damping chamber (D) is shown. This is a cavity in the hydraulic block with a connection to the outlet side of the recirculation pump and a connection to the brake MC. The connection to the brake MC has a small orifice. The combination of the chamber and the orifice damps the pump pulsations in the fluid pressure and thus reduces the pump noise.

The inlet and the AVs are shown in Figure 30.17. The fluid filters are required to keep particles away from the valve seat, otherwise the valve may leak. The check valve function of the EV is realized by the special sealing of the valve in the housing.

The block diagram of the electronic control unit (ECU) is shown in Figure 30.18a. Inputs to the ECU are the four signals from the wheel speed sensors (WSSs). Outputs from the ECU are the stimulation voltages of the eight valves (9). The signals are processed (4) to derive the wheel velocities. The control logic is programmed in a microprocessor (6). For safety reasons, the ECU houses microprocessors which work in parallel. By continuous comparisons between the results from the microprocessors, the proper function of them is checked. If the results deviate for some time, a failure code is written to the EEPROM (8), the system is switched off (11), and the warning light is lit (13). With a diagnostics reader of the workshop (2), the failure can be read out. The ECU

is attached to the valve block of the hydraulic unit (HU). Since the HU is often mounted under the hood, near the engine, the ambient temperature can be high and specified to be up to 120°C. Figure 30.18b shows the ECU as a micro hybrid with the redundant microprocessors.

Figure 30.19 shows the complete HU with the attached ECU. The HU is mounted in a bracket with rubber mounts which is attached to the chassis of the car.

For the measurement of the wheel velocity, a WSS is used (Figure 30.20). The gear ring rotates with the wheel, while the sensor element is attached to the wheel carrier. The sensor works like an AC generator. It has a permanent magnet and a pole pin. If the gear ring rotates, then the magnetic flow from the magnet through the pole pin to the ring varies. The flow is high if a tooth of the ring is opposite to the pin and low between the teeth. Because of the varying magnetic flow, an alternating

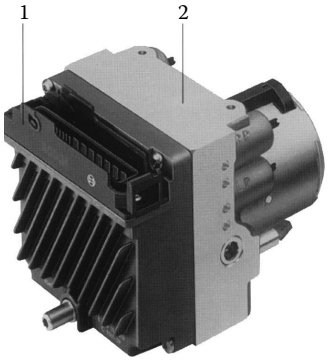

FIGURE 30.19 HU with attached ECU (1) and hydraulic block (2).

voltage is induced in the coil. The frequency of the alternating voltage is proportional to the wheel velocity. In the ECU, the periodical time of the alternating voltage is measured, transformed, and filtered to deliver the wheel velocity.

All components mounted in the car are shown in Figures 30.21 and 30.22. At the rear axle of the rear wheel driven car, a single WSS can be used (Figure 30.21), which picks up the average

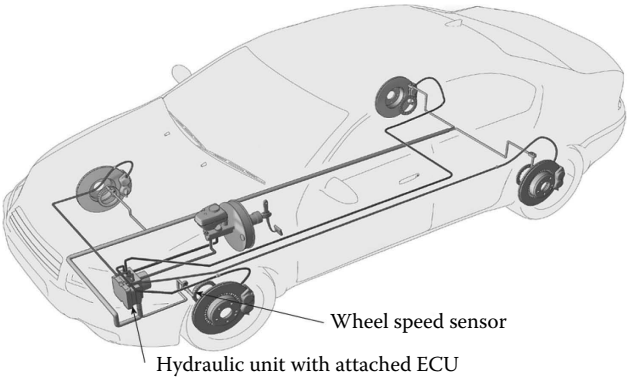

FIGURE 30.22 ABS mounted in the car.

velocity of the rear wheels at the drive axle (multiplied by the transmission ratio of the differential). This is possible in combination with select low control at the rear axle. By adaptation of the thresholds of the control logic, both wheels can be controlled on the basis of this single signal. If a system failure is detected, then the ECU must warn the driver by lighting the warning lamp (6).

30.1.4 Traction Slip Control System

Soon after ABS entered the automotive market, developments on the traction control system (TCS) started. The first implementations needed many expensive additional components like a high-pressure accumulator [7]. Since the main property of TCS for rear-wheel drive vehicles was seen as an improvement of vehicle stability, further developments of TCS concentrated on improved control of the engine output torque [8,9]. In order to avoid the cost of the "electronic accelerator pedal," simplified methods like "fuel injection suppression" were implemented to control the engine output torque [10]. These simplified methods have disappeared with the standard introduction of the electronic accelerator pedal on all vehicles.

If the driven wheels spin, the driver cannot control his car. The first requirement of TCS is to prevent the driven wheels from spinning. On the one side, the spin of the driven wheels can be controlled by controlling the engine torque. On the other side, wheel spin can also be controlled by active braking (i.e., the driver does not apply the brake) of the driven wheels. In general, TCS uses both controls. In principle, TCS controls the wheel slip to be close to λ_0.
The most important requirements of TCS are as follows:

1. Prevention of wheel spin and provision of track stability (neither drift nor swerve) while cornering.
2. Prevention of wheel spin on split-μ and slippery road surfaces and provision of sufficient traction.
3. Prevention of wheel spin at drive off uphill.
4. Priorities during handling:
   a. At high velocities:
      i. Vehicle stability
      ii. Comfort (noise, jerk)
      iii. Traction
   b. At low velocities:
      i. Vehicle stability
      ii. Traction
      iii. Comfort (noise, jerk)

5. Priorities during straight-line acceleration at low velocities:
   a. Traction
   b. Vehicle stability
   c. Comfort (noise, jerk)
6. Priorities during drive off and driving on split-μ:
   a. Traction
   b. Vehicle stability
   c. Comfort (noise, jerk)
7. Reduction of tire wear.
8. Reduction of the stress of the differential.
9. Warning to the driver if the control (control of the engine torque) is active.
10. Many of the ABS requirements are also valid for TCS.

The control concept of stand-alone ABS (control of the wheel acceleration and deceleration) cannot be used for the stand-alone TCS control. The reason is that by using the wheel acceleration and deceleration values, it is not possible to clearly differentiate between stable and unstable slip values. On the one side, the accelerations and decelerations are small in particular in the first gear of the transmission. On the other side, the engine torque is not independent of the engine rotational velocity. Therefore, it was necessary to find another control concept different from that used for ABS. Fortunately, it is possible to realize a slip control concept for TCS. The nondriven wheel velocities can be used to determine the free rolling wheel velocities and thus the drive slip of the driven wheels. However, this is not possible for four-wheel driven cars. With four-wheel driven cars, it is not possible for stand-alone TCS to keep the wheels from spinning.

TCS control can be basically split into slip control on homogeneous roads and on split-μ roads. On homogeneous roads, the coefficient of friction is the same at all driven wheels. Because of the differential, the drive torque is equally divided between the driven wheels at the drive axle. For straight-line maneuvers where the normal forces on both tires are equal, the drive slip is still the same at the two wheels. If the drive torque exceeds the maximum road torque, then both wheels on the axle will spin. In this case, it is sufficient to decrease the drive torque in order to reduce the slip at both wheels. This is realized by the engine management system. With gasoline engines, this is done by control of the throttle valve (Figure 30.23), and optionally, for fast torque control, by additional control of the spark timing

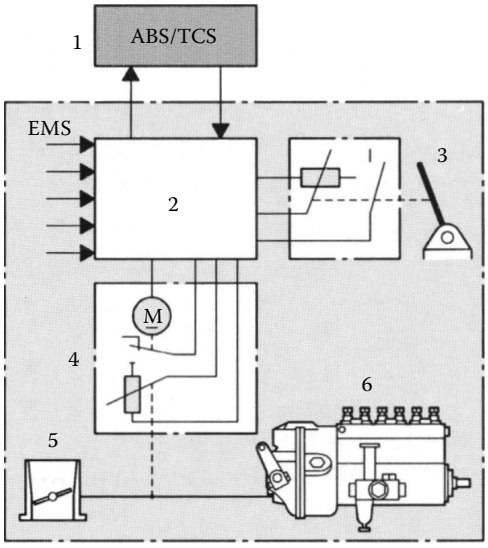

FIGURE 30.23 Electronic engine power control (EMS) with interface to ABS/TCS (1), ECU (2), accelerator pedal (3), stepped motor (4), throttle valve body of the gasoline engine (5), control rack of the injection pump of the diesel engine.

and fuel injection. With diesel engines, it suffices to control the control rack of the fuel injection pump. The controller (2) continuously sends the actual engine torque to the TCS. If the engine torque must be reduced, then TCS sends a reduced torque request to the controller. Since this request has a higher priority than the request from the driver (3), the torque is reduced to that requested by TCS. The actuator (4) of the controller then adjusts the throttle valve angle of the gasoline engine, respectively, and the rack of the diesel engine. Note that TCS can only reduce the engine torque from that requested by the driver (3).

On split-μ roads, the wheel on the low-μ surface (μ_l) tends to spin first if the drive torque at the cardan axle M_{Ca} is increased (Figure 30.24). A similar situation exists during cornering. The wheel on the inside of the turn tends to spin first and corresponds to the wheel on the low-μ surface, while the wheel on the outside of the turn corresponds to the wheel on the high-μ surface. Because of the differential, the drive torque on the wheel on the high-μ surface (μ_h) is limited to that of the wheel on the low-μ surface. The traction forces on both wheels (F_l) are correspondingly small. In order to achieve a larger traction force at the wheel on the high-μ surface, the wheel at the low-μ surface can be actively braked by the hydraulic system of TCS. The brake torque is controlled such that the slip velocity of the wheel on the low-μ surface lies below a velocity threshold which depends on the vehicle velocity. As long as the wheel on the high-μ surface does not spin, the engine torque is not reduced. However, if the slip velocity of the wheel on the high-μ surface also exceeds the velocity threshold, the engine torque will be reduced by TCS. Several slip velocity thresholds are used. The larger ones are used for the higher vehicle velocities. Their values are chosen such that a good compromise is reached between stability and traction during cornering and split-μ driving.

Sometimes the engine torque cannot be reduced fast enough to have a sufficient lateral stability margin at the driven wheel. In particular, for gasoline engines, pure throttle control can be too slow in decreasing the engine torque (Figure 30.25) and a large slip velocity results for a long time. In these cases, the control

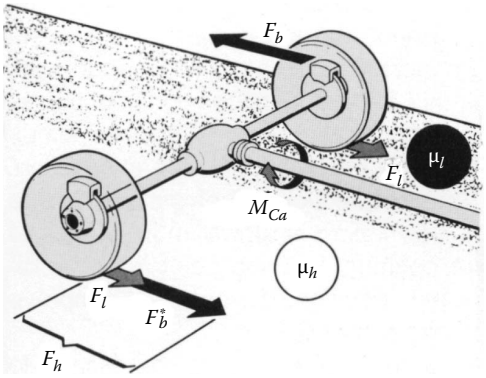

FIGURE 30.24 Principle of brake control for traction on split-μ road surfaces (μ_l is the low coefficient of friction and μ_h is the high coefficient of friction of the road surface): F_b is the force on the brake pad, F_b^* is the increment in the traction force, F_h is the enhanced traction force, and F_l is the maximum traction force on the slippery road surface.

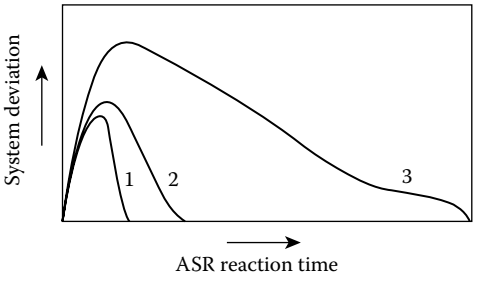

FIGURE 30.25 Influence of fast and slow interventions on the magnitude and the duration of the actuating signal of the TCS engine control: (1) fast brake intervention using a high-pressure accumulator, (2) fast engine intervention by spark-timing control, (3) slow engine intervention by throttle control.

of the spark timing and fuel injection can improve the situation. If a fast active brake system like the electrohydraulic brake system is available, the brakes can also be used to decrease the slip velocities at the driven wheels. In general, the brakes, the spark timing, and the fuel injection are only used to control the fast part of the drive torque reductions. They should only take care of the difference between the engine torque as a result of the throttle valve angle control and the required (nominal) engine torque. As soon as the required engine torque is reached, by throttle control, these fast parts of the control vanish. Since the control of the spark advance and the fuel injection has an influence on the exhaust gas emissions, there is a tendency to limit these control interventions to certain time slots or to forbid them all.

It is important to keep the difference in the velocities between the driven wheels small. The larger the velocity difference, the faster the differential rotates. Since the differential is also heavily loaded by the brake torque of the wheel on the low-μ surface, the power dissipated at the differential increases as much as the differential velocity increases. This dissipation may damage or even destroy the differential which is not designed for such large power dissipations.

On snow-covered roads, the wheel must not spin too long at the same spot since then the snow may get polished and turn into ice whose coefficient of friction is much lower than that of snow. Also, on deep sand tracks like in the desert, the wheels must not spin too long at the same spot since then they may dig holes into the sand and it is much more difficult to get out of the hole then to drive off on a smooth surface.

The use of the electronic accelerator pedal, EMS (Figure 30.23), allows also for the control of the slip of the driven wheels during lift-off of the accelerator pedal. If the accelerator pedal is released, then the engine torque acts like a brake torque at the driven wheels (engine drag torque). Particularly, on road surfaces with a low coefficient of friction, the slip of the driven wheels may become large because of the engine drag torque. In order to reduce this slip, the engine rotational velocity must be increased. This increase is realized in a special controller, the "Engine Drag Controller," whose acronym is MSR. In the MSR case, it is allowed to request an engine torque which is larger than that requested by the driver. If the MSR increases the engine rotational velocity, then the drive slip of the driven wheels is increased (the absolute value is decreased) and the side force reduction due to slip is reduced. Thus, the lateral stability margin of the driven wheels is increased.

The components of TCS are the same as those used for ABS. However, each of the driven wheels must have an individual WSS in order to allow for individual wheel brake control. The HU must be modified and extended in order to actively brake each of the driven wheels individually (Figure 30.26). The most important additions are two new valves in each brake circuit (3, 4). The most important modification is that the recirculation pump (7) is self-priming and can suck brake fluid through the brake MC from the brake fluid reservoir (1). During TCS operation, the suction valve (3) is opened and the pump supplies fluid to the brake BCs of the driven wheels. This valve has a large seat diameter so that the flow resistance for the brake fluid is low (Figure 30.27). In order to prevent the brake fluid from flowing back to the brake MC, the active pressure valves (4) are closed. The pressure-limiting function of the active pressure valves (4) is required to prevent pressure in the HU from increasing so much that the EVs are forcefully opened or that the HU gets damaged. If the pressure in the HU reaches this limiting value, the stem of the valve moves against the pressure-limiting spring to open the valve.

The TCS components in the car are shown in Figure 30.28. If the engine output torque is controlled by the system, then the TCS information light starts to blink. In case of a system failure, the TCS light is permanently on.

30.1.5 Electronic Stability Program

The first investigation of a feedback control of the stability and steerability of a vehicle realized by control of the individual wheel slips was given in 1973, much before ABS entered the automotive market [11]. Industrial realizations were proposed in the late eighties [12–14]. These proposals also communicated the need of system integration in the future and considered active suspension and active steering control. The first realization of active rear wheel steering control entered the automotive market in 1991, where a yaw velocity sensor was used for feedback control of the yaw rate of

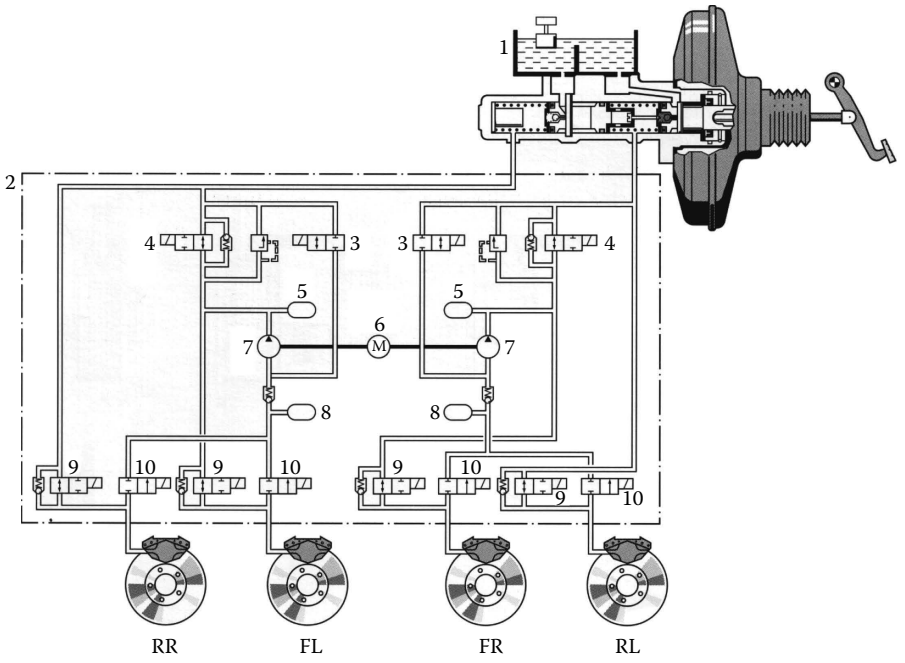

FIGURE 30.26 Block diagram of a typical hydraulic system for TCS: (1) brake MC with brake pedal, brake booster, and brake fluid reservoir, (2) HU, (3) suction magnetic valve, (4) active pressure magnetic valve with pressure-limiting function, (5) damping chamber, (6) pump motor, (7) self-priming recirculation pump, (8) low-pressure accumulator, (9) inlet magnetic valve, (10) outlet magnetic valve.

the car [15]. Other realizations followed where the feedback control of the yaw rate was realized by control of the brake or traction force distribution [16–18].

ESP entered the automotive market in 1995 [19,20]. The system uses a hierarchical control structure and will be discussed in this paragraph. With rapid succession, further systems entered the market [19–31]. Many of these systems used the stand-alone ABS and TCS controller structures to

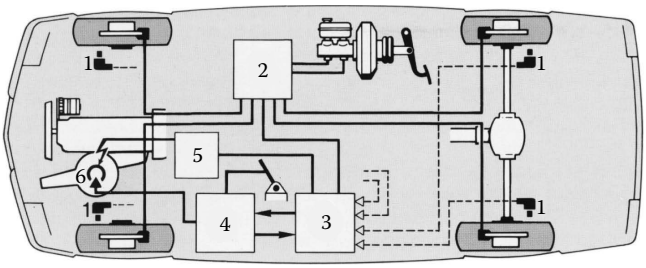

FIGURE 30.28 Integration of TCS in the vehicle system: (1) wheel velocity sensors, (2) hydraulic modulator, (3) TCS ECU, (4) electronic engine power control, (5) electronic injection and spark control, and (6) throttle actuator.

realize ESP and are called modular systems (see e.g., [29]). Further developments' main goal was to improve system reliability and reduce system cost [32,33]. A new proposal by Toyota, called VDM (Vehicle Dynamics Management), to fill the gaps between the different controller parts of the modular approach is based on a hierarchical controller structure and includes tire force signals [34].

Car swerve and drift are described by the body slip angle. The slip angle of the car has also a large influence on the controllability of the car by the driver and on the vehicle stability as described earlier. Therefore, in order to keep the car stable, the slip angle must be limited and also kept small so that the car behaves as usual and the driver can control his car. In this respect, it is useful to formulate the usual behavior of an average driver on dry roads during normal driving.

- The average driver steers such that the lateral acceleration is usually less than 0.2 g.
- The average driver drives such that the slip angle of the car is usually less than 2°.
- The average driver applies the brake pedal such that the vehicle deceleration is usually less than 0.4 g (brake pressure about 40 bar).

The average driver therefore is used to drive in the linear region of the slip and the slip angle curves of the tires where the car behavior is linear. His experience in the nonlinear region of the car behavior is virtually zero. He has no idea of the coefficient of friction of the road and of the stability margin of the car [35]. If the car behaves nonlinearly and its stability margin is small, the driver is caught by surprise by its substantially different behavior. Often he panics and does not act thoughtfully but, for example, steers too much. It is therefore not legitimate to expect thoughtful behavior of the driver in the nonlinear region of the car behavior while designing active safety systems like ESP. In order to avoid panic by the driver, it seems to be a good idea to start out with a nominal behavior of the car which is close to linear.

ESP is designed to improve the track stability of the car in every driving situation. However, it is not designed to control the brakes and the engine for the improvement of the basic handling behavior of the car. Therefore, ESP must start the control only if the physical limit of the car motion is reached. As ESP was installed on cars which may tow large trailers, the control has been extended to stabilize such combinations if the trailer starts to sway. Furthermore, as ESP also gets installed on vehicles with a soft suspension and with a high center of mass like on off-road vehicles and on Sport Utility Vehicles (SUV), its capabilities have been expanded to also improve the rollover stability.

30.1.5.1 System Concept

The first requirement on ESP is to keep the slip angle of the car limited to small values. From the discussion on vehicle controllability, it is important to keep the slip angle small and to keep the combination $(\beta, \dot{\beta})$ in the stable area. A sensor for the slip angle would allow for an easy formulation of the actuating signal. However, such a sensor for automotive applications (reliability at all

weather conditions, cost) is not available. As an alternative, a yaw rate sensor in combination with a lateral acceleration sensor is used. The derivation of the slip angle from these sensor signals is not always sufficiently reliable and a second actuating signal is required based on the nominal yaw velocity of the car. For the derivation of the nominal yaw velocity, the steering angle at the front wheels, the vehicle velocity, MC brake pressure, and the engine torque is required. Thus, the resulting system concept requires, besides the WSSs, a yaw rate sensor also, a lateral accelerometer, a steering wheel sensor, and a brake pressure sensor. The engine torque value is supplied by the engine management system. Figure 30.29 shows the system concept.

Since the vehicle moves at the physical limit, it is not possible to increase the side forces on the wheels and thus reduce the slip angles without influencing the longitudinal forces. Instead, ESP controls the yaw motion to indirectly control the slip angles. Thus, ESP computes the required yaw moment from the actuating signals. Increments in the yaw moment can be generated by modifying the lateral and the longitudinal forces on the tires. However, with the brakes alone, the slip angles of the tires cannot be directly modified. Indirectly, the lateral forces can be modified by the tire slip as can be seen from Figure 30.9, but not independent from the longitudinal force. Both forces have to be considered if a change in the slip is made to generate the required yaw moment. As an example, the yaw moment due to a change in the longitudinal slip of the left front wheel ($\Delta\lambda_1$) is (Figure 30.31).

$$\Delta M_{Yw} = -\frac{\partial F_{S1}}{\partial \lambda_1} \cdot \Delta\lambda_1 \cdot (a \cdot \cos\delta_W - b \cdot \sin\delta_W) + \frac{\partial F_{B1}}{\partial \lambda_1} \cdot \Delta\lambda_1 \cdot (b \cdot \cos\delta_W + a \cdot \sin\delta_W) \qquad (30.2)$$

If the partial derivatives in Equation 30.2 are known, then the slip increment for each wheel can be computed using, for example, the steepest descent method. The partial derivatives represent the slopes of the brake and side force coefficient curves in Figure 30.9 for a constant wheel load. Since they are unknown, vary rapidly with the slip value, and may vary with the tire make and state, they may be computed by fast identification. However, for fast identification, the (pressure) input should be rich enough, for example, a pressure pulse or a pressure step. But then transients in the wheel dynamics are excited and the result of a stepwise increase in the brake pressure is shown in Figure 30.30 [36]. This shows that the slope of the steady-state brake force–slip curve of Figure 30.9 cannot be determined by

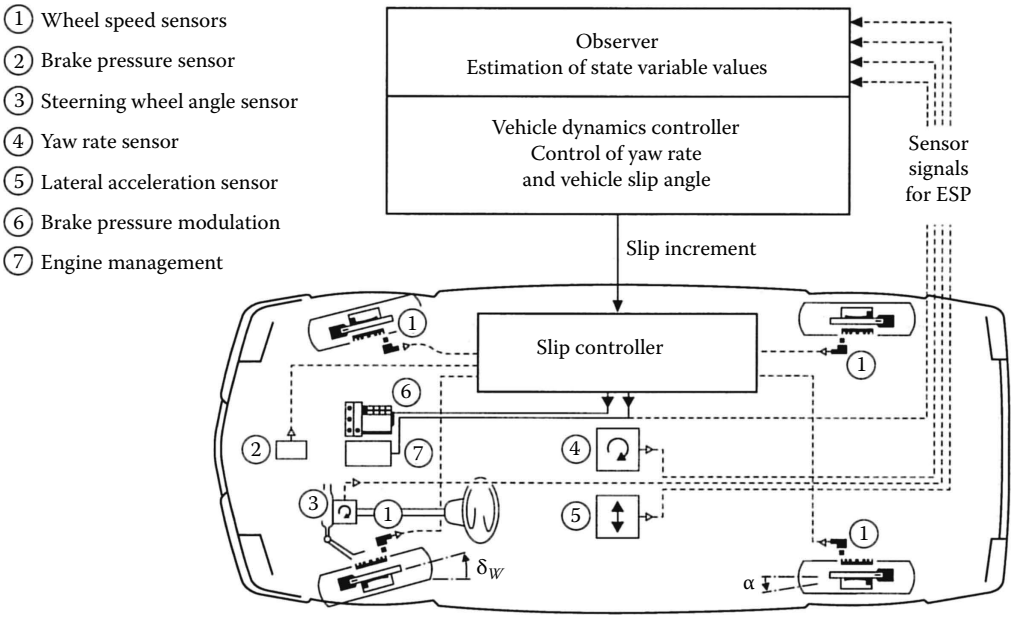

FIGURE 30.29 System concept of ESP with hierarchical control structure.

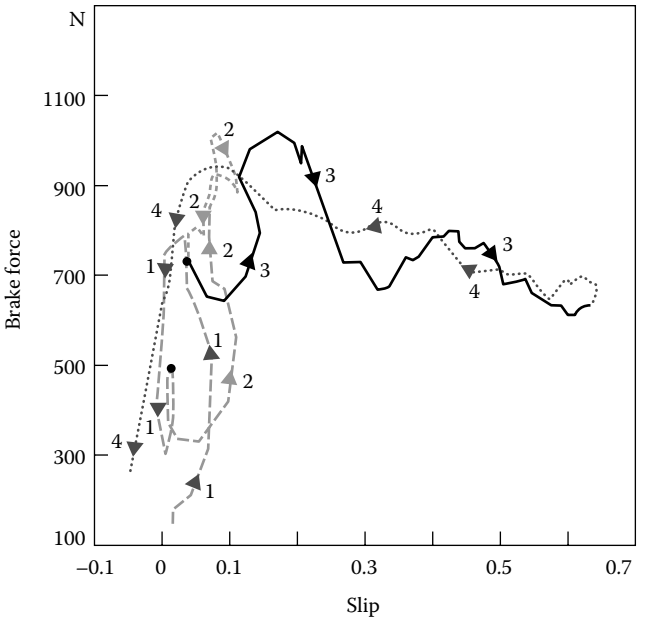

FIGURE 30.30 Dynamic brake force—slip phase diagram where the brake torque is increased in a stepwise manner (from number 1 to number 3) and decreased (number 4).

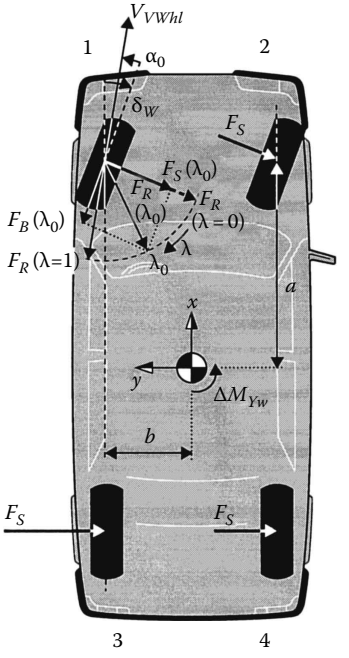

FIGURE 30.31 Influence of brake slip modification on the yaw moment on the car.

identification without consideration of wheel dynamics. The identification then becomes complex with many unknown variables and is no longer practical.

Instead, the friction ellipse concept is used (Figure 30.31). The assumption is that the friction force between the tire and the road has reached its maximum value (i.e., the car motion has reached its physical limit). For simplicity of explanation, the friction ellipse is approximated by a friction

circle. If the wheel slip is zero, then there is no longitudinal force and the yaw moment of the side force of the left front tire, wheel number 1, is with $F_{S1} = F_{R1}(\lambda = 0)$

$$M_{Yw} = -F_{S1} \cdot (a \cdot \cos\delta_w - b \cdot \sin\delta_w) \tag{30.3}$$

If the wheel slip is increased to λ_0, then a corresponding brake force ($F_{B1} = F_{B1}(\lambda_0)$) results and the side force is reduced to $F_{S1}(\lambda_0)$. The vectorial sum of the side and the brake force is denoted as $F_{R1}(\lambda_0)$, which has the same magnitude as the initial side force because of the preceding assumptions. Since F_{R1} has a direction which is different from that of the side force F_{S1}, the yaw moment on the car has changed due to the increment in the wheel slip (in the explanation the increment is the change in slip from 0 to λ_0). The gain (yaw moment increment due to an increment in the tire slip) is determined using the friction ellipse for which knowledge of the slip is required. One limiting condition is that the brake slip can only be increased up to the point where the wheel locks. Another limiting condition is that the engine torque cannot be increased beyond that value induced by the driver (except if the drag torque of the engine is too large such that large slip values result). During partial braking, however, increase in the brake pressure is allowed at any wheel beyond that value induced by the driver.

The change in the yaw moment is therefore controlled by changes in the wheel slips, which can be calculated from the friction ellipse using the wheel slips. The slip controller, which is below the vehicle dynamics controller in the hierarchical control system, can do both tasks. It computes the wheel slips and controls the wheel slip increments. Since by design, the stand-alone ABS is not able to control brake slip increments and to determine the wheel slip, the brake slip controller (BSC) of ESP is designed differently (for a different ESP design based on stand-alone ABS and TCS see [29]). A special feature of the slip controller, which computes the target slip λ_T which is close to the maximum of the μ-slip curve, allows it to be used for the ABS-function. With some modification, this special feature is also used for the TCS function of the slip controller. Furthermore, the slip controller is also used for all other driving situations such as coasting and partial braking to control the slip increments as commanded by the superimposed vehicle dynamics controller. It is important to notice that the structure of the underlying slip controller with its ABS and TCS functions is independent of the interventions of the superimposed vehicle dynamics controller.

In the stable area of the μ-slip curve, a unique relation exists between the wheel slip and the brake and drive torques. Here, nominal slip values can be replaced by nominal torque values and the brake and engine torque may be controlled to this nominal value. Care must be taken, however, that during this control to a nominal torque, the wheel does not lock nor spin, for example, because of sudden changes in the longitudinal tire force value. For slip values in the unstable area, this control to a nominal pressure is not possible. For improved yaw control performance, the control to a nominal wheel torque is used for very small nominal slip values. The reason here is that the μ-slip curve is very steep and small estimation errors in the slip result in large errors in the brake and drive torques from their nominal values. The decision to control the slip to the nominal slip value or to control the wheel torque to the nominal torque value is taken in the slip controller.

The hierarchical algorithm will be discussed using Figure 30.32 (see also [34] for a hierarchical design of ESP). On the top left side of the figure, the driver's desire in terms of the desired vehicle motion is derived from his inputs, while on the top right side, the actual motion of the car is measured and motion variables that are not measured are estimated.

The desired vehicle motion is derived using the linear steady-state bicycle model. From this model, the first nominal values of the yaw velocity $\dot{\psi}_M$ and the slip angle β_M are obtained, using the vehicle velocity. Since the lateral acceleration of the bicycle model is limited by the coefficient of friction of the road, the yaw velocity has to be limited also. At high vehicle velocities, the allowed slip angle is reduced in order to give the driver better support in controlling his car. These desired motion values must be compared with the actual motion values of the car to deliver the actuating signals. The actual yaw velocity is measured so that only the actual slip angle must be estimated. This is done by an observer

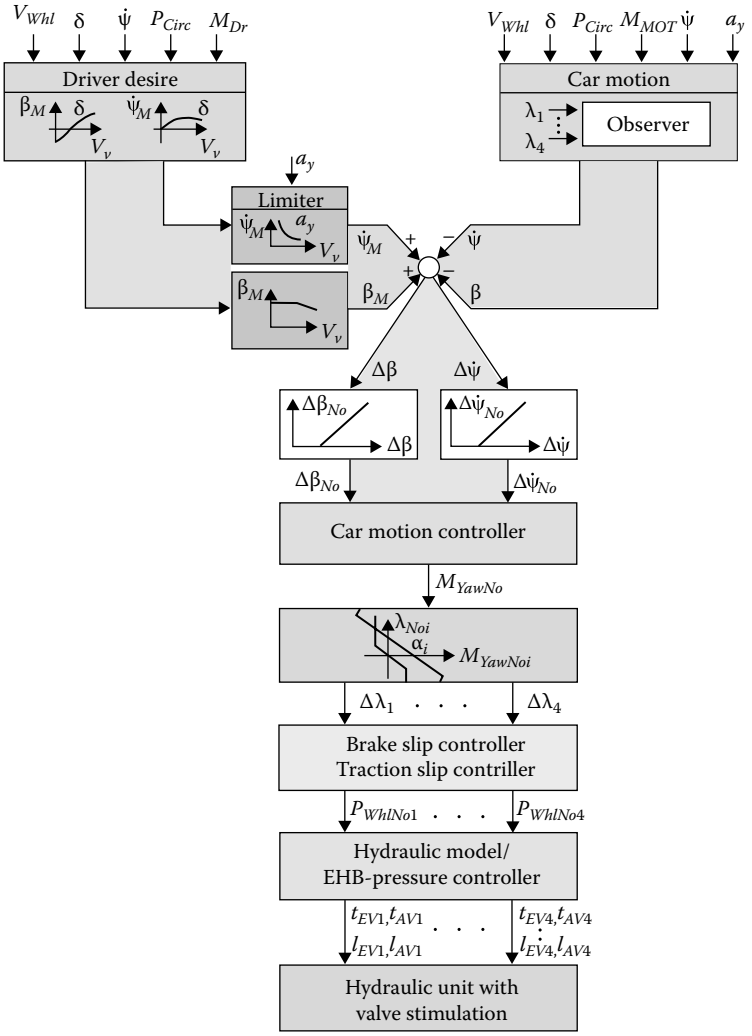

FIGURE 30.32 Control blocks of ESP.

who, among others, needs the actual slip values of the tires. The deviations between the desired and the actual motion values are filtered by a dead zone in order to avoid interventions which result, for example, from modeling, measurement, and estimation errors. The resulting filtered deviations are the actuating signals for the car motion controller. Using a simple proportional-integral-differential-type controller (PID) controller from the actuating signals, the required yaw moment on the car is determined. The gains are variable and depend among others on the magnitude of the slip angles of the tires.

In the next lower block, the nominal value of the slip for each wheel is computed using the friction ellipse (30.12) in order to achieve the desired yaw moment on the car. Usually, the slip is modified only at two wheels. For instance, during full braking in a turn if the vehicle shows an incipient swerve and the motion has to be stabilized, the slip at the front wheel on the outside of the turn is increased while the slip at the rear wheel on the inside of the turn is decreased. On the other side, if during full braking in a turn the drift has to be reduced, the slip at the front wheel on the outside of the turn is reduced while the slip at the rear wheel on the inside of the turn is increased. If the brake slip of the rear wheel on the inside of the turn is zero, it is not possible to reduce it further. Therefore, if the coasting vehicle has to be stabilized in a turn, the brake slip on both wheels on the outside of the turn is increased. If the vehicle has to be stabilized during partial braking in a turn,

the slip at both wheels on the outside of the turn may be increased while the slip at the front wheel on the inside of the turn may be decreased. Therefore, the choice of the wheels used for the control of the yaw moment on the car depends on the driving situation. The difference between the desired slip value λ_{Noi} of wheel number i and the target slip value λ_{Ti} that is determined by the slip controller is sent to the slip controller as a desired increment in the tire slip $\Delta\lambda_i$.
The slip controller consists of two parts:

- The BSC. In this controller, the positive slip values are controlled as they occur during braking and during engine drag. Also, the ABS function is implemented and improved as compared with the stand-alone ABS by utilizing all additional sensor signals which are used for ESP. The target slip λ_{Ti} for ABS is tuned for each wheel number i such that a good compromise exists between stopping distance and vehicle controllability.
- The traction slip controller (TSC). In this controller, the negative slip values are controlled. Also, the TCS function is implemented and in particular for four-wheel drive vehicles improved as compared with the stand-alone TCS, by utilizing all additional sensor signals which are used for ESP. The target slip λ_{Ti} for TSC is tuned for each driven wheel number i such that a good compromise exists between traction and vehicle controllability.

The slip controller determines the target slips λ_{Ti} for the ABS and the TCS functions according to the coefficient of friction of the road. In general, the target slip increases as the coefficient of friction of the road increases. Simple PI and PID controllers are used in the slip controller to compute the required brake and traction torques on the wheels. While the traction torque can directly be requested from the engine management, the required brake torque must be transformed to valve stimulations of the hydraulic block. If the system includes an electrohydraulic brake system (EHB) [37], then the pressure request can directly be sent to the electronic pressure controller. Otherwise, the valve stimulations are computed using a hydraulic model of the actuator.

30.1.5.2 Performance Requirements

The requirements of ESP relate to the behavior of the car at the physical limit where the resultant tire forces are near their maximum values. At the physical limit, the longitudinal and lateral forces at the wheels depend on each other as shown by the friction ellipse. Therefore, the car behavior results from a compromise between the longitudinal and the lateral forces on the wheels. The car behavior is judged by expert drivers. Their judgment is based on measurements but their subjective judgment plays a dominant role. The subjective judgment relates to the compromise. Therefore, the requirements refer mainly to this compromise.

30.1.5.2.1 General Requirements

- The driver must feel safer with the system than without the system (i.e., system failures must not lead to dangerous vehicle behavior).
- The driver must feel safe with respect to the vehicle behavior (plausibility of the interventions).
- ESP must improve the track stability with respect to understeering and oversteering in all driving situations like braking and accelerating, at all road friction levels, and in particular on split-μ surfaces and at μ-jumps.
- ESP must perform on all road types, uphill and downhill, and on banked roads.
- ESP must keep the vehicle stable and steerable in all driving situations if the steering angle is continuously increased to large values or continuously decreased from large values.
- ESP must reduce the steering effort of the driver.
- The driver must not have the impression that with ESP the vehicle is slower than without ESP.
- Inputs from the driver must not lead to instability of ESP.

- ESP must be able to keep the slip angle of the vehicle smaller than a certain value, which may be reduced depending on the vehicle velocity, lateral acceleration, friction coefficient of the road, and steering wheel motion. If that is not possible, ESP must limit the slip angle velocity to such values which can be managed by the driver to keep the vehicle stable.
- The vehicle must react immediately to the steering input of the driver in order to keep the driver from steering too much. The settling (oversteering) intervention to reduce drift must not be too violent since the future driving situation cannot be predicted.
- ESP must immediately recognize the recovery to a stable vehicle motion.
- ESP must be able to deal with the kinematics and with the tolerances of the steering column.
- ESP must not intervene in banked turns on public roads (bank angle <20°) if the physical limit is not reached.
- ESP must not degrade the vehicle behavior in any circumstance (e.g., flat tire, trailer, bad shock absorbers).
- It is not required that ESP should work if the vehicle is not driving forward. Reverse driving must, however, be definitely recognized.
- ESP must show full performance on elevated roads up to 2500 m above sea level.
- The driver must maintain the possibility to drive his vehicle close to the physical limit without ESP interventions. Otherwise, he may complain about too early ESP interventions.
- The TSC must be tuned for an optimal compromise between traction and vehicle controllability such that the ESP interventions, which are annoying because they decelerate the vehicle, are minimized.
- The requirements of ABS and TCS also apply to ESP.
- The application effort of ESP should be as small as possible. The application should be possible using a minimum number of parameters. The controller structure should be clear and simple, otherwise the application effort increases. The application effort increases if various parameters cannot be independently applied and controller functions are not independent of each other.

30.1.5.2.2 Requirements during Full Braking (ABS Function)

1. Priorities during handling, high velocities, and full braking:
   a. Vehicle stability: $\beta < 5°$
   b. Braking distance: the braking distance must not increase because of the vehicle dynamics control
   c. Comfort (noise, brake pedal pulsation)
2. Open loop jump in steering angle during full braking:
   Within the first 3 s, the slip angle value must not exceed 6°.
3. During split-μ braking with friction coefficients 1.0 on the one vehicle side and 0.1 on the other side, the deceleration must not be smaller than 0.3 g.

30.1.5.2.3 Requirements during Partial Braking

- The vehicle deceleration must follow the pressure in the brake MC.
- The electronic brake force distribution (EBD) control must be tuned such that a minimum of ESP interventions is required.

30.1.5.2.4 Requirements during Traction Control (TCS Function)

Priorities in handling at high velocities:

1. Vehicle stability: $\beta < 6°$
2. Comfort (noise, vehicle jerk)
3. Traction

30.1.5.2.5 Miscellaneous Requirements

1. Closed-loop lane change while coasting:
   a. Slip angle $\beta < 5°$
   b. Angular speed of the steering wheel:
      i. On low μ: < 300°/s
      ii. On high μ: < 400°/s
2. Open-loop cornering: The lateral displacement of the vehicle must be less than 0.5 m (relative to the middle of the track).
3. In case of understeering, the vehicle may be decelerated.
4. The "Moose Test" (also called the "VDA-Test") must be passed [1].

30.1.5.3 Vehicle Dynamics Controller

The two main parts of the vehicle dynamics controller are the determination of the nominal yaw velocity and the determination of the vehicle slip angle. These parts will be discussed in the following paragraphs.

30.1.5.3.1 Computation of the Nominal Yaw Velocity

The nominal value of the yaw velocity is derived primarily from the linear steady-state bicycle model (Figure 30.33). The equations for this model are shown in Table 30.1.

The total lateral stiffnesses at the front and at the rear wheels, $C_{\alpha,F}$ and $C_{\alpha,R}$, respectively, include influences from the tires and from the compliance of the suspension and the steering system. The quotient $(a + c)/R_T$, in which R_T is the radius of the turn, is called the Ackermann steering angle δ_A. If the slip angle at the front axle is equal to that at the rear axle, then the steering angle is equal to the Ackermann steering angle. The vehicle handling behavior is then called "neutral steer." If the slip angle at the front axle is larger than that at the rear axle, then the vehicle handling behavior is called "understeer." If the slip angle at the front axle is smaller than that at the rear axle, then the vehicle handling behavior is called "oversteer." It can be easily shown that, for small vehicle slip angles, the product of the vehicle velocity and the yaw velocity equals the lateral acceleration. By definition, the characteristic velocity v_{CH} depends on the lateral tire stiffnesses, and also on the vehicle mass,

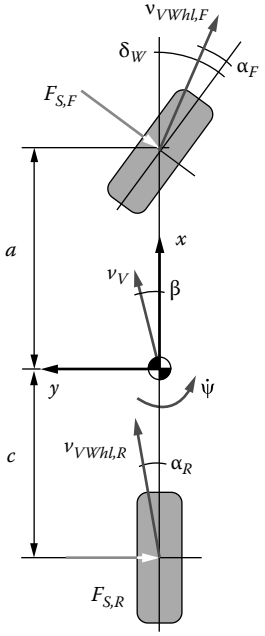

FIGURE 30.33 The bicycle model of the vehicle.

TABLE 30.1
Basic Equations and Results of the Linear Bicycle Model

Basic Equations	Results
Kinematic relationship	Yaw velocity
$\delta_W = \frac{a+c}{R_T} + \alpha_F - \alpha_R = \delta_A + \alpha_F - \alpha_R$	$\dot{\psi} = \frac{v_V}{(a+c)\cdot\left(1+{v_V}^2/{v_{CH}}^2\right)}\cdot\delta_W$
$\beta = \frac{c}{R_T} - \alpha_R$	Yaw gain
	$\frac{\dot{\psi}}{\delta_W} = \frac{v_V}{(a+c)\cdot\left(1+{v_V}^2/{v_{CH}}^2\right)}$
Linear tire relationship	
$F_{S,F} = C_{\alpha,F}\cdot\alpha_F, \quad F_{S,R} = C_{\alpha,R}\cdot\alpha_R$	$\frac{1}{{v_{CH}}^2} = \frac{m_V}{(a+c)^2}\cdot\left(\frac{c\cdot C_{\alpha,R} - a\cdot C_{\alpha,F}}{C_{\alpha,F}\cdot C_{\alpha,R}}\right)$
Dynamic equation	
$F_{S,F} + F_{S,R} = m_V\cdot v_V\cdot\dot{\psi}$	Vehicle slip angle
Steady-state equations	$\beta = \delta_A\cdot\left(\frac{c}{a+c} - \frac{a}{(a+c)^2}\cdot\frac{m_V}{C_{\alpha,R}}\cdot{v_V}^2\right)$
$F_{S,F}\cdot a - F_{S,R}\cdot c = 0$	
$v_V = R_T\cdot\dot{\psi}$	

the wheel base ($a + c$), and on the location of the center of mass. If the vehicle behavior is understeer, then the characteristic velocity exists. For sports cars, the value is larger (e.g., 30 m/s) than for other cars (e.g., 20 m/s). If the vehicle behavior is neutral steer, the characteristic velocity is infinity, and if the vehicle behavior is oversteer, then the characteristic velocity is imaginary. By design, all cars are understeer in their handling behavior.

The relations between the yaw velocity and the vehicle velocity for some steering wheel angles are shown in Figure 30.34. The curves show an almost linear increase in the yaw velocity with increasing vehicle velocity for low vehicle velocities, but for larger velocities the increase is smaller and for very large vehicle velocities the yaw velocity decreases with increasing vehicle velocities. It can be shown that the vehicle velocity at the maximum of the curves equals the characteristic velocity and that at the maximum the yaw velocity is half the yaw velocity of the neutral steer car. Since the lateral acceleration equals the product of the vehicle velocity and the yaw velocity,

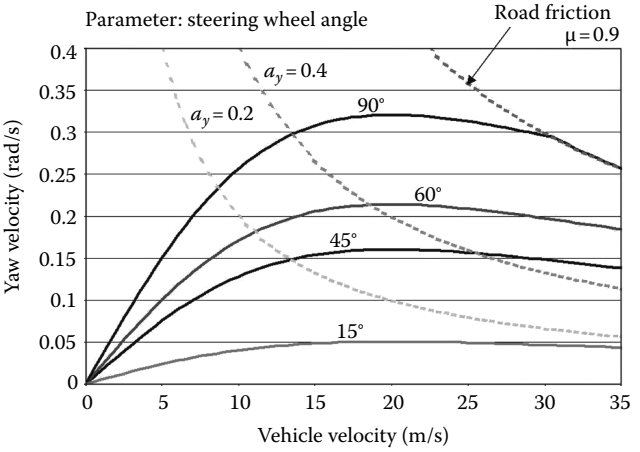

FIGURE 30.34 Handling characteristic of the linear steady-state bicycle model for some steering wheel angles.

curves of equal lateral acceleration are hyperbolas. If the vehicle velocity increases from zero, then the yaw velocity and the lateral acceleration also increase from zero. As shown for the steering wheel angle of 90°, the curve can cross the hyperbola of lateral acceleration of 0.9 g at a certain vehicle velocity. At this point, the lateral acceleration equals the coefficient of friction of the road. For larger vehicle velocities, the lateral acceleration according to the yaw velocity curve would be larger than the coefficient of friction of the road. This is not possible; hence, for larger vehicle velocities the yaw velocity is limited by the hyperbola representing the coefficient of friction of the road. The yaw velocity at a certain vehicle velocity increases proportionally with increasing steering wheel angle. Therefore, the yaw gain, which is the yaw velocity divided by the steering angle, is independent of the steering angle, that is, it is one curve for all steering angles.

The linear relationship between the side force and the slip angle holds only for small slip angles, that is, for small lateral accelerations. For larger slip angles, the relationship is nonlinear, so that different curves may be expected. Figure 30.35 shows the yaw velocity and the yaw gain curves for some steering wheel angles as measured in a front-wheel driven car. The curves show that the lateral acceleration of 1.0 g which corresponds to the coefficient of friction of the road is not reached for

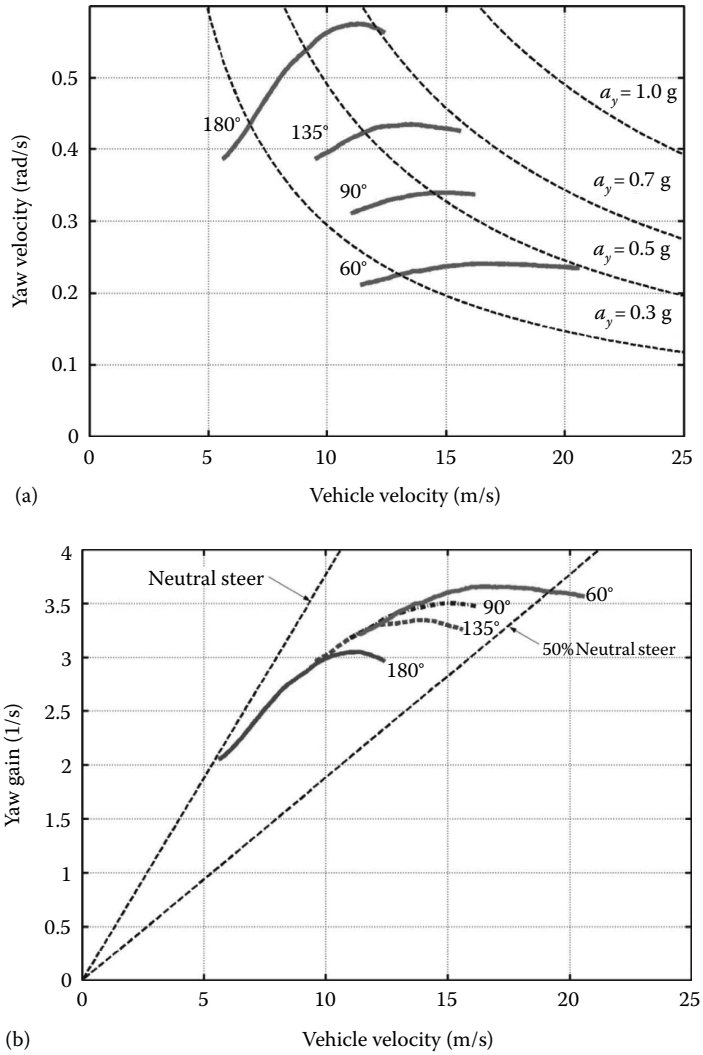

FIGURE 30.35 Handling characteristic of a front-wheel driven car for some steering wheel angles. (a) Yaw velocity, (b) Yaw gain.

any steering wheel angle because at the front axle the maximum of the μ-slip angle curve is reached while at the rear axle the maximum is not yet reached. The larger the steering angle, the smaller the vehicle velocity at the maximum of the yaw velocity curve. Contrary to the linear bicycle model, the yaw gain depends on the steering wheel angle and the maximum yaw gain decreases as the steering wheel angle increases. Therefore, the handling behavior of the linear bicycle model differs from that of the vehicle and the model must be extended to better represent the true handling behavior. Otherwise, the difference between the nominal yaw velocity computed by the model and the measured yaw velocity may become so large that an ESP intervention occurs although the physical limit is not reached.

The characteristic velocity v_{CH} varies with the vehicle mass (e.g., laden/unladen) and with the tire stiffness (e.g., summer/winter tires) and so also does the true handling behavior of the vehicle. Since these variations are unknown, ESP must be tuned to be robust enough to prevent interventions before the physical limit is reached. This robustness is reached by specifying a dead zone about the nominal yaw velocity as computed from the extended linear bicycle model.

As explained earlier, the lateral acceleration is limited by the coefficient of friction of the road surface (30.4).

$$\mu \geq |a_y| \tag{30.4}$$

Using (30.5) for a steady cornering motion, it follows that the yaw velocity must be limited by (30.6).

$$a_y = v_V \cdot \dot{\psi} \tag{30.5}$$

$$|\dot{\psi}| \leq \frac{\mu}{v_V} \tag{30.6}$$

As long as the coefficient of friction of the road is unknown, the lateral acceleration a_y is taken instead of μ. This choice will prevent ESP interventions before the physical limit is reached.

Before the yaw velocity computed from the extended bicycle model can be compared with the measured yaw velocity, it must be filtered to simulate the phase shift between the steering angle and the yaw velocity of the vehicle. Similarly, before the yaw velocity can be limited corresponding to the coefficient of friction of the road and the vehicle velocity, it must be filtered to simulate the phase shift between the yaw velocity and the lateral acceleration.

Two special situations need some attention. First, if the vehicle performs an ABS-braking maneuver on a split-μ road surface, then the driver has to countersteer to keep the vehicle on track. This countersteering must not be interpreted as a cornering desire from the driver. From the difference between the brake pressures at each axle, the yaw moment on the car is computed and the steering angle evaluated, which is required to countersteer against this yaw moment. This steering angle is used as an offset and the calibrated steering angle is used in the bicycle model to derive the nominal yaw velocity. Second, if the vehicle moves though a banked turn, then the gravitational acceleration has an influence on the measured lateral acceleration and the measured lateral acceleration may even become zero. Without special care, this situation may be interpreted as a vehicle which is swerving on an icy road surface. Since from the available sensors the situation at hand cannot be detected (swerving on ice or stable driving in a banked turn), a plausibility check is made. If the driver countersteers, then the situation is interpreted as swerving on ice and the driver is supported by ESP to stabilize the vehicle. If the driver does not countersteer, then the situation is interpreted as stable driving in a banked turn. In the latter situation, offsets for the lateral acceleration and for the steering angle may be computed and the sensor signals may be calibrated with these offsets. Further ESP control is then on the basis of these calibrated signals. As an alternative to the compensation of the sensor signals, it is also possible to increase the dead zones for the actuating signals of the vehicle dynamics controller.

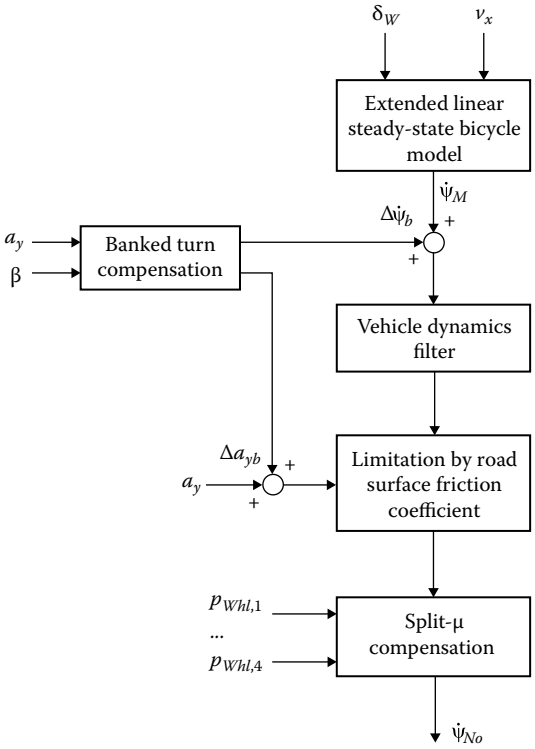

FIGURE 30.36 Derivation of the nominal yaw velocity of the vehicle.

The interventions are then also avoided. For violent driving maneuvers, however, the driver has still some support from the ESP system. See also [38] for an alternative analytic approach to determine the bank angle of the road.

Figure 30.36 shows the principle of the computation of the nominal yaw velocity.

The nominal yaw velocity is derived using the steady-state linear bicycle model, that is, for a coasting vehicle with a constant steering angle. During braking and lift-off of the accelerator pedal, the vehicle velocity is not constant and the vehicle tends to oversteer. Also, care must be taken here that ESP does not intervene before the physical limit is reached. Such an intervention is felt by the driver as a sudden deceleration of the vehicle. Also, the noise from the system may be noticed by him. Therefore, the nominal yaw velocity must be modified in these situations. A special situation is ABS control. Since during ABS control the vehicle decelerates already with maximum deceleration and the system already makes noise, ESP interventions are not noticed. In particular, slip increments that increase the slip hardly change the brake force and their influence can hardly be felt by the driver. Therefore, the nominal yaw velocity as computed by the bicycle model with its limitation by the coefficient of friction of the road surface (30.6) can be used for ABS without any problem.

30.1.5.3.2 Computation of the Vehicle Slip Angle

Since the slip angle of the vehicle is an important indicator of the vehicle stability, many proposals have been made for its estimation. Here, the proposal of [39] is discussed. Other proposals can be found in [40–43].

For the derivation of the vehicle slip angle, the signals from the sensors installed in the vehicle are used. These sensors measure the physical values in the body fixed coordinate system (X, Y) (Figure 30.37).

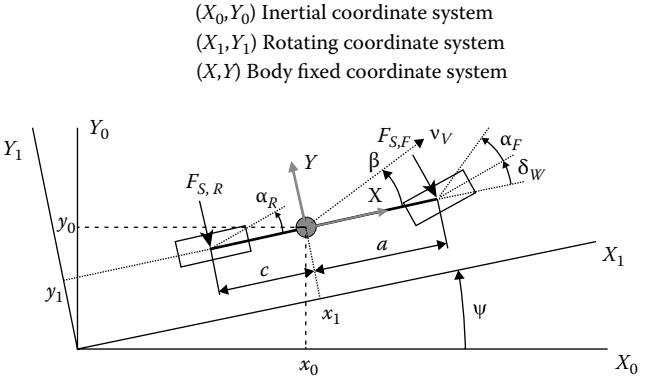

FIGURE 30.37 Definition of the inertial, reference, and body fixed coordinate systems.

The relations between the body fixed coordinate system and the inertial coordinate system (X_0, Y_0) are

$$\begin{aligned}
\dot{x}_0 &= v_x \cdot \cos\psi - v_y \cdot \sin\psi \\
\dot{y}_0 &= v_x \cdot \sin\psi + v_y \cdot \cos\psi \\
\ddot{x}_0 &= a_x \cdot \cos\psi - a_y \cdot \sin\psi \\
\ddot{y}_0 &= a_x \cdot \sin\psi + a_y \cdot \cos\psi
\end{aligned} \tag{30.7}$$

From Figure 30.37, it follows:

$$\begin{aligned}
&\tan(\beta+\psi) = \frac{\dot{y}_0}{\dot{x}_0}, \quad \beta = -\psi + \tan^{-1}\left(\frac{\dot{y}_0}{\dot{x}_0}\right) \\
&\dot{\beta} = -\dot{\psi} + \frac{1}{v_V{}^2} \cdot (\ddot{y}_0 \cdot \dot{x}_0 - \ddot{x}_0 \cdot \dot{y}_0) \\
&\dot{\beta} = -\dot{\psi} + \frac{1}{v_V}(a_y \cdot \cos\beta - a_x \cdot \sin\beta)
\end{aligned} \tag{30.8}$$

For small values of the slip angle, the equation for the slip angle velocity can be reduced and the slip angle obtained by direct integration.

$$\dot{\beta} = \frac{a_y}{v_V} - \dot{\psi}, \quad \beta(t) = \beta_0 + \int_0^t \left(\frac{a_y}{v_V} - \dot{\psi}\right) \cdot dt \tag{30.9}$$

Since the lateral acceleration and the yaw velocity are measured and the vehicle velocity is estimated, the vehicle slip angle can be computed if its initial value is known. However, since each of these signals may be biased, the computed vehicle slip angle error may grow in time to large values and the slip angle value must be frequently reset.

If the tire slips at the wheels are large, for example, during ABS, a Kalman filter may be used to obtain an alternative estimate of the vehicle slip angle [44]. For the Kalman filter, the dynamic equation for the lateral vehicle motion is used while the dynamic equation of the yaw motion of the vehicle is used to obtain the measurement equation. Figure 30.38 shows the idea of the Kalman filter. The estimates of the lateral velocity $\tilde{v}_y$ are obtained from the measurement equation. Since the sensor signals are corrupted by noise, they are filtered to obtain a filtered estimate of the lateral velocity $\hat{v}_y$. The filter equation is the transition function of the lateral velocity, which is the solution of the equation of lateral motion of the vehicle.

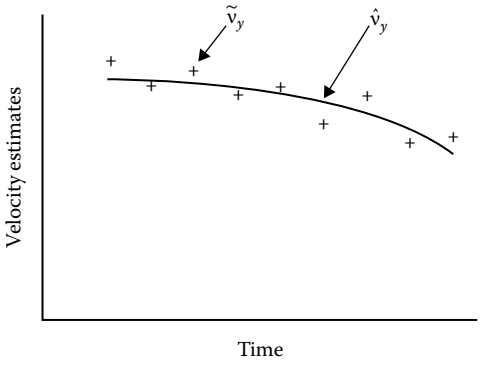

FIGURE 30.38 Principle of the Kalman filter for the vehicle lateral velocity with measurements $\tilde{v}_y$ and estimates $\hat{v}_y$.

The dynamic equations are based on a horizontal surface (no road slope) and wind forces are not considered (see Figure 30.37 for sign conventions).

$$m_V \cdot (\dot{v}_y + v_x \cdot \dot{\psi}) = -(F_{S1} + F_{S2}) \cdot \cos\delta_W - (F_{B1} + F_{B2}) \cdot \sin\delta_W - F_{S3} - F_{S4} \tag{30.10}$$

$$\begin{aligned} J_V \cdot \ddot{\psi} = &-(F_{S1} + F_{S2}) \cdot a \cdot \cos\delta_W - (F_{S1} - F_{S2}) \cdot b \cdot \sin\delta_W \\ &-(F_{B1} + F_{B2}) \cdot a \cdot \sin\delta_W + (F_{B1} - F_{B2}) \cdot b \cdot \cos\delta_W \\ &+(F_{S3} + F_{S4}) \cdot c + (F_{B3} - F_{B4}) \cdot b \end{aligned} \tag{30.11}$$

By using the friction ellipse, it can be shown that for small slip angles where $\tan\alpha \approx \alpha$ and for slip values that are not zero, a simple relation between the brake and side forces exists, which is also valid for large slip values, that is, for values in the nonlinear region of the μ-slip curve.

$$\begin{aligned} &F_B = \lambda \cdot \frac{F_R}{\sqrt{\lambda^2 + (C_\alpha / C_\lambda)^2 \cdot \alpha^2}}, \quad F_S = \alpha \cdot \left(\frac{C_\alpha}{C_\lambda}\right) \cdot \frac{F_R}{\sqrt{\lambda^2 + (C_\alpha / C_\lambda)^2 \cdot \alpha^2}} \\ &\Rightarrow F_S = \frac{C_\alpha \cdot \alpha}{C_\lambda \cdot \lambda} \cdot F_B \end{aligned} \tag{30.12}$$

Furthermore, by using the dynamic equation of the wheel velocity, the brake force can be related to the brake pressure at each wheel (the drive torque M_{CaHalf} has to be considered at the driven wheels only).

$$F_B = C_p \cdot \frac{p_{Whl}}{R} - \frac{M_{CaHalf}}{R} + \frac{J_{Whl}}{R^2} \cdot \dot{v}_{Whl} \tag{30.13}$$

If the slip angles at the front tires are small, then they are approximately equal. Similarly, if the slip angles at the rear tires are small, then they are also approximately equal. The slip angles can then be computed as

$$\alpha_F = \frac{v_y + a \cdot \dot{\psi}}{v_x}, \quad \alpha_R = \frac{v_y - c \cdot \dot{\psi}}{v_x} \tag{30.14}$$

Inserting (30.12–30.14) into (30.10 and 30.11) and after collecting terms, the equations can be written in reduced form by

$$\begin{aligned} \dot{v}_y &= A_{11} \cdot v_y + A_{12} \cdot \dot{\psi} + u_1 \\ \ddot{\psi} &= A_{21} \cdot v_y + A_{22} \cdot \dot{\psi} + u_2 \end{aligned} \tag{30.15}$$

These equations must be integrated to obtain the transition function and the measurement equation for the Kalman filter. Since the control function is realized as a discrete time controller, a numerical integration is a simple alternative to the analytic solution of the linear differential Equations 30.15. Here, the simplest method, the Euler method, is used.

$$v_{y,k+1} = (A_{11} \cdot T + 1) \cdot v_{y,k} + A_{12} \cdot T \cdot \dot{\psi}_k + u_{1,k} \cdot T \tag{30.16}$$

$$\dot{\psi}_{k+1} = A_{21} \cdot T \cdot v_{y,k} + (A_{22} \cdot T + 1) \cdot \dot{\psi}_k + u_{2,k} \cdot T \tag{30.17}$$

In order to use (30.17) as a measurement equation, a linear extrapolation of the yaw velocity is used.

$$\dot{\psi}_{k+1} = 2 \cdot \dot{\psi}_k - \dot{\psi}_{k-1} \tag{30.18}$$

If (30.18) is inserted into (30.17), then the measurement equation results

$$v_{y,k} = \frac{(1 - A_{22} \cdot T) \cdot \dot{\psi}_k - \dot{\psi}_{k-1} - u_{2,k} \cdot T}{A_{21} \cdot T} \tag{30.19}$$

Figure 30.39a shows a comparison between the estimated slip angle at the front wheels and the measured value, while Figure 30.39b shows the comparison at the rear wheels for an ABS braking and double-lane change maneuver on ice. The comparison shows an excellent result of the estimation. Also, for large slip angles, the estimation is close to the measured values. On ice, the μ-slip angle curve has its maximum at approximately 5°. This shows that the estimation produces good results also for slip angles which are in the nonlinear and in the unstable region of the μ-slip angle curve. Since in all equations the quotient of the lateral and the longitudinal tire stiffness is used (30.12), the estimation of the slip angle is robust with respect to changes in the tire properties. For instance, if winter tires are used instead of summer tires, then both the longitudinal and the lateral tire stiffness decrease significantly as compared with those of summer tires; the quotient,

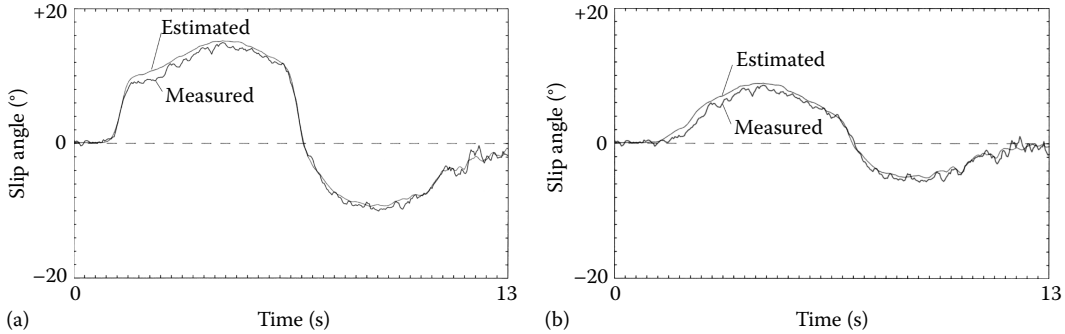

FIGURE 30.39 Comparisons between measured and Kalman-filtered estimates of the slip angles of the car at the front axle (a) and at the rear axle (b) during an ABS braking with double-lane change maneuver on ice.

however, does not change significantly. Similarly, if the tires are worn, the longitudinal and lateral stiffnesses increase significantly as compared with those of new tires; however, the change in the quotient is not significant. It is therefore not required to change the estimation depending on the tire make and state.

30.1.5.3.3 Control Algorithm

A PID control is used to compute the required yaw moment. Inputs to the PID controller are the actuating signals of the slip angle and the yaw velocity. In situations where the slip angle cannot be computed with sufficient accuracy, the control of the yaw velocity becomes dominant. As has been shown earlier, it is difficult to obtain the nominal value of the yaw velocity. Moreover, the vehicle handling behavior and therefore also the value of the yaw velocity may change significantly with changing lateral tire stiffnesses (winter/summer tires) and with changing vehicle mass and changing location of the center of mass. These changes are unknown to the controller and thus interventions may occur within the physical limit because of the different basic handling behavior of the vehicle. But these early interventions must be avoided. Often, such early interventions are avoided by enlarging the dead zone for the yaw velocity.

The yaw moment is generated by slip changes at selected wheels. If the slip values are well below the value λ_0, the nominal slip value is converted to a nominal wheel torque value and the wheel torque is controlled to this nominal value. The required slip changes at the wheels are chosen such that the sum of the yaw moment changes from the selected wheels equals the required yaw moment on the vehicle. The slip change at a wheel is proportional to the gain between the yaw moment and the slip change. The gain may be computed from the friction ellipse (30.12) using the actual slip and slip angle values.

During braking and driving on a split-μ road surface, a yaw moment on the vehicle is generated because of the difference in longitudinal forces on the wheels on the left and on the right side of the vehicle. This yaw moment is directly controlled by the vehicle dynamics controller by specification of the brake torque (or pressure) difference between the left and the right side of each axle. For braking maneuvers, the time derivative of the brake torque difference is also specified (Figure 30.40). In Figure 30.40, the maximum pressure differences Δp_1 and Δp_2 and the time points t_1 and t_2 as measured from the start of the braking maneuver can be chosen freely for each axle to fulfill the requirements (the braking maneuver starts at time point $t = 0$ s). For driving maneuvers, the vehicle dynamics controller reduces the brake torque difference by ΔM_{NoLock} from that set as target by the TSC M_{NoLock}.

Instead of controlling the traction slip individually of each driven wheel, the TSC controls the average slip λ_{MA} and the difference slip of the driven wheels of the driven axle. If the vehicle motion differs from the nominal motion, the vehicle dynamics controller reduces the average slip

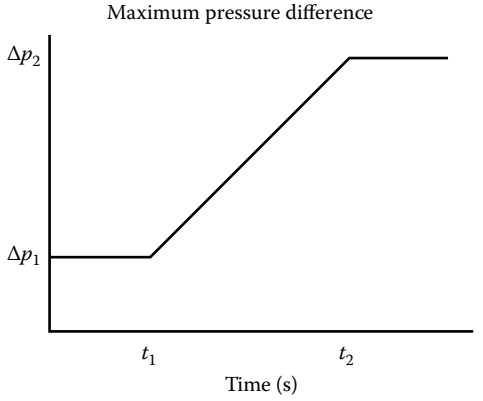

FIGURE 30.40 Limitation of the brake pressure difference between the wheels at one axle for split-μ braking.

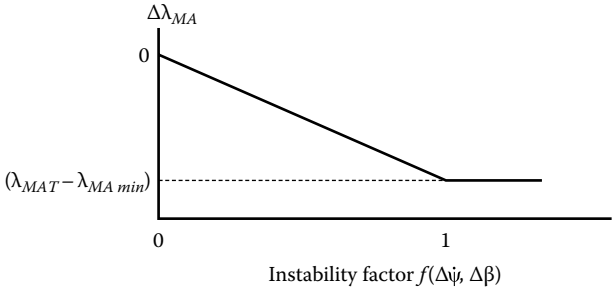

FIGURE 30.41 Reduction of the cardan slip from its target value depending on the stability margin of the vehicle.

by sending a slip increment (reduction) to the TSC $\Delta\lambda_{MA}$. This will then reduce the engine output torque. The reduction depends on an instability factor $f(\Delta\beta,\Delta\dot{\psi})$ which itself depends on the stability margin of the vehicle (Figure 30.41). The instability factor also considers the limit in the engine torque (its maximum value, idle torque, idle rotational velocity). The larger the instability factor f, the smaller the stability margin. If the instability factor is 0, then the average traction slip is not reduced from its target value, which is the value for optimal traction and stability λ_{MAT}. If the instability factor is 1, then the slip increment reduces the average slip from the target slip to the velocity-dependent minimal value for maximum vehicle stability λ_{MAmin}. Further details will be discussed in Section 30.1.5.5.

For each vehicle situation, wheels that are selected to generate the yaw moment are defined. There is some ambiguity during the transition from one vehicle situation to another one, for example, from coasting to partial or full braking. In each vehicle situation, different wheels are selected to generate the yaw moment. The transitions must be carefully tested and adjusted so as to not switch too early or too late from one selection to the other. Since the controllers do not change their structure with the driving situation and since in all controllers the slip is the fundamental variable, the hierarchical control structure presented seems to be the right choice to cope with these transition problems best.

30.1.5.4 Brake Slip Controller

The BSC is used to control the wheel slip for positive values (brake slip). The controller consists of several main tasks (Figure 30.42). These are as follows:

- Estimation of the vehicle velocity.
- Determination of the target wheel slips for ABS.
- Control of the wheel slip.
- Determination of the valve stimulations.

In Figure 30.42, the input and output variables are shown. The slip increment $\Delta\lambda$ is supplied for each wheel by the vehicle dynamics controller to control the yaw moment on the vehicle.

30.1.5.4.1 Estimation of the Vehicle Velocity

For the determination of the actual value of the wheel slip, the free rolling wheel velocity v_{WhlFre} is required. The idea of calculation of the free rolling wheel velocity is given as follows. If during certain time periods in the slip control the brake torque is kept so low that a stable slip results, then by extrapolation of the brake torque to a value which is zero the free rolling wheel velocity can be evaluated. The time periods are called "adaptation phases." From the free rolling wheel velocity, the longitudinal velocity of the center of mass of the vehicle v_x can be computed using the lateral and the yaw velocity of the vehicle and the steering angle of the wheel. From the velocity of the vehicle center of mass, the free rolling velocities of the other wheels can be subsequently computed.

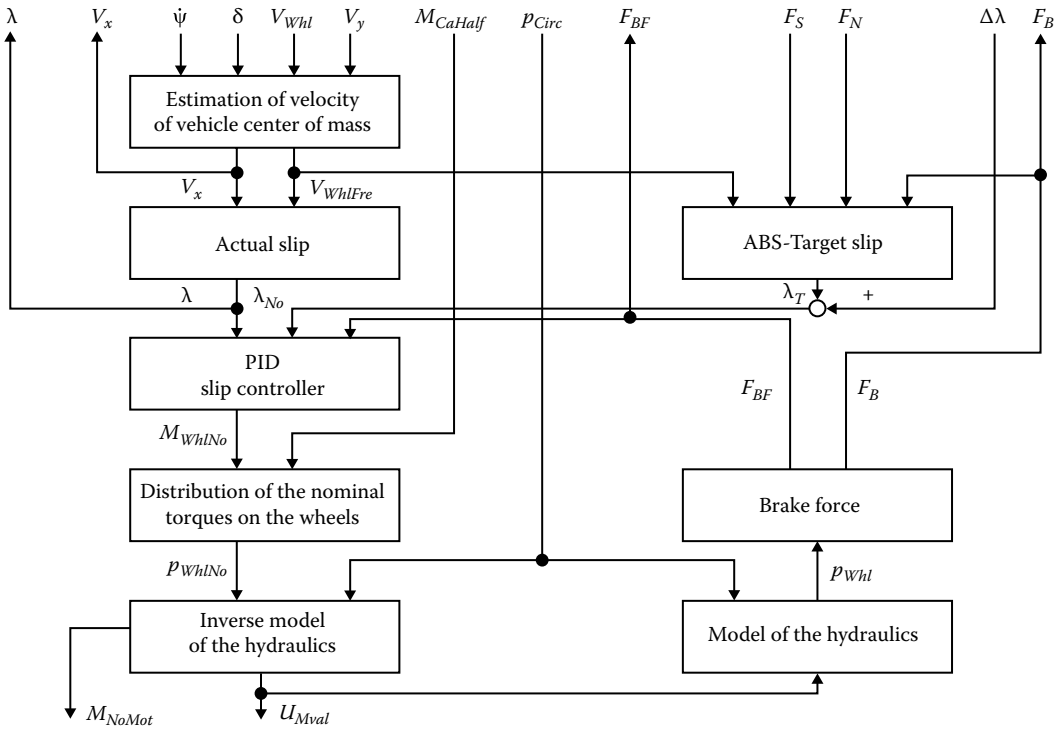

FIGURE 30.42 Block diagram of the BSC.

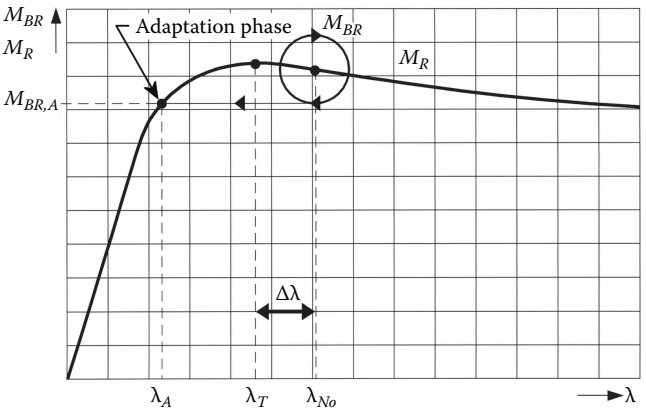

FIGURE 30.43 Determination of the free rolling wheel velocity during the adaptation phase of an ABS-braking maneuver.

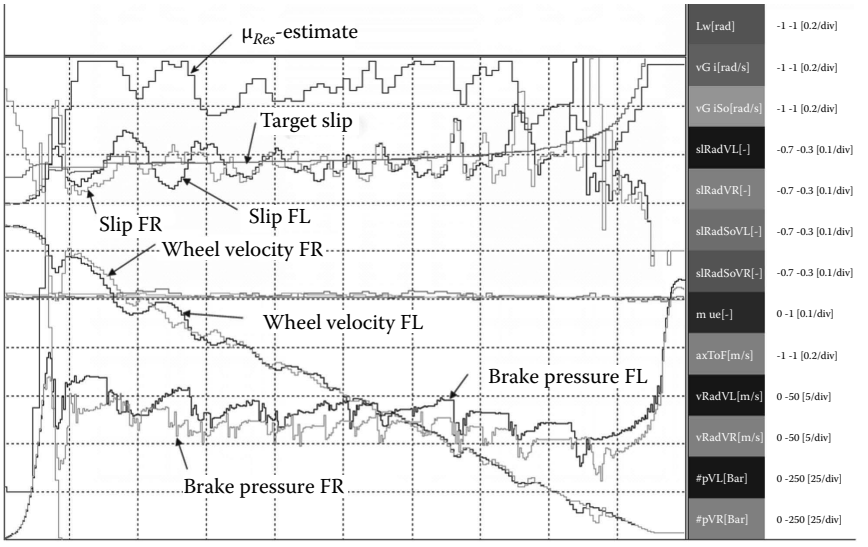
The idea is shown in Figure 30.43. The circle symbolizes the brake torque modulations in order to maintain the wheel slip λ close to the nominal slip value λ_{No}. During the adaptation phase, the brake torque is kept fixed at its lowest value $M_{BR,A}$ during the modulation. The stable slip λ_A results. If the brake torque $M_{BR,A}$ is known, then the brake force $F_{B,A}$ during the adaptation phase can be computed. In order to eliminate influences from variations in the normal force F_N during the adaptation phase, the computation uses the μ-slip curve and the coefficient of friction μ_A instead of the brake force–slip curve. Furthermore, it is assumed that the point (λ_A, μ_A) lies on that portion of the μ-slip curve where it can be approximated by a straight line from the origin (0,0).

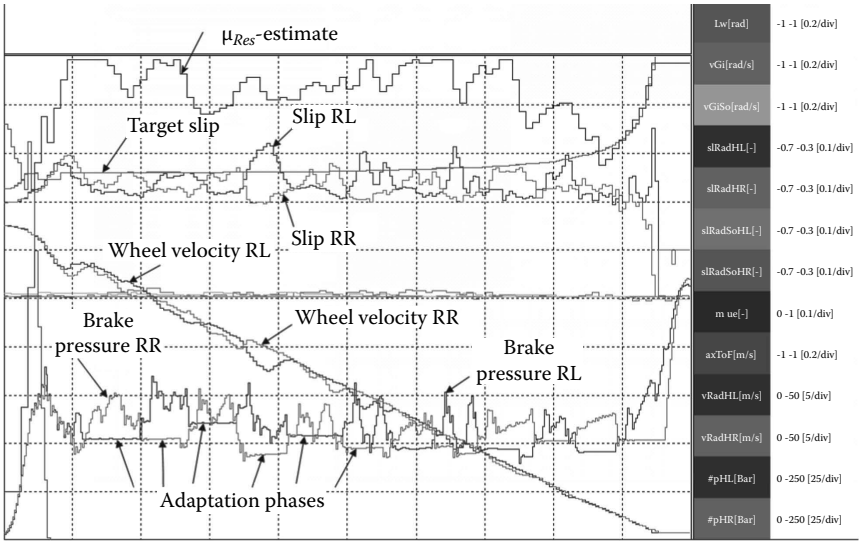
$$\mu_A = \frac{F_{B,A}}{F_N} = C_\lambda \cdot \lambda_A = C_\lambda \cdot \frac{v_{WhlFre} - v_{Whl,A}}{v_{WhlFre}}$$
$$\Rightarrow v_{WhlFre} = v_{Whl,A} \cdot \frac{C_\lambda}{C_\lambda - (F_{B,A} / F_N)} \tag{30.20}$$

At every sample point in time, the free rolling wheel velocity and the vehicle longitudinal velocity v_x can thus be estimated. Usually the left and the right rear wheels are alternatively in the adaptation phase. This improves the vehicle stability and the loss in braking distance is not as large as if one of the front wheels is used for the adaptation phase. For best estimation results, there should always be one of the wheels in the adaptation phase. If that is not possible, then between the adaptation phases the vehicle velocity is obtained by linear extrapolation. Figure 30.44b shows the pressures at the rear wheels and the rear wheel velocities with the adaptation phases during a straight-line ABS-braking maneuver from 120 km/h on a dry and smooth asphalt road surface.



Since the above estimates of the vehicle velocity are error prone, a Kalman filter is used to filter the estimates. For the filter equation, the equation of motion of v_x is used.

$$\dot{v}_x = \frac{1}{m_V} \cdot \left\{ (F_{S1} + F_{S2}) \cdot \sin\delta_W - (F_{B1} + F_{B2}) \cdot \cos\delta_W - (F_{B3} + F_{B4}) \right\}$$
$$- \frac{c_w \cdot A \cdot v_x^{\,2} \cdot \rho / 2}{m_V} - \dot{v}_{x,off} \tag{30.21}$$
$$\ddot{v}_{x,off} = 0$$



In the acceleration term, the product of the lateral velocity and the yaw velocity is neglected as compared with the time rate of change of the longitudinal velocity. The slope of the road, $\dot{v}_{x,off}$, is assumed to be constant and is also estimated by the Kalman filter. The brake and the side forces are estimated by (30.12) and (30.13).

At this point, the evaluation of the vehicle longitudinal velocity v_x will be discussed for the other driving situations also. In these other driving situations, one or more wheels may have a slip value which is in the stable portion of the μ-slip curve, such as during partial braking. Such wheels may then be used to determine the free rolling wheel velocity by extrapolation immediately, that is, without reduction of the brake torque. If there is more than one such wheel, then more than one evaluation of v_x may be obtained at each sample time point. The selection of the best estimate of v_x out of the two, three, or four estimates of v_x has been made on the basis of a selection logic. This selection logic is considered based on the following: if the brake or the accelerator pedal is applied, if the switch "ESP off" has been activated, the magnitude of the engine torque and the engine rotational velocity, the magnitude of the brake pressure at the wheel, stable or unstable behavior of the wheel, the magnitude of the sensor signals, and so on. Since the selection logic is very complex, in particular for four-wheel drive vehicles, it has been replaced by fuzzy logic.

The vehicle velocity estimation using fuzzy logic takes the v_x estimate of each wheel and computes a weighted average. The weight of each estimated v_x is determined by fuzzy methods and depends of the stability probability of each wheel. The weight is large if the wheel behavior is very stable and small if the wheel behavior is nearly unstable. The stability probability is judged on the basis of the wheel velocity, the wheel acceleration, and on the basis of the wheel jerk. The weighted average is then used and filtered by the Kalman filter.

30.1.5.4.2 Determination of the Target Wheel Slips for ABS

As the first approach, the target brake slip for each wheel is determined by the BSC to achieve minimal stopping distances during full braking. Since the brake slip at which the brake force is at its maximum is larger for high friction road surfaces than for low friction road surfaces, the target slip is computed depending on the coefficient of the road surface. Figure 30.45 shows the idea. In this figure, two μ-slip curves are drawn: one for a low friction and one for a high friction road surface, each with their own maximum. The idea is that the line which connects the two maxima indicates at which slip value the maximum of the μ-slip curve of all other road surfaces lies. So, if the coefficient of friction of the road surface is μ_{Res}, then the slip value at the maximum of the μ-slip curve of the road surface is said to be $\lambda_0(\mu_{Res})$.

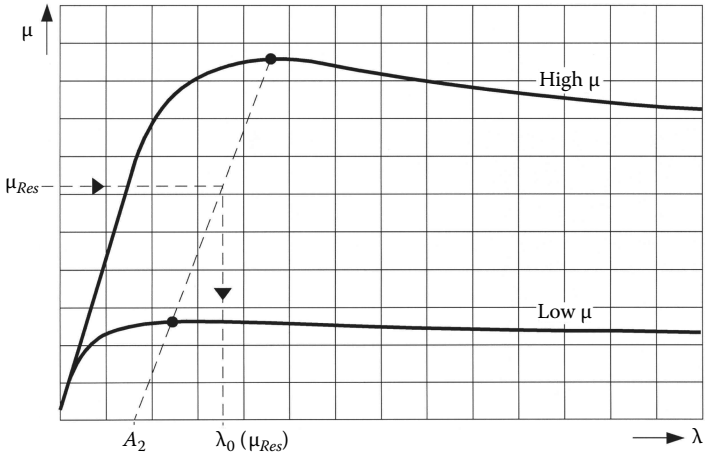

FIGURE 30.45 Computation of the target slips of the wheels for an ABS-braking maneuver.

For low, free rolling wheel velocities, the target slip is increased from λ_0 to improve the slip control. For improved stability of the vehicle, the target slip of the wheels at the rear axle is taken to be smaller than that for the wheels at the front axle.

$$\lambda_T(\mu_{Res}) = A_2 + A_0 \cdot \mu_{Res} + \frac{A_1}{v_{WhlFre}}$$
$$\mu_{Res} = \frac{\sqrt{F_B{}^2 + F_S{}^2}}{F_N} \tag{30.22}$$

Figure 30.44 shows the estimate of the coefficient of friction of the road surface μ_{Res} and the corresponding determination of the target slip of the wheels on the front and on the rear axles. It can be seen from this experiment that the target slip is found very quickly from the beginning of the braking maneuver.

30.1.5.4.3 Control of the Wheel Slip

The nominal wheel slip λ_{No} results from the addition of the target slip $\lambda_T(\mu_{Res})$ in case of ABS and the slip increment $\Delta\lambda$ requested by the vehicle dynamics controller. If the steady-state brake force at the nominal wheel slip λ_{No} is denoted by F_{BF}, then the nominal brake torque at the wheel is computed by (30.23) in which "SUM" stands for the time integral.

$$M_{WhlNo} = F_{BF} \cdot R + K_p \cdot (\lambda_{No} - \lambda) \cdot R + K_d \cdot (\dot{v}_{Whl} - \dot{v}_{WhlFre}) \cdot \frac{J_{Whl}}{R}$$
$$+K_i \cdot C_p \cdot SUM\left\{(\lambda_{No} - \lambda) \cdot D_T\right\} \tag{30.23}$$

The steady-state brake force at the nominal wheel slip is estimated by low pass filtering of the brake force, which is computed by (30.13).

$$T_1 \cdot \dot{F}_{BF} + F_{BF} = F_B \tag{30.24}$$

From the nominal brake torque, the nominal brake pressure can readily be found by consideration of the drive torque on the wheel M_{CaHalf}, if the wheel is a driven wheel.

$$p_{WhlNo} = \frac{M_{WhlNo} + M_{CaHalf}}{C_p} \tag{30.25}$$

If this brake pressure is negative, then the drag torque of the engine on the driven wheel is too high and the engine output torque must be increased to M_{NoMot}. In the evaluation of the nominal engine torque, a dynamic term for the acceleration of the power and drive train is included. For the computation of the engine torque, the driven wheel with the largest absolute value of the drag torque is considered (i.e., with the minimum drive torque).

$$M_{NoMot} = -\frac{2 \cdot m}{I_{Tr}} + \frac{J_{Mot} \cdot I_{Tr}}{R} \cdot \dot{v}_x \tag{30.26}$$

$$m = \text{MIN}(M_{Whl3No}, M_{Whl4No}) \quad \text{(for a rear wheel driven vehicle)} \tag{30.27}$$

For a good slip control performance, it is important that the steady-state brake force F_{BF} is found as quickly as possible. Otherwise, the control may start to oscillate which has a negative influence on the control performance (stopping distance, comfort).

30.1.5.4.4 Determination of the Valve Stimulations

If the nominal wheel brake pressure is positive, then by using a model of the hydraulic system the valve stimulation time periods can be obtained. The simplest model is based on Bernoulli's law for the flow of incompressible fluids. In order to compute the times during which an inlet or AV must be opened, the inverse model is used.

$$U_{Mval} = \frac{p_{WhlNo} - p_{Whl}}{(x_1 + x_2 \cdot p_{Whl}) \cdot \sqrt{|p_{Circ} - p_{Whl}|}}$$

$$U_{Mval} > 0 \quad \text{Pressure increase} \tag{30.28}$$

$$U_{Mval} = 0 \quad \text{Pressure hold}$$

$$U_{Mval} < 0 \quad \text{Pressure decrease}$$

The parameters x_1 and x_2 depend on the volume–pressure characteristic curve and on the throttle bores of the hydraulic system (valves). The computed positive value U_{Mval} is the time period the EV is opened. If the value U_{Mval} is negative, then its absolute value is the time period the AV is opened. Since the valve current periods can only be realized for certain discrete values (1, 2, 3 ms, …), the value U_{Mval} is rounded and the resulting actual pressure value at the wheel brake p_{Whl}, because of the rounded stimulation time periods, must be computed. For the computation, the model of the hydraulic system is used again. Using the brake pressure value, the brake force F_B can be computed by (30.13).

30.1.5.5 Traction Slip Controller

The TSC controls the negative slip (drive slip) of the driven wheels. Instead of controlling the wheel drive slip for each tire individually, the TSC controls the average slip of the driven wheels λ_{MA} and the dead zone for the difference in the drive slip of the driven wheels D_λ. The idea behind this choice is that the average slip can be controlled by the engine output torque and the slip difference by the brake torque at the fastest wheel. Thus, the control is split into a slow part (engine control with the large inertia of the power and drive train) and a fast part (brake control with a small inertia of one

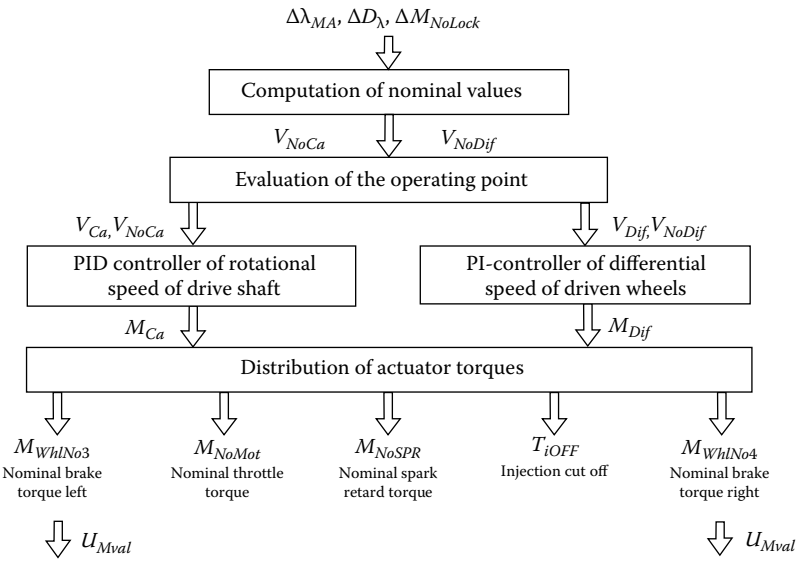

FIGURE 30.46 Block diagram of the TSC.

wheel of the driven axle). The principle of the TSC will be explained for a rear wheel driven car first. The TSC consists of two main parts (Figure 30.46):

- The average slip controller (also called the cardan slip controller), with output, the nominal engine output torque.
- The difference slip controller, with output, the nominal brake torque at one wheel.

30.1.5.5.1 Average Slip Controller

This part of the TSC controls the average value of the slips of the driven wheels by controlling the engine output torque. The target value of the average slip λ_{MAT} is computed similarly as for ABS by (30.22). Similar to the ABS function of the BSC, the TCS function is started if the average slip of the driven wheels exceeds the target slip. The nominal value λ_{MA} of the average slip is computed by adding the increment value $\Delta\lambda_{MA}$ computed by the vehicle dynamics controller to the target value λ_{MAT}. Using the average value of the free rolling velocities of the driven wheels and dividing it by $(1 + \lambda_{MA})$, the nominal average velocity of the driven wheels v_{NoCa} is computed (30.30). The actuating signal for the cardan slip controller is then $v_{NoCa} - v_{Ca}$ in which v_{Ca} is the average velocity of both driven wheels.

$$v_{Ca} = \frac{v_{Whl,3} + v_{Whl,4}}{2} \quad \text{(for a rear wheel drive vehicle)} \tag{30.29}$$

The actuating signal is the input of a PID controller. The output of the PID controller is the torque of the cardan axle multiplied by the ratio of the drive train M_{Ca} from which the engine torque can be easily computed by using the total transmission ratio of the power and drive train I_{Tr}.

The gains of the PID controller depend on the following driving situations:

- The gear position of the transmission
- The efficiency of the converter if the vehicle has an automatic transmission
- The distance of the actual engine torque value to its limits (maximum/minimum values)

- The gradient with which the hydraulic system can generate active brake pressure at the driven wheels
- The coefficient of friction of the road surface
- The need for side forces on the driven wheels

Since the drive train can oscillate with a damping factor whose value can be very low, the gains of the PID controller must be chosen to be small enough in order to avoid control instability. Furthermore, the average velocity of the driven wheels is filtered by a low pass filter in order to make the controller insensitive to these oscillations. The frequency of the oscillations depends on the gear position of the transmission and can be as low as 2.0 Hz. Therefore, the bandwidth of the low pass filter is chosen to be 2 Hz.

Because of the low gains of the controller and because of the low pass filtering of the average wheel velocities, changes in the cardan slip cannot be realized fast enough for the required TCS vehicle stability and vehicle dynamics control performance. The reduction in the engine output torque may be so slow that the wheel with the larger traction force will also start to spin. Therefore, the engine output torque is also controlled by a fast parallel control depending on the behavior of the wheel with the larger traction force, that is, if the wheel starts to spin. The smaller one of the two torques of the cardan axle (output of the PID controller and fast reduction of the cardan torque) is passed on as M_{Ca}.

The reduction in the drive torque at the wheels may be realized by reducing the throttle angle, by reducing spark advance, by reducing the amount of fuel injected, and sometimes by fuel injection cut off. Because of the legal requirements on the limitation of the engine exhaust emissions, modification of the spark timing and the amount of fuel injected are not always allowed. The reduction in the drive torque on the driven wheels may then not be fast enough. In that case, both driven wheels may be actively braked in order to reduce the net drive torque on them. This brake intervention to support the decrease in the drive torque on the driven wheels is called the "symmetric brake intervention." The required engine torque is sent to the engine controller where the interventions in the throttle angle, the spark timing, and the injection amount are controlled in an integrated manner. The actual engine output torque is computed by the engine controller and its value is sent to the ESP-control unit by the controller area network (CAN) bus.

30.1.5.5.2 Difference Slip Controller

The other part of the TSC controls the slip difference between the driven wheels to be smaller than D_λ by controlling the brake torque on the wheel with the lowest traction force. This control maximizes the traction forces on the wheels during cornering and on split-μ road surfaces. Although for straight-line driving on a homogeneous road surface D_λ can be chosen to be zero for optimal traction for driving in a turn or on split-μ road surfaces, this choice cannot be made. Because the normal force on the wheel on the inside of the turn is smaller than that on the wheel on the outside of the turn, the slip value of the wheel on the inside of the turn will be larger than that of the wheel on the outside of the turn, although the drive torques on both wheels are equal. A similar situation exists during driving on a split-μ road surface. In both situations, there exists always a difference in slips between the left and the right wheels but interventions must not occur if no wheel spins. Only if the difference in the slips between both wheels exceeds a threshold (also called dead zone) D_λ, the slip difference control is activated to reduce the slip difference to a value below this threshold. The threshold D_λ specifies a dead zone within which no brake control happens. Instead of controlling the difference in the slips between both wheels, the difference in the wheel velocities is controlled. During straight-line driving, D_λ is zero and the difference in the nominal velocities between the two wheels v_{NoDif} is also zero.

During cornering, the situation is more complex because the wheel on the inside of the turn has a smaller free rolling velocity than the wheel on the outside of the turn. If wheel 3 is on the outside and wheel 4 on the inside of the turn, then v_{NoDif} can be evaluated as follows.

$$\begin{aligned}
\lambda_{WhlNo3} &= \lambda_{MA} = \frac{v_{WhlFre3} - v_{WhlNo3}}{v_{WhlNo3}} \\
\lambda_{WhlNo4} &= \lambda_{MA} + D_{\lambda} = \frac{v_{WhlFre4} - v_{WhlNo4}}{v_{WhlNo4}} \\
v_{WhlNo3} &= \frac{v_{WhlFre3}}{1+\lambda_{MA}} \\
v_{WhlNo4} &= \frac{v_{WhlFre4}}{1+\lambda_{MA}+D_{\lambda}} \\
v_{NoDif} &= v_{WhlNo4} - v_{WhlNo3} \\
v_{Dif} &= v_{Whl,4} - v_{Whl,3} \\
e_{\Delta v} &= v_{Dif} - v_{NoDif} \quad \text{(actuating signal)}
\end{aligned} \tag{30.30}$$

If the actuating signal is negative, that is, if the difference in the wheel velocities is smaller than the nominal difference, then v_{Dif} lies inside the dead zone and the controller is not activated. Otherwise the velocity difference is controlled with a resulting brake torque M_{NoLock} which works like a differential lock. From the brake torque, the valve stimulations can be computed by using the model of the hydraulic system described at the BSC.

If the brake at one of the driven wheels is activated, then a yaw moment on the vehicle results. If the yaw moment on the vehicle must be reduced, the vehicle dynamics controller first reduces this yaw moment since this reduction is more comfortable than a brake intervention at a front wheel. The reduction from the vehicle dynamics controller is ΔM_{NoLock}. This reduction will increase the slip difference between the driven wheels. Therefore, the vehicle dynamics controller must also increase the dead zone by ΔD_{λ} at the same time when the vehicle dynamics controller requests a reduction in the brake torque. Otherwise the slip difference controller will immediately increase the brake torque again.

30.1.5.5.3 Four-Wheel Drive Vehicles

The principle of the TSC for two-wheel drive vehicles can be extended to result in the principle of the controller for four-wheel drive vehicles. Figure 30.47 shows the principle of a typical four-wheel drive train. After the transmission 2, the central cardan torque is split by the central differential 3 between the front cardan axle and the rear cardan axle. The front cardan axle torque is split by the differential 4 between the left and the right wheels at the front axle while the rear cardan axle torque is split by the differential 5 between the left and the right wheels at the rear axle. The differential 3 or 5 may have a coupling like a viscous coupling in order to connect the rear axle with the power train.

Figure 30.48 shows the principle of the TSC. The longitudinal lock of the brake controller at the front axle can reduce the difference velocity between the front cardan axle and the rear cardan axle if the front cardan axle spins by symmetric braking of the front wheels. Similarly, the longitudinal lock of the brake controller at the rear axle can reduce the difference velocity between the front cardan axle and the rear cardan axle if the rear cardan axle spins by symmetric braking of the rear wheels. By symmetric braking of all four wheels, the engine output torque (or cardan torque) can be reduced. The lateral lock function of the brake controller reduces the velocity difference between the wheels at the front and the rear axle.

Figure 30.49 shows the control of a four-wheel drive vehicle during drive-off on a split-μ uphill road surface with a slope of 20°. The engine torque request from the driver is seen to be a steady increasing torque M_{Dr}. After about 1.2 s, the front left wheel on the slippery road surface suddenly starts to spin (Figure 30.49a). Both the brake at this wheel is actuated $p_{Whl,1}$ and the torque at the

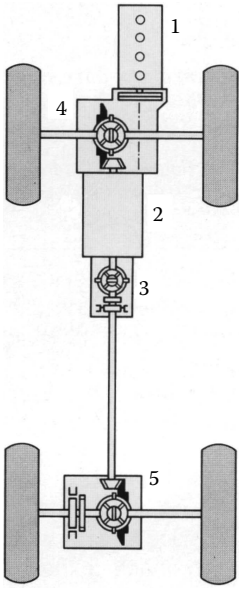

FIGURE 30.47 Principle of a four-wheel drive and power train with optional viscous clutches at the central and rear axle differentials (1) engine, (2) transmission, (3) central differential, (4) differential at the front axle, (5) differential at the rear axle.

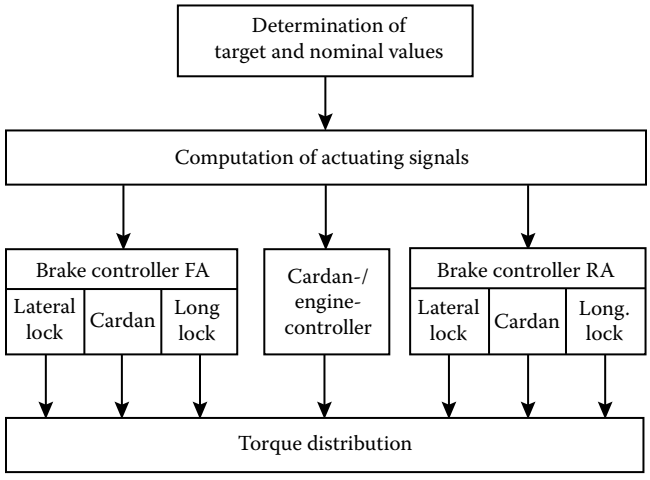

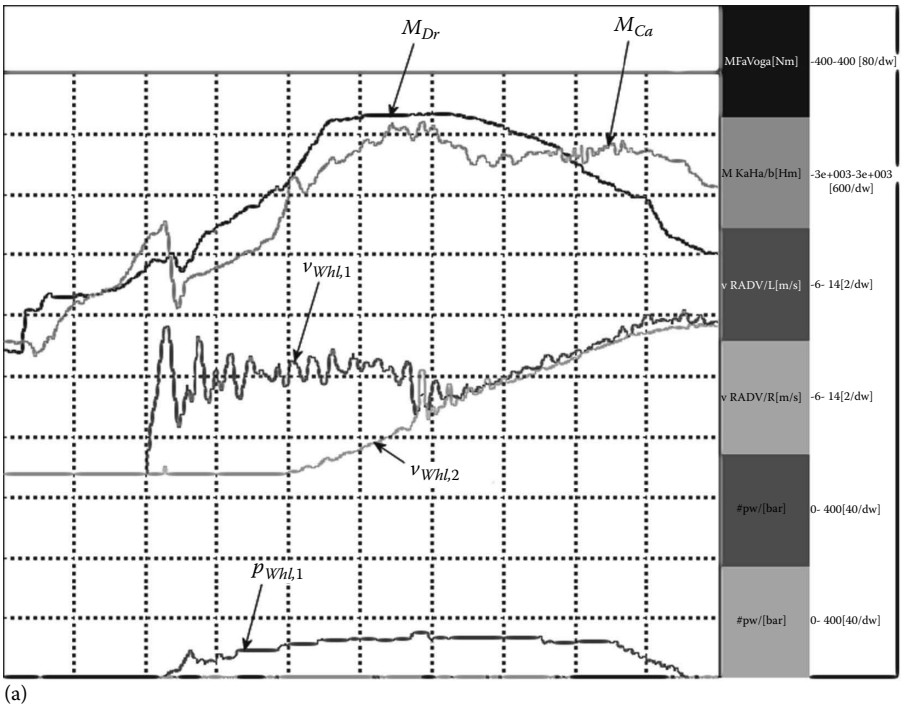

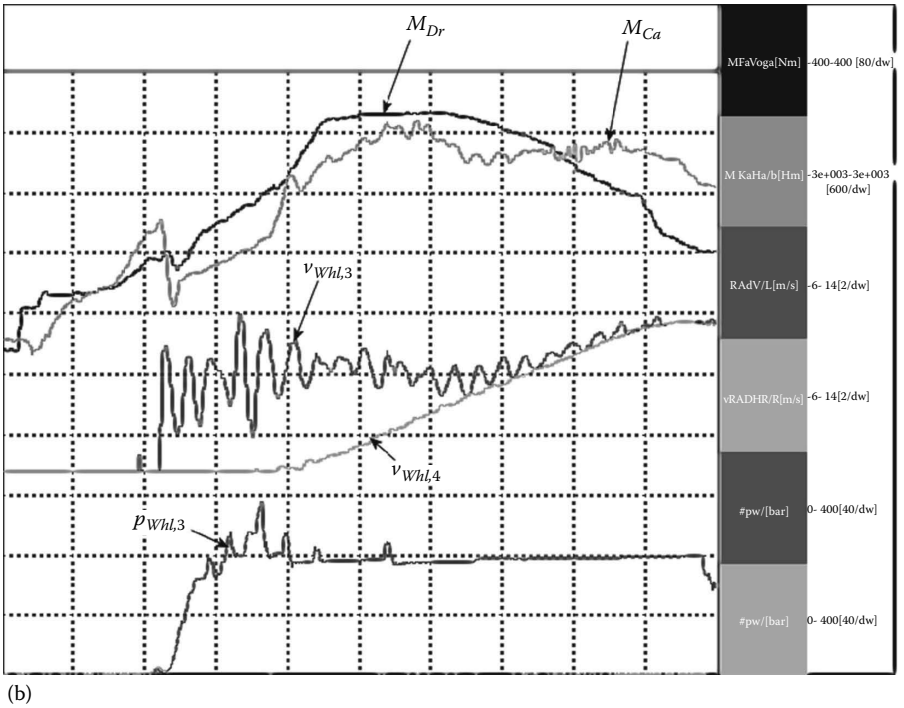

FIGURE 30.48 Block diagram of the TSC for a four-wheel drive vehicle.

central cardan axle M_{Ca} is reduced by the control system. The delay in the control is clearly visible. Because of the strong filtering of the wheel velocity, the pressure at the wheel does not follow the oscillations in the wheel velocity. A similar situation can be found at the rear axle (Figure 30.49b). As the brake torques at the left wheels increase, the torque at the central cardan axle can be increased again. The right front wheel starts to rotate after about 4.8 s and so does the right rear wheel, that is, the wheel velocities are then larger than the minimum velocity that can be measured (2.75 km/h). It is likely that at this time the vehicle already moves. After about 7 s, the difference in the velocity between the two front wheels has dropped to a small value and the wheel brake pressure at the front wheel can be kept constant. At the end of the maneuver, the driver releases the accelerator pedal and the brake pressure at the left wheels can be reduced. Because the rear brakes are smaller than the front brakes, the pressure at the rear brake is higher than that at the front brake.

30.1.5.6 Results

Figure 30.50 shows the results from an ABS maneuver with a rear wheel drive test vehicle. The results are obtained from a closed-loop test maneuver in which the vehicle performs a lane change during full braking on polished ice ($\mu \cong 0.15$). The maneuver starts with an initial speed of 50 km/h, and braking and steering start at the same point in time. The test vehicle was alternatively equipped with series ABS and ESP. In Figure 30.50, the results of the maneuver using ABS are depicted on the left while those using ESP are shown on the right. The results of the maneuver with ABS show that both the yaw velocity and the vehicle slip angle attain large values right from the beginning so that the driver after 4 s has to quickly and heavily countersteer. He is barely able to bring the vehicle to a stable stop on the other lane. The results of the maneuver with ESP shown on the right of Figure 30.50 prove the superior handling performance of the vehicle. The driver need not countersteer nor does the steering angle have to be large, so the driver has an easy job. Also, both the yaw velocity and the vehicle slip angle follow the driver's steering input immediately and stay within a small range of values. The vehicle performs almost like it would do if the coefficient of friction would be much larger and therefore the driver is not surprised by a sudden change in the vehicle behavior. Surprisingly enough though is that the stopping distance of the ESP vehicle with the considerably improved handling performance is also considerably shorter than that of the more difficult to handle ABS vehicle. This can be explained by the limitation of the vehicle slip angle by the ESP system to small values and by the improved ABS regulation.

Figure 30.51 shows the simulation results of a rear wheel drive vehicle running on a circular track while the vehicle speed is increased slowly. Comparison is made between a conventional vehicle without ESP (Figure 30.51a) and the same vehicle with ESP (Figure 30.51b). The track is homogeneous and the coefficient of friction is high ($\mu = 1.0$). This is a closed-loop maneuver in which the driver has to keep the vehicle on the track. The diagrams show the required steering wheel angle, the resulting vehicle slip angle, and the resulting lateral deviation from the track. The dashed curves in both graphs are the collections of stationary points which are iteratively computed for each vehicle speed by the simulation program through variations of the steering wheel angle and the throttle valve angle. These dashed curves represent limit curves for the maneuver with the slowly increasing speed.

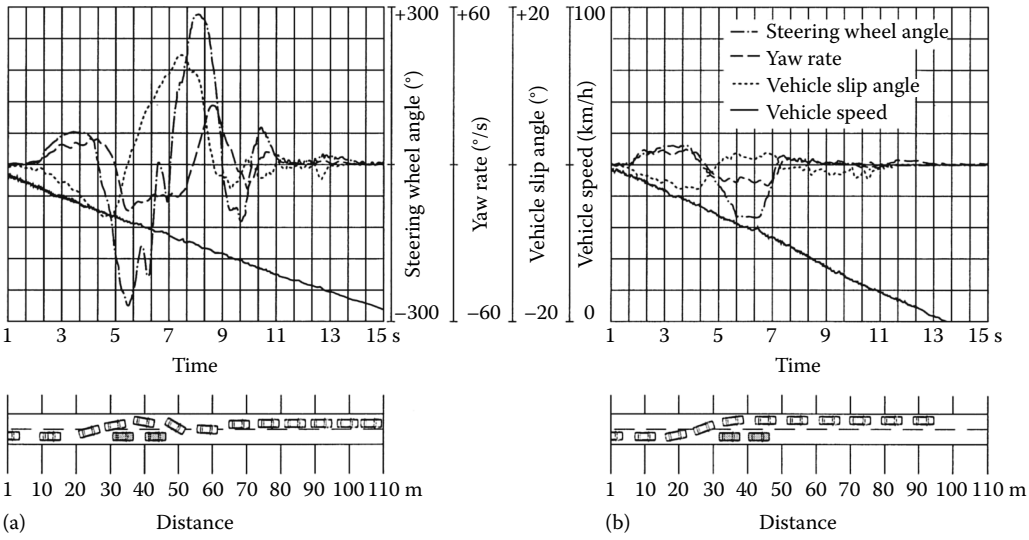

FIGURE 30.50 Comparison of the performance between stand-alone ABS and ESP during an ABS braking maneuver including a lane change. (a) Lane change with ABS ($V_V \approx 50$ km/h, $\mu \approx 0.15$) Full braking. (b) Lane change with ESP ($V_V \approx 50$ km/h, $\mu \approx 0.15$) Full braking.

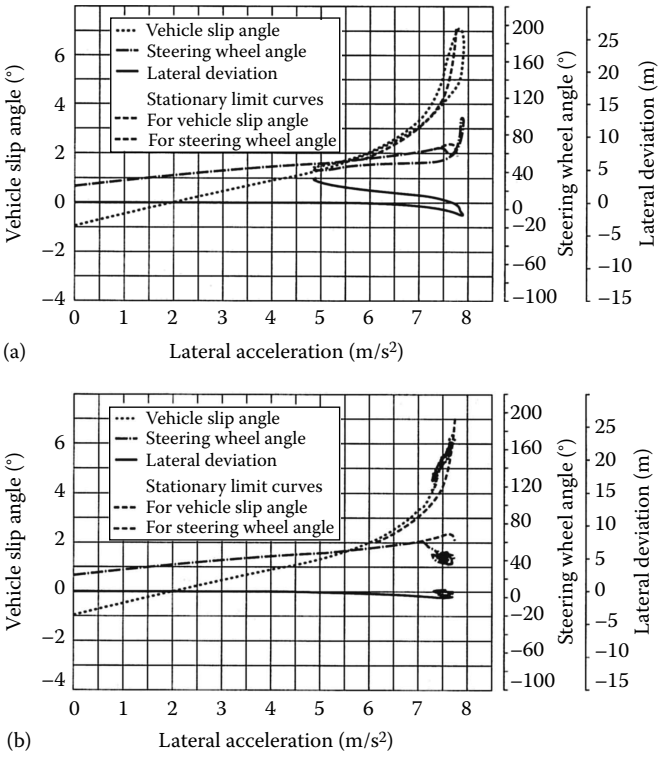

FIGURE 30.51 Comparison of the performance between a vehicle without (a) and one with (b) ESP for a steady-state cornering maneuver with constant radius of the turn and with slowly increasing velocity.

Up to a lateral acceleration of approximately 7 m/s^2, the behavior of the conventional vehicle and the ESP vehicle is identical and almost equal to the stationary behavior. Beyond this lateral acceleration value, the behavior of the conventional vehicle becomes different from that of the ESP vehicle and from the stationary behavior. The vehicle slip angle and the steering angle increase rapidly and progressively. At the lateral acceleration of 7.5 m/s^2, the conventional vehicle drifts out of the circle. Beyond the lateral acceleration value of 7 m/s^2, the ESP system intervenes such that the required steering angle values are reduced and such that the vehicle slip angle value stays at an almost constant value. Although the driver still gradually increases the accelerator pedal position value, the engine output torque is kept limited under the influence of the ESP and the vehicle speed is no longer increased since the physical limit of the vehicle motion is reached. The small lateral deviations of the vehicle from the track are reduced by the steering actions of the driver. As can be seen from the results, the driver's actions at the lateral acceleration value of 7.5 m/s^2 do not result in an unstable vehicle behavior. The resulting changes in the vehicle slip angle and the lateral deviations of the vehicle from the track both stay within a small range.

The simulation results were obtained using a modular vehicle dynamics simulation package called FASIM [45]. The simulation program has been validated and accurately reproduces the dynamic behavior of the test vehicle. The results presented earlier have been verified with the test vehicle.

Figure 30.52 shows the simulation results of a slalom maneuver in which the performance of a conventional vehicle without ESP is compared with that of the same vehicle with ESP. The steering wheel is rotated stepwise, in opposite directions, at regular time intervals and with increasing step values. The road surface is homogeneous with a medium value of the coefficient of friction ($\mu = 0.45$). During the maneuver, the accelerator pedal position is gradually increased in order to

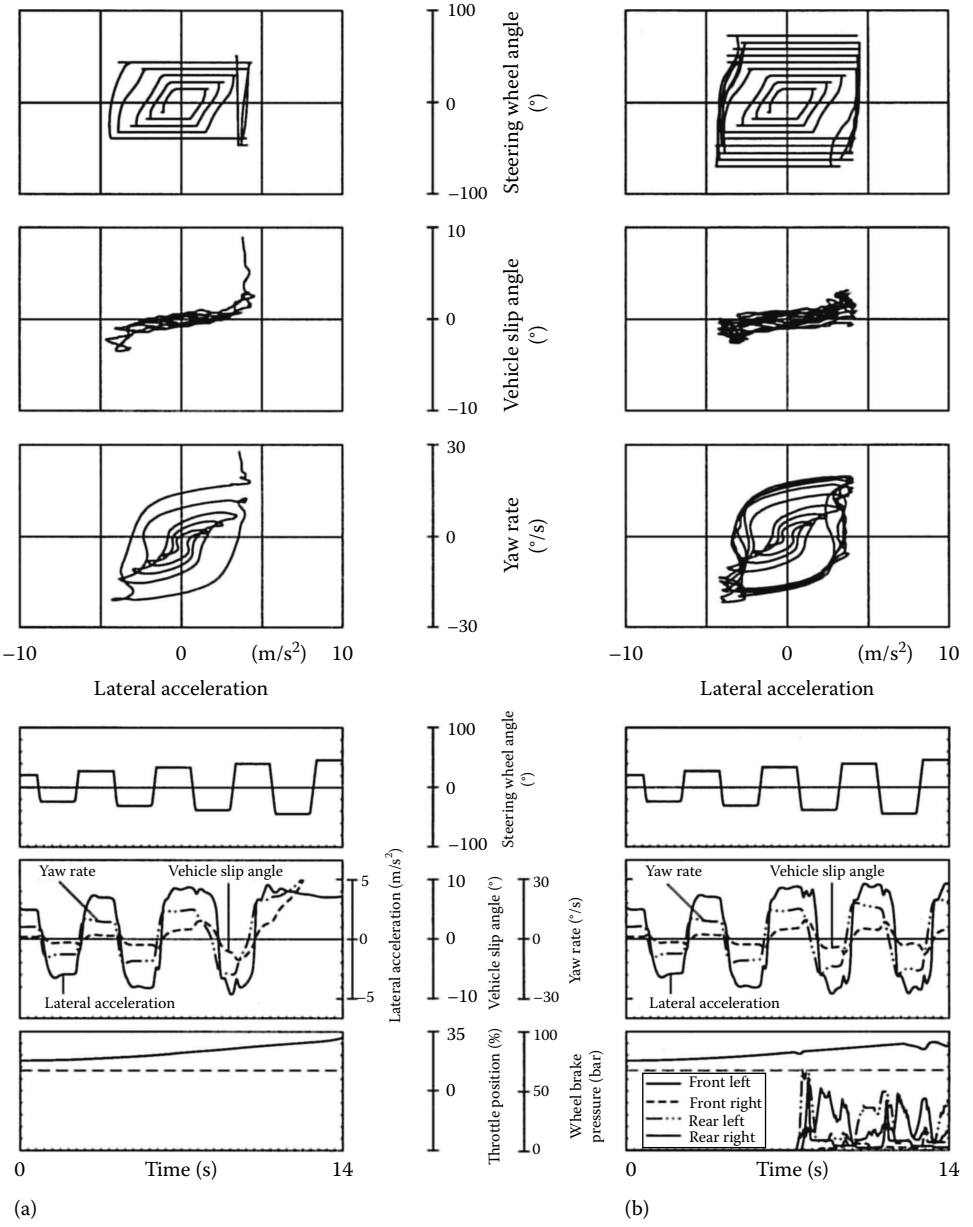

FIGURE 30.52 Comparison of the performance between a vehicle without (a) and one with (b) ESP for a slalom maneuver with increasing steering wheel angle amplitude and constant vehicle velocity.

keep an approximately constant vehicle speed. This will result in a steady increase in the drive slip at the driven rear wheels. On the left of Figure 30.52, the results of the conventional vehicle are depicted (Figure 30.52a), while on the right of Figure 30.52, the results of the vehicle with ESP are shown (Figure 30.52b). The upper portion of Figure 30.52 shows the results as phase plots depending on the lateral acceleration of the vehicle. The lower portion of Figure 30.52 shows the results as time histories.

The conventional vehicle becomes unstable after the fourth positive steering wheel step input. The steering wheel angle is then 40°. Both the yaw velocity and the vehicle slip angle increase rapidly while the lateral acceleration stays at an almost constant value. The results of the maneuver

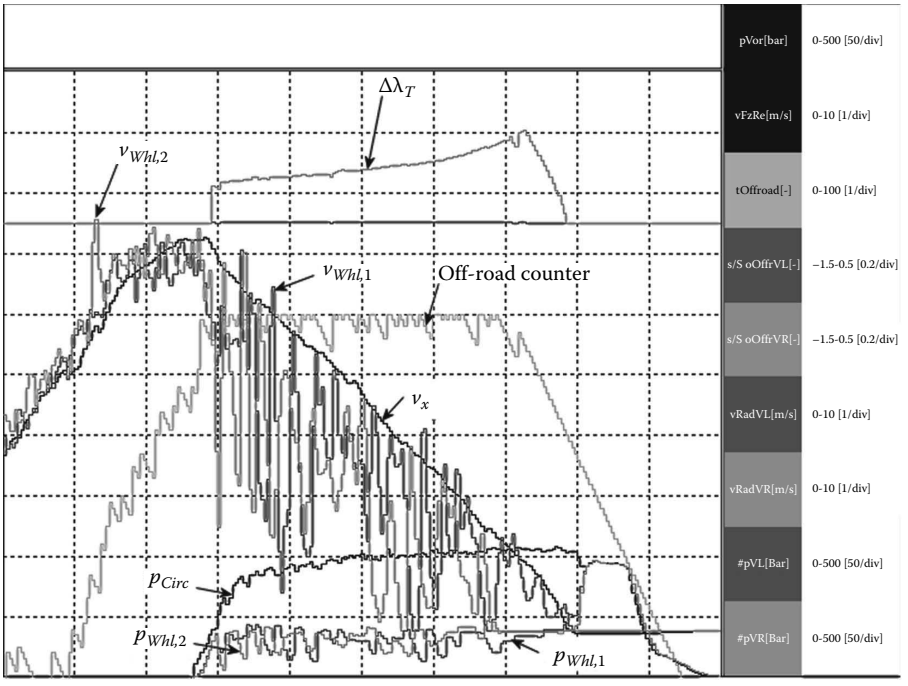
with the vehicle with ESP show that the ESP system intervenes already after the third positive steering step input with a slight reduction in the value of the throttle valve angle and with active braking at the front and rear wheels in order to improve the steerability of the vehicle and in order to keep the vehicle stable. The vehicle motion also follows the sequentially increasing steering wheel step inputs stably, with values of the vehicle slip angle and yaw velocity that are limited by the physical properties of the environment.

30.2 SPECIAL FUNCTIONS OF ESP

30.2.1 Off-Road Vehicles

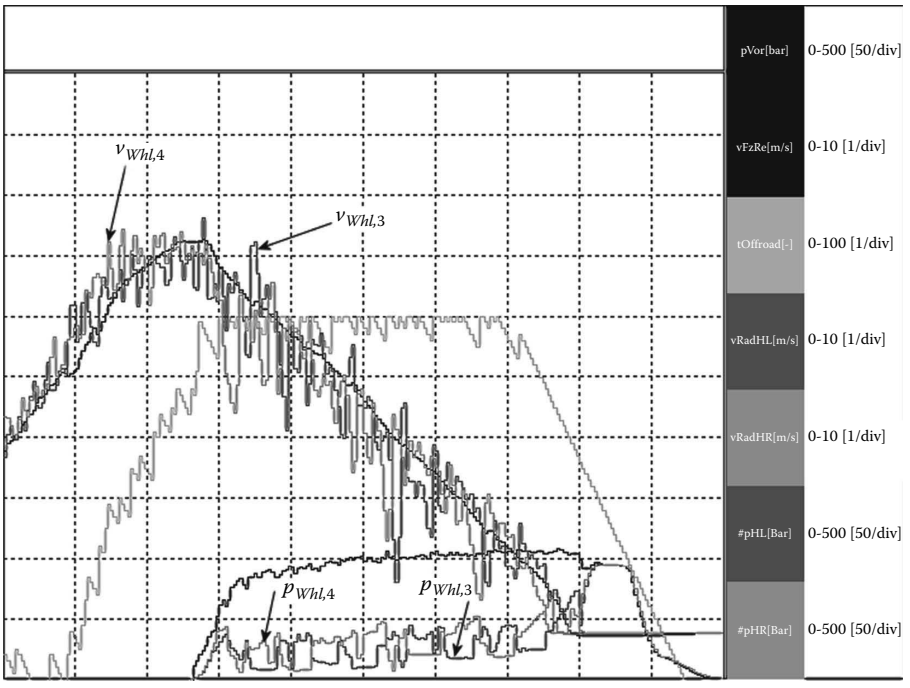
30.2.1.1 ABS Braking Off Road

The extensions of four-wheel drive vehicles to off-road vehicles refer to the special environment in which these vehicles may be operated. In particular, the road surface may be loose like a sandy surface. One extension of ESP with reference to this aspect is discussed here [46].



It is well known that on loose road surfaces like deep sand (and deep snow), the maximum brake and traction forces are achieved at large slip levels, that is, slip levels that are much larger than those on asphalt road surfaces. The brake coefficient of friction of a wheel in deep sand whose slip is λ_0 of dry asphalt (e.g., $\lambda_0 = 0.1$) may be about 0.3, while that of the locked wheel may be 0.7. For improved stopping distances, it would be of great advantage if during ABS the average slip could be increased. This is easily implemented by using the BSC of ESP. The extension of ESP for off-road ABS braking is therefore straightforward.

First, it must be detected that the vehicle is driving in off-road conditions. For this purpose, an off-road counter is introduced. If the off-road counter reaches a certain threshold value, then an off-road condition is expected. The off-road counter is increased if the wheel velocity oscillates with high frequencies. The larger the amplitude of the high frequency oscillations, the larger is the increment in the off-road counter. If the high frequency oscillations in the wheel velocity vanish, then the off-road counter is decremented.



As soon as the off-road condition is expected, the target value of the ABS slip is increased at both front wheels. If it is not very clear that the off-road condition is valid, then the slip is increased at one front wheel only. There may be some ambiguity between braking on a packed snow surface and braking on deep sand, because for a small wheel slip the coefficients of friction are approximately equal. To differentiate between the two surfaces, the combination of slip and coefficient of friction of the road is investigated. If the wheel slip is large and the coefficient of friction is small, then the road surface is assumed to be packed snow or ice. If the wheel slip is large and the coefficient of friction is also large, then the road surface is assumed to be off road. If the distinction is not so clear, then the target slip is incremented at only one front wheel. The target slips at the rear wheels are left unmodified.

Figure 30.53 shows such a case in which it was not clear if the environment is off road or if the road surface is packed snow or scraped ice. At the beginning of the plot, the car accelerates and there are clear oscillations at the front and at the rear wheel velocities, particularly at the right front wheel. During the acceleration, the off-road counter is incremented and decremented as the amplitude of the oscillation increases and decreases, respectively, but in average the counter value increases. At the time the ABS braking maneuver starts (at 27 km/h), the counter has reached its threshold value and the target slip at the right front wheel is incremented initially by about $\Delta\lambda_T = 15\%$ and toward the end of the braking maneuver by about 30%. The increment $\Delta\lambda_T$ is added to the target slip $\lambda_{T,2}$ found by (30.22), so that the resulting target slip is set to about 25% at the beginning and to about 45% at the end of the braking maneuver.

The feature is available only at vehicle velocities below 40 km/h in order to keep the vehicle stable and steerable at larger velocities. Furthermore, the slip increment is reduced to zero immediately if the driver turns the steering wheel.

(a)

(b)

FIGURE 30.53 Time histories of some variables at the front wheels (a) and at the rear wheels (b) of a four-wheel drive vehicle during an ABS straight-line braking maneuver with off-road conditions.

30.2.1.2 Hill Descent Control

Many off-road vehicles have an additional countershaft transmission with which the total transmission ratio can be increased and which can be switched on or off depending on off-road conditions. The gear can be specially used for hill descent situations. The driver does not have to continuously brake by going downhill in off-road situations and he can pay full attention to the task of steering the vehicle. Other off-road vehicles may not have the additional countershaft transmission. For those vehicles, ESP has a feature called "Hill Descent Control" with which the vehicle can be braked automatically so that the driver can again pay full attention to the steering task [46].

The feature HDC can be activated by the driver by pushing the HDC button. The feature is activated only if the vehicle is moving downhill. Since the slope of the road is already obtained by the estimation of the vehicle velocity, using the Kalman filter (30.21), the implementation of the feature is also straightforward. The larger the offset, the larger is the slope of the road. A key factor for the controlled downhill braking is the information on the road slope. The feature keeps the vehicle velocity at a constant value of 8 km/h by automatically applying the brakes at all wheels. By active braking and modulation of the brake pressures, the vehicle velocity is kept constant depending on the road surface friction. It is possible that the road friction is locally so low that the wheel may start to lock during the hill descent braking control. In such cases, the BSC will limit the wheel slip to the nominal slip value on top of the hill descent control. This means that an ABS-braking maneuver may be in operation, although the driver does not apply the brakes. The coefficients of friction of off-road surfaces are typically in the range of 0.2–0.6. As reported earlier, on deep sand roads (also deep snow and deep gravel), the coefficient of friction may reach values (depending on the slip value) between 0.3 and 0.7.

30.2.2 Rollover Mitigation

The standard tuning of ESP is usually sufficient to reduce the danger of rollover for all cars [47]. However, for vehicles with a soft suspension and with a high center of mass, the special function "ROM" may be activated to even further reduce the rollover instability. This function contains a prediction of an incipient vehicle rollover. The prediction is based on the rate of change of both the steering angle and the lateral acceleration of the vehicle. If an incipient rollover is predicted, then the front wheel on the outside of the turn is actively braked to reduce the lateral acceleration of the vehicle. Braking will also reduce the vehicle velocity and with that the centripetal acceleration and the threat of rollover.

Other systems may use a second yaw rate sensor to measure the rotational velocity of the vehicle about its longitudinal axis (x-axis) [48]. Both the rotational velocity and the rotation angle, which is obtained by the integration of the rotational velocity, are used to predict the danger of rollover. If a rollover danger exists, both wheels on the outside of the turn are automatically braked.

30.2.3 Trailer Oscillation Mitigation

A well-known situation for a vehicle towing a trailer is that the trailer can spontaneously start to oscillate about the hitch of the towing vehicle and about the vertical axis (z-axis) of the trailer. The situation arises if the velocity of the vehicle–trailer combination lies above the so-called critical velocity. If the velocity of the combination is below the critical velocity, then the oscillations about the z-axis are damped. Using a simple bicycle model, it can easily be shown that the damping ratio has the vehicle velocity in its denominator. This means that the damping of the oscillation depends on the vehicle velocity. The damping ratio decreases, the closer the velocity approaches the critical velocity. If the velocity is above the critical velocity, the damping ratio becomes positive, the trailer oscillation becomes unstable, and the amplitude of the oscillation increases. Drivers of such combinations are recommended to firmly apply the brake pedal and slow down the vehicle. If the vehicle is slowed down to below the critical velocity, the oscillation will vanish by itself.

ESP contains a feature to recognize the oscillation in the trailer [49]. If the trailer oscillation continues for some periods and does not vanish by itself, then the brakes are applied automatically. The recognition of the trailer oscillation is possible since the oscillations of the trailer can be seen in the yaw velocity of the towing vehicle. It takes about 3–6 periods of the trailer oscillation to recognize the oscillation of the trailer by analysis of the vehicle yaw velocity signal. The brakes are applied by specifying the vehicle deceleration and adjusting the brake pressures by the hydraulic model. Two deceleration levels are used. If the amplitude of the oscillation is large, then the large level (0.5 g) is used. Otherwise the small level is used (0.3 g). If the amplitude of the yaw velocity oscillation of the towing vehicle becomes very large, ESP may intervene ahead of the deceleration command to reduce the yaw velocity. Additionally, ahead of the deceleration braking, the braking of the towing vehicle may be asymmetric to actively damp the oscillation.

30.2.4 Electronic Brake Force Distribution

Brake regulations require that the brakes are dimensioned such that the front wheels lock before the rear wheels lock. If the vehicle deceleration is larger than 0.85 g, then the requirement does not apply. Since the dimensioning of the wheel brakes is fixed, there is a linear relationship between the brake forces on the front axle and on the rear axle. The result is that usually the rear wheels do not contribute much to the deceleration of the vehicle.

The situation is shown in Figure 30.54. The brake force distribution is called "ideal" if the coefficients of friction of the wheels at both axles are equal. The fixed brake force distribution cuts the ideal brake force distribution at the vehicle deceleration of 0.85 g. For this fixed brake force distribution, the rear brake force is much smaller than the brake force of the ideal brake force distribution, in particular for small brake forces, that is, small vehicle decelerations. That means, for small vehicle decelerations (i.e., for by far the most brake applies), the brake forces at the rear wheels according to the fixed brake force distribution contribute much less to the deceleration than the front wheel brakes do. In order to improve the situation for small decelerations, the line of the fixed brake force distribution can be made steeper. But then the line cuts the ideal brake force distribution at a much lower vehicle deceleration (e.g., at 0.5 g), which is not allowed by the brake regulations. In order to still comply with the brake regulations, the ABS is used to reduce the brake force at the rear axle if the deceleration is larger than at this intersection. This function is called EBD. Although the brake pressure at the rear axle is not measured, this is still possible by control of the velocities of the rear wheels.

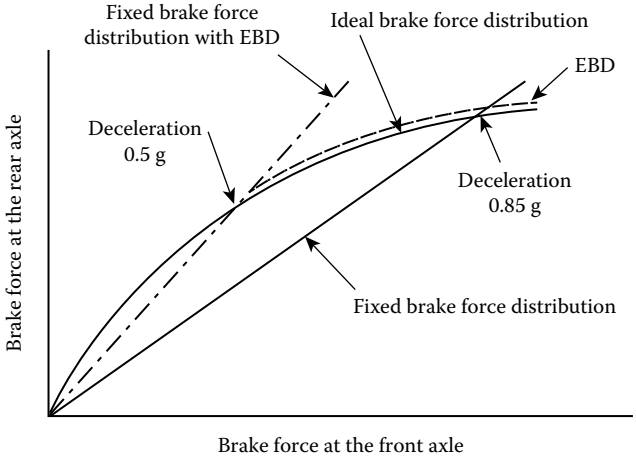


FIGURE 30.54 Principle of a fixed brake force distribution in combination with the EBD.

Along the ideal brake force distribution curve, the coefficients of friction of the wheels at both axles are the same. Since the road surface is homogeneous, the slips of the wheels at both axles are then also equal. But this means that along the ideal brake force distribution curve, the wheel velocities at the rear axle equal those at the front axle. If the wheel velocities at the rear axle are smaller than those at the front axle, then the slips at the rear axle are larger than those at the front axle and then the coefficient of friction at the rear axle is larger than that at the front axle and then the rear wheels lock first. It is therefore sufficient to monitor and control the difference in wheel velocities between the front wheels and the rear wheels and to keep the velocities of the rear wheels larger than the velocities of the front wheels. For best utilization of the rear wheel brakes, the velocities of the rear wheels should be close to the velocities of the front wheels.

In fact, the velocities of the rear wheels are kept slightly below the velocities of the front wheels. As soon as the velocities at the rear wheels become smaller than those at the front axle and the difference is larger than the first threshold (which depends on the vehicle velocity), the brake pressure at the rear axle is no more increased. If the velocities of the rear wheels are smaller than the velocities at the front axle and the difference becomes larger than a second threshold, then the brake pressure at the rear axle is so much reduced that the difference becomes smaller than the second threshold. If the velocities of the rear wheels are smaller than the velocities of the front wheels but the difference is smaller than the first threshold, then the pressure in the rear wheel brakes is increased in a stepwise manner.

If a failure in the system prevents the EBD function and a vehicle deceleration of 5.8 m/s cannot be achieved without the locking of the rear wheels, then the EBD warning light in the dashboard should be lit.

30.2.5 Brake Assistant

The brake assistant (BA) belongs to the so-called driver assistance functions. Since its introduction, the number of assistance functions has increased steadily (see earlier text). The idea of the assistance functions is to assist the driver operating his vehicle and to improve the traffic safety in general. The goal of the BA is to help him in panic-braking situations and to reduce the stopping distance.

Investigations by Mercedes using a full-size driving simulator have shown that in panic situations many average drivers apply the brake with some period of hesitation at the beginning (Figure 30.55) [50]. This hesitation has a large influence on the stopping distance since it occurs at the highest vehicle velocity. If the panic situation is recognized by the BA, the pressure in the brake BCs is automatically increased during the hesitation period to a higher level from that commanded by the driver. Together with the assistant, the average driver can then perform an emergency-braking maneuver as well as an expert driver can do.

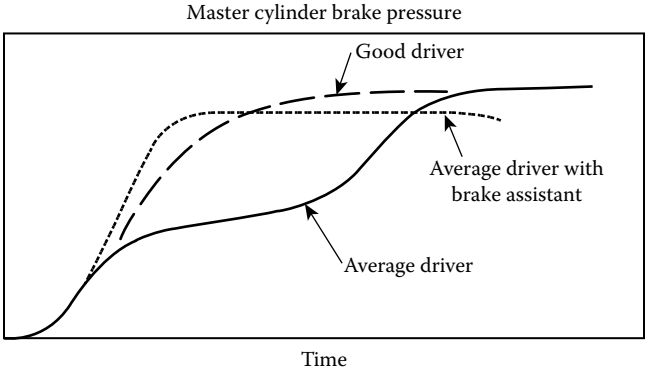

FIGURE 30.55 Principle of the support of an average driver using a pneumatic brake assistant.

The most important functional requirements of the BA are the following.

- Support of the driver in emergency brake situations and reduction in the stopping distance to values that can be achieved by well-trained drivers.
- Elimination of the support if the driver reduces the force on the brake pedal significantly.
- To leave the conventional brake booster function unchanged. Brake pedal feel and comfort must comply with the usual standard during normal braking.
- Activation of the BA only in real emergency situations such that the driver does not adjust his habitual behavior to the BA.
- If the BA is switched off, the conventional brake must not be impaired.

The key task of the BA is to recognize the emergency situation on the basis of the driver behavior. The recognition depends on the type of the BA. There are three types of BAs:

- The pneumatic mechanic BA called "emergency valve assistant" (EVA)
- The pneumatic electronic BA (PBA)
- The hydraulic electronic BA (HBA)

The EVA is realized by an extended design of the vacuum brake booster. Depending on the velocity with which the brake pedal is applied, the gain of the booster is switched to a larger value.

The PBA is realized by using a smart vacuum booster. Using a magnetic valve, the smart booster can allow air to enter the booster up to the maximum support for the driver. For the analysis of an emergency situation, the movement of the booster membrane is measured. The BA support is switched off if the membrane has moved back again and has pushed a release switch.

The HBA will be discussed now in some more detail [51]. The concept of the hydraulic brake assistant is shown in Figure 30.56.

Using the pressure sensor of ESP, the BA function is activated in phase 1 or deactivated in phase 2 according to the logic of Table 30.2. The thresholds can be chosen to adapt the function to the vehicle and its brake system. Furthermore, the thresholds are modified depending on the vehicle velocity, the brake MC pressure, the state variables of the BSC, and the analysis of the time history of the brake maneuver.

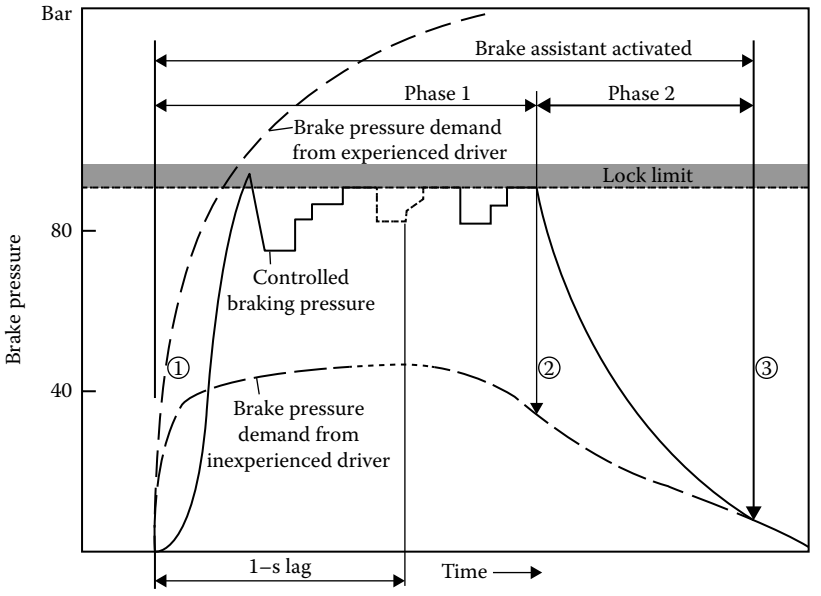

FIGURE 30.56 Principle of the hydraulic brake assistant.

TABLE 30.2
Concept of the Hydraulic Brake Assistant

Situation	Detection Logic
Phase 1 (Figure 30.56) Emergency situation Panic braking	Brake pedal applied *and* MC-pressure gradient above threshold-1 *and* MC-pressure above threshold-2 *and* vehicle velocity above threshold-3
Phase 2 (Figure 30.56) Reduced brake demand	Pedal force (derived from MC-pressure) below threshold-4
Renewed activation	MC-pressure gradient above threshold-1
Standard braking	Brake pedal not applied *or* MC-pressure below switch-off threshold-1 *or* vehicle velocity below switch-off threshold-2 *or* pedal force large enough

As soon as the emergency situation is detected, the BA support is activated (number 1 in phase 1). The BA function increases the brake pressure at all wheels until ABS control starts using the recirculation pump of the HU of ESP. The control situation is comparable with the ESP brake control interventions during partial braking. If the force on the brake pedal is reduced such that the brake pressure in the MC drops below threshold −4 (number 2), then the brake pressure support of the BA is reduced (phase 2). The control strategy is changed now. The goal is then to make the brake pressure at the wheels follow the pressure in the MC and to find a comfortable transition to a standard brake situation. The BA is switched off as soon as the increased brake pressure reaches the value of the MC or if the MC pressure has reached the switch-off threshold. In contrast with the PBA, all wheels are in ABS control while the support of the PBA may not be sufficient enough to reach that situation.

30.3 ESP SAFETY CONCEPT

ESP is a complex mechatronic system because of the large number of sensors and actuators, and the consideration of the vehicle and driver behavior (Figure 30.57) [32]). The ESP system requires information from several sources (four-wheel velocities, yaw velocity, lateral acceleration, steering wheel angle, brake pressure, brake light switch, hand brake switch, and a few signals from the engine and

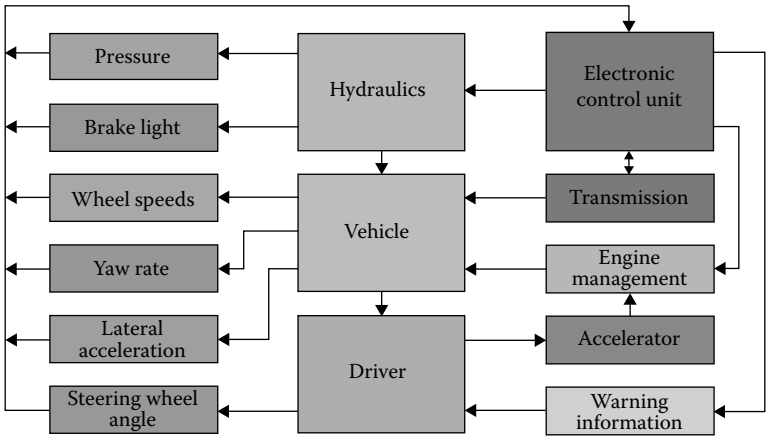

FIGURE 30.57 System components included in the monitoring concept of ESP.

transmission controller). Based on this information, the ESP controller calculates the signals for up to twenty-one actuators (12 valves, pump motor, engine and transmission control, up to three driver information lamps, the optional buzzer, and the lamp in the ESP ON/OFF switch), which modify the wheel forces or inform the driver. In the case of a failure, the ESP system must not use these components improperly. The main purpose of the ESP safety concept is to avoid such malfunctions.

30.3.1 Requirements of the Safety System

- The behavior of the vehicle with ESP must not be worse in any situation as compared with a vehicle without the system (i.e., component failures must not lead to dangerous driving situations).
- System failures must be detected sufficiently fast so that the safety of the passengers and other traffic participants is not impaired.
- Only one front wheel may be controlled to very high slip values at the same time, so that in an emergency situation the other front wheel can be used for handling maneuvers.
- After a system failure has occurred, the best possible switch-off strategy must be chosen as defined by the vehicle manufacturer.
- If a system failure is detected during an ESP intervention, the control must continue with a limp home functionality up to the end of the ESP-relevant situation.
- ESP must provide fallback functions. It is required that the ABS function is kept alive as long as possible, preferably also if only four WSSs are available.
- With some faults of short duration (like electromagnetic interference), the system can be kept activated if the control performance is still acceptable. Otherwise, if the control performance is reduced repeatedly or reduced for a longer period of time, then the system must be switched off.
- The control may be activated only after the safety system has released the control system.

The current status of the basic principle of the ESP safety concept is (Figure 30.58):

- Failure avoidance by analysis of potential problems before the effects influence the controller
- Self-monitoring and self-test functions for key sensors
- A complex and sophisticated monitoring logic which can detect components which are slightly beyond specification and which can decrease the controller sensitivity in the case of suspicion of a failure
- Gradual or immediate shutdown of the system depending on the type of failure
- Limp home functionality depending on the type of failure

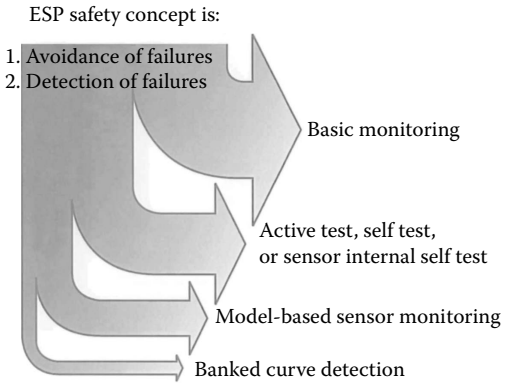

FIGURE 30.58 ESP safety concept.

30.3.2 Avoidance of Failures

Experience with the first ESP implementations has shown that an intensive and early discussion between the supplier and the customer about the safety concept of the ESP system is essential. Only a comprehensive approach to all possible influences during the whole life of the vehicle and a thorough discussion between the customer and the supplier can sufficiently reduce the risk of malfunction of the system or the components. Failures and their effects caused by abuse, modifications in the specification of shared components, and/or their use, mistake or damage during a service, or as a result of an accident must be considered. For this reason, problem-solving analysis using the FMEA principle (failure mode and effect analysis [FMEA]) has been implemented early in the development programs. In these extensive discussions, misunderstandings or vagueness of definitions can be prevented; on the other hand, the customer is very well instructed about ESP and his requirements are integrated into the safety concept. In case the customer contributes important components, for example, the brake MC, the WSSs, or the engine and transmission controller, not only the definition of a functional interface is necessary but also a comprehensive consideration of the safety techniques and equipment concerning these components is essential. Since in the end, the safety and the availability of ESP are determined by the weakest link of the whole mechatronic system; this effort is always justified and worthwhile.

Most suppliers use FMEA to analyze the possible problems. The first FMEA meeting starts as early as possible and continues during the course of the project. As a result, changes and commonly defined measures can be incorporated in the design in a timely manner. The FMEA produces a guide to realize improvements and to avoid failures. These considerations and discussions of the system by means of the FMEA go deep into the details of the system and are a cornerstone of the safety concept.

An important aspect of the FMEA is the judgment of the severity of the effect of failures. Here are some examples of the severest effects (rated 10 and 9):

1. Unintentional braking of one or more wheels outside ESP operation, which leads to a clear lateral motion of the vehicle.
2. Unintentional acceleration of the vehicle (>1.5 m/s^2).
3. Unintentional deceleration of the vehicle (>2.0 m/s^2).
4. Impossibility to brake (e.g., all EVs are closed).
5. Fire or smoke.
6. The warning light is not lit despite a detected failure.
7. The brake lights are not lit although the driver applies the brake.
8. The minimal deceleration required by law cannot be achieved.
9. Unintentional braking of one front wheel during TCS operation.
10. ESP is switched off or its performance reduced during an intervention or shortly before an intervention is necessary, which leads to a drifting or swerving vehicle.
11. Significant reduction in the brake efficiency:
    a. Stopping distance increased by more than 40%.
    b. No brake pressure at the front axle.
    c. No brake pressure at the rear axle.
    d. No brake pressure in one brake circuit.
    e. No brake pressure at one front wheel.

Here are some examples of severe effects (rated 8 and 7):

1. Unintentional braking of one or more wheels outside ESP operation, which is noticed by the driver but which does not lead to a clear lateral motion of the vehicle.
2. Unintentional acceleration of the vehicle (>1.2 m/s^2 but <1.5 m/s^2).
3. Unintentional deceleration of the vehicle (>1.5 m/s^2 but <2.0 m/s^2).
4. Rear wheels are locked during braking.

5. Unintentional braking of one driven wheel during TCS operation.
6. ESP is switched off or its performance is reduced during an intervention or shortly before an intervention becomes necessary, which leads to an insecure feeling in the driver, although the vehicle does not clearly drift or swerve.
7. Reduction in the ESP performance, which causes fear in the driver:
   a. Stopping distance increased, however, less than 40%.
   b. No brake pressure at one rear wheel.

30.3.3 Self-Test, Self-Monitoring, and Tests of Components

Since sensor redundancy is expensive, self-test, self-monitoring, active tests, and analytical redundancy are used for sensor monitoring. Besides the yaw rate sensor, the steering wheel angle sensor is very important to the ESP system. Since the measurement of angles is state of the art and can be done in a very robust and reliable way, the steering wheel angle sensor has been defined as the "master sensor" of the system. This means that the sensor must be able to detect internal failures by itself and to report any failure to the ECU. The time granted to recognize failures is fitted to the requirements of the ESP system and is less than 100 ms. If possible, the system uses a robust digital interface (CAN bus) to transfer data from the sensor to the control unit. Only if the chosen steering wheel angle sensor meets these demands, will the safety algorithms, especially the model-based sensor monitoring, detect the occurring failures in time and with the necessary accuracy and identify the defective component.

Self-test functions are also integrated in the yaw rate sensor, the lateral acceleration sensor, and the brake pressure sensor. The yaw rate sensor is provided with a built-in self-test (BITE), which is triggered externally by the ECU every 40 ms. Because of the test, the yaw velocity can be measured only every 40 ms. Figure 30.59 shows the signal of the yaw rate sensor. During the test mode, the externally stimulated self-test function (from the ECU) causes a superimposed bipolar test signal of ±25°/s at the output to the yaw velocity signal, after the transients have died out. The tolerance of this test signal is ± 9°/s. The analog-to-digital (A/D) converter samples the yaw velocity signal every 1 ms, and then with a delay of 20 ms after the stimulation the response to the test input is calculated by using the last three measured yaw velocity values. This filtering is done in order to take into account the changes in the yaw velocity signal itself as precisely as possible, during high dynamic driving conditions also. Because of the robust evaluation during these three cycles, a very fast reaction of the system is possible in case of a detected failure.

By analogy to the yaw rate sensor's BITE, the lateral acceleration sensor contains a similar test function, which however is fully integrated in the sensor. In case of a failure, the sensor signal is switched into the out-of-range band, which can quickly and safely be classified as a defective state of the sensor.

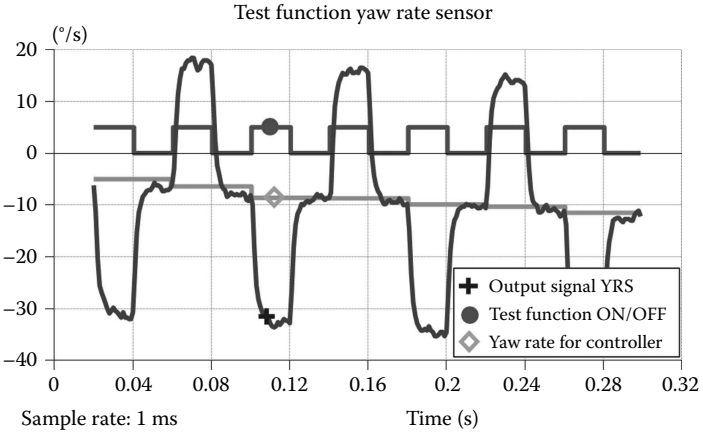

FIGURE 30.59 Yaw velocity signal including the self-test function.

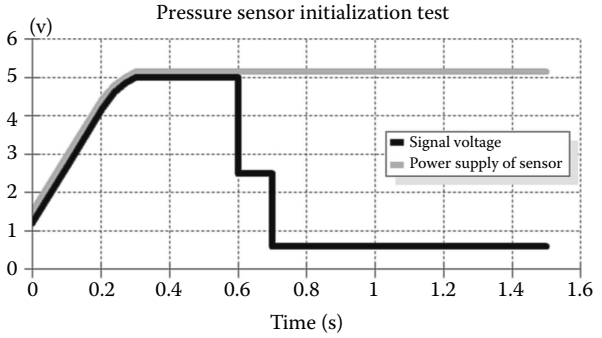

FIGURE 30.60 Power on test of the pressure sensor.

The brake pressure sensor is provided with an internal monitoring of its sensitivity and offset, which in case of a failure pulls the output signal into the out-of-range band. In addition, the sensor is provided with an initial self-test in order to detect failures due to resistance of connectors and to check the functionality of monitoring. Figure 30.60 shows the output signal of the brake pressure sensor during the build up of the supply voltage. The output runs parallel to the supply voltage up to its maximum value of 5 V. About 300 ms later, the sensor must show a predefined value of 2.5 V for a period of approximately 100 ms. Only then does it show the measurement signal.

Besides these self-test functions of the ESP sensors, active tests can be realized by means of the complex hydraulic system. Its components can be activated and the results of this activation can be examined by the sensors. For example, the precharge pump can be tested if it is switched on while the EVs of the HU are closed and the increase in the pressure in the push rod brake circuit due to the activated pump is examined (Figure 30.70). At the same time, using the same procedure, a crude test of the pressure sensor can be obtained. Even the hydraulic system can be tested and it is possible to distinguish between the two brake circuits by measuring the spin downtime of the recirculation pump for each of the brake circuits. By this procedure, called "active hydraulic test," it is possible to detect mechanical defects in the hydraulic system and to prevent an active pressure build up in case of a failure. It should be noticed, however, that this test significantly increases the stress on the HU during its lifetime.

30.3.4 Failure Detection Logic

The failure detection logic is divided into the following parts (Figure 30.58):

- Basic monitoring
- Evaluation of the active tests
- Self-test functions
- Model-based sensor monitoring
- Measures which reduce the effect of unrecognized failures

The first part, the basic monitoring, includes most of the well-known monitoring logic of ABS and TCS. It monitors the electrical functions of the valves and the pump motor, the correct function of the WSSs, the power supply for the ECU and the additional sensors, the electronic components inside the ECU, the wires and the connectors to the ESP sensors, and the CAN bus. The logic is extended to wheel speed monitoring because the ESP controller uses very low thresholds for the slip controller. Improved failure detection logic was necessary in order to prevent malfunction of the system.

The second part of the safety logic is the evaluation of the self-test functions of the yaw rate sensor and the pressure sensor as described earlier and the realization of the active tests. The other parts will be discussed in the following sections.

30.3.4.1 Model-Based Sensor Monitoring

The model-based sensor monitoring is used for two purposes. First, it is used to improve the fault tolerance of ESP, for example, errors in the sensor signals do not reduce the system performance. Second, it is used to detect failures of the sensors. The concept of the model-based sensor monitoring is discussed here on the basis of [52]. Further discussions can be found in [53,54].

30.3.4.1.1 Fault Tolerance of ESP

In order to satisfy the requirement that the system must be fault tolerant, the sensors are continuously calibrated if the ignition is on. The steering wheel angle and the lateral acceleration signals are calibrated based on the assumption that on average every car moves straight ahead. Thus, the offset of the steering wheel angle signal and the lateral acceleration signal are obtained by very low pass filtering of each signal. Special care must be taken if the driver steers continuously in one direction, for example, as is the case during high-speed test maneuvers on special tracks at proving grounds. In this case, the offset filtering must be interrupted.

The offset of the yaw rate sensor is computed based on the assumption that if the vehicle stands still then the yaw velocity is zero. Thus, the measured yaw velocity signal at vehicle standstill is the offset of the signal. Special care must be taken at "zero" vehicle velocity. Since, using passive WSSs, the wheel velocity cannot be measured; if the velocity of the wheel is smaller than 2.75 km/h, the car may creep forward but the measured wheel velocities are zero. If the steering wheel is turned all the way up to its limit (usually ± 720°), then the yaw velocity may be high (e.g., 10°/s) and this value must not be interpreted as the signal offset. Furthermore, there are parking buildings which use an elevator for the vehicles to transport them to the different floors (e.g., in Tokyo, Japan). These elevators can rotate, for example, by 90°, to let the vehicle out and this rotation is measured as the yaw velocity of the vehicle, although the vehicle is really standing still.

In addition to the offset compensation of the yaw velocity during vehicle standstill, there is the possibility to determine the offset during driving. For this offset calibration, a reference yaw velocity must be determined whose value is very reliable and then the measured yaw velocity can be compared with the reference yaw velocity to determine the yaw velocity offset. The reference yaw velocity is obtained by the "model-based sensor signal monitoring" (also called "analytic redundancy"). The basic principle of this part of the safety concept is shown in Figure 30.61. This monitoring method works very well and even sensitivity changes of the yaw rate sensor can be determined.

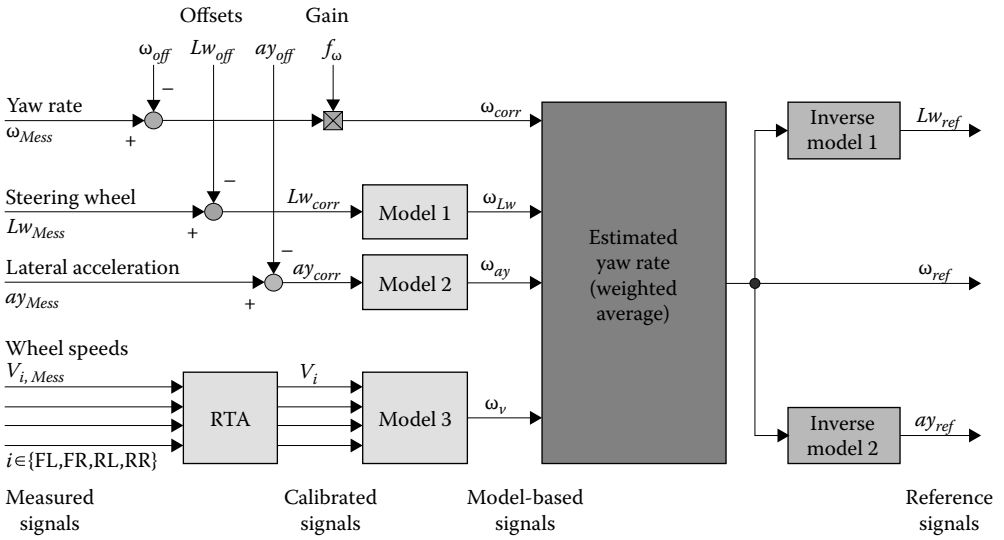

FIGURE 30.61 Model-based monitoring of the sensor signals.

The measured signals from the sensors for yaw velocity, lateral acceleration, steering wheel angle, and wheel velocity are offset corrected. An additional sensitivity correction of the yaw velocity signal is implemented. With the corrected steering wheel angle, lateral acceleration, and wheel velocity signals, yaw velocity estimates can be obtained by using several models. Model 1 is the linear steady-state bicycle model (Table 30.1). Model 2 is Equation 30.5. Model 3 can be found from the difference in the velocities of the wheels at one axle divided by the track width. It is important to have the wheel velocities calibrated first (the calibration is called RTA) before model 3 can be applied. Because the estimates depend on the validity of the models used, the yaw velocity can only be estimated if the vehicle motion is well within the physical limits (i.e., if the slip angles at the wheels are well within the linear region of the slip angle curves).

Together with the measured yaw velocity, four analytically redundant yaw velocity values are derived from which a reference yaw velocity value ω_{ref} is determined by computation of a weighted average of the four values. The reference yaw velocity obtained is insensitive to a sensor fault and corresponds with large probability to the actual vehicle yaw velocity. With the help of inverted models, it is possible to determine in addition to the reference yaw velocity, a reference steering wheel angle and a reference lateral acceleration. A residual is then built by comparing the reference signals to the measured signals. If the integrated residual grows too large, the ESP function is turned off. The model-based fault detection is so accurate that it is possible to detect absolute faults in the yaw velocity signal down to 3°/s.

The total procedure of determination of the offset and of the sensitivity change of the yaw velocity signal and the detection of sensor faults is shown in Figure 30.62.

The offset computation during vehicle standstill has been discussed earlier. Since it is not always possible to obtain the offset during vehicle standstill, a fast offset computation is performed in such situations during drive off. This will result in the first crude information on the offset. Input to the fast offset computation is the difference between the sensor signal ω_{Mess} and the reference signal ω_{ref}. During normal driving the normal offset computation runs. It is the same computation as the fast offset computation, however, with a large time constant. Also, the sensor sensitivity is calibrated during normal driving. For the sensitivity calibration, large yaw velocity values are required as is the case for driving in urban areas. The vehicle dynamics control starts with the ignition on, with enlarged dead zones of the actuating signals of the yaw velocity and body slip angle; and, only if a precise estimate of the offset is obtained, the dead zones are reduced to the normal values. Offset and sensitivity are stored in EEPROM.

As long as the models shown in Figure 30.61 are valid, precise estimates of the offset and sensitivity of the yaw velocity signal can be obtained. Figure 30.63 shows how often the models are valid during driving on different roads and conditions. It shows that the models are most of the time valid while driving on normal roads, but that the situation is different during driving in the mountains with sharp and steep turns.

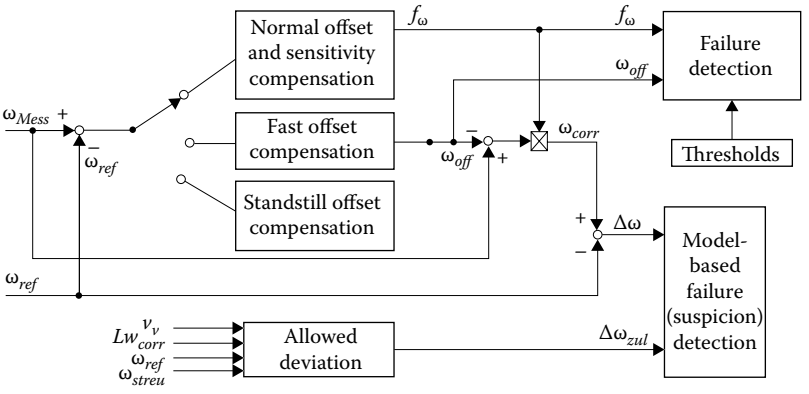

FIGURE 30.62 Calibration and fault detection in the yaw velocity signal.

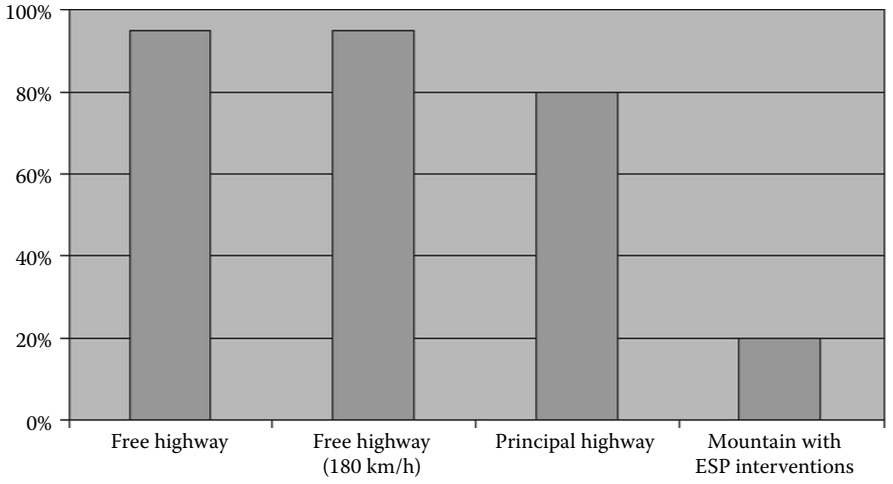

FIGURE 30.63 Validity of the models in percent of the traveling time on various roads.

30.3.4.1.2 Detection of Failures

Another purpose of the model-based fault detection is to deactivate the vehicle dynamics controller if a sensor failure occurs. For example, if a noticeable deviation of the measured yaw velocity or lateral acceleration from their reference values occurs, this will result in a suspicion of a sensor failure. The model-based fault detection will decide within 250 ms if the expected control intervention is allowed or if a faulty sensor signal is present and the controller is to be deactivated. In a very short time, the model-based sensor fault detection locates the failure, deactivates the ESP system, and turns the driver information lamp on.

The model-based failure detection of the yaw rate sensor will be discussed using Figure 30.62.

First, the computed offset and sensitivity faults are compared with the allowed thresholds and a failure is detected if their values are larger than those thresholds.

Second, the calibrated signal ω_{corr} is compared with the reference signal ω_{ref} and the difference $\Delta\omega$ is compared with a variable threshold $\Delta\omega_{zul}$. Now, if the difference is larger than the threshold, then the path chosen in the failure detection system depends on the driving situation.

- If the models are valid, then a failure is detected.
- If the models are not valid but the yaw velocity signal is "observable," then a failure might be present and since it is not sure if a failure has definitely happened only a "failure suspicion condition" flag is set. The calibrated yaw velocity sensor signal ω_{corr} is said to be observable if the computed yaw velocity values, ω_{Lw} from the steering angle, ω_{vR} from the wheel velocities, and ω_{ay} from the lateral acceleration, are close together in a narrow yaw velocity band for several sequential sampling points in time. So the models are still used for failure detection but not for the calibration of the sensor signal. If the failure suspicion condition flag is set, then the dead zones for the vehicle dynamics controller are enlarged in order to prevent unintentional yaw moment interventions. Depending on the magnitude of the difference $(\Delta\omega - \Delta\omega_{zul})$ and the time duration, the failure suspicion condition flag is set when a failure is detected.

The variable threshold $\Delta\omega_{zul}$ depends mainly on the specification value of the yaw rate sensor. Since the models are abstractions of the reality, the model-based yaw velocities also have some error. Therefore, the threshold must be larger than that defined in the specification. Furthermore, the model-based yaw velocities are derived from sensor signals that also have some error even after calibration. This is considered with the computation of the allowed error $\Delta\omega_{zul}$ by the value of ω_{streu}.

Based on the concept of using reference signals, it is also possible to improve the diagnostic function of ESP. If the basic monitoring or the evaluation of the self-test functions detects a malfunction, normally the influenced components are known. In case of model-based sensor monitoring, this is possible with the concept described. For instance, a difference between the yaw velocity signal and that derived from the steering wheel angle signal may show that there is a failure in the relationship of the signals and the system can react. But it is not possible to determine which of the two components is defective and to design an optimized shut-off strategy. An additional calculation would be necessary. By estimation of a reference signal, the monitoring can find differences in the signal path of the failed component and it is possible to store correct information into the EEPROM of the ESP ECU.

30.3.4.2 Measures for Unrecognized Failures

Failures that are not detected by the outlined detection functions could cause an unintended control intervention. But even for this unlikely case, consequence-restricting measures are taken. The most effective preventive measure appears to be the logic for preventing controller interventions during stable driving around banked turns. For instance, if the lateral accelerometer is stuck and continuously shows a zero acceleration value, then the combination of the yaw velocity signal and the lateral acceleration signal is similar to driving in a banked turn and similar to swerving on ice. The controller recognizes such situations by the described logic and prevents control interventions by compensation of the sensor signals (Figure 30.36). Thus, an unintended intervention is avoided in case the failure in the lateral accelerometer signal has not been detected yet.

Other plausibility checks reduce the length in time of the intervention. For instance, if the ABS control lasts implausibly long, then the control is stopped and the system is switched off. Also, if the brake light switch is set but the pressure sensor signal is zero for some length in time, the system is switched off.

30.3.5 System Behavior after Detection of Failure

The response of the ESP system after detection of a failure is based on the strategy which is regulated for the ABS and TCS systems. In the case of ECU and electrical failures of the hydraulic components, the whole system is shut off immediately and all warning lamps are switched on. In the case of WSS failures and pressure sensor failures, which occur while the control is active, it is possible to maintain some control with failure strategies until the end of the intervention. When failures of these components happen outside of active control, the ESP system and all its functions have to be shut down. In the case of failure of the yaw rate sensor, lateral acceleration sensor, or steering wheel angle sensor, control is switched over to a fallback ABS as described in the following text. The switchover to the fallback ABS function is indicated to the driver by switching on the ESP warning lamp.

After completely switching off the ESP system or the fallback ABS function, the EBD function or its limp home function is still available under certain circumstances. If even this function can no longer be maintained, the driver is informed by a red warning lamp (see the description of the EBD function).

30.3.6 Fallback Functions

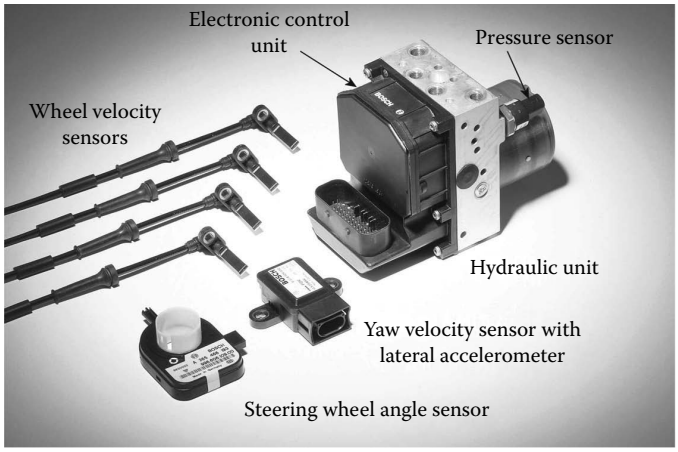
The primary goal of very low failure rates of all ESP components in the field and therefore a very high availability of full ESP performance has been reached and proven in the past years. Despite this fact, further developments were carried out to keep partial functions of ESP available should failures occur, instead of switching off the system completely. Partial functions are, for example, that ESP is only available for free rolling and braking, or that ESP is only available during braking, or that basic ABS functions are only available, or that a controlled brake force distribution is

only given. The last item is of importance for vehicles with a critical brake force distribution. For instance, the system is switched to the first fallback stage—ESP only available for free rolling and braking—whenever a failure in the engine management interface occurs. In this case, full performance for all driving conditions except during drive, acceleration, and accelerator pedal lift-off is given. Almost the same holds true in case of a precharge pump failure (Figure 30.70).

In order to keep the basic ABS functionality available, even if one or more of the three sensors—steering wheel angle sensor, yaw rate sensor, or lateral acceleration sensor—fail, a new ABS reference speed algorithm without using one of these sensor signals was developed. It is designed to operate as a modular replacement for the standard velocity estimation of ESP and to work together with the unchanged BSC. This algorithm also uses the described adaptation phases to derive the free rolling wheel velocity. It is made robust by combining the reference speed of the wheels sidewise. The fallback algorithm runs in parallel to the standard velocity estimation of ESP. In the case of a sensor failure, the running ABS fallback reference speed module immediately replaces the standard one. At the same time, the vehicle motion controller is switched off and some state variables of the BSC are set to default values. In this manner, full ABS performance is achieved immediately after any failure of the above-mentioned three ESP sensors. Not only does the availability of the ABS function improve but so does the safety, since the system does not have to be switched off completely because of a sensor failure which occurs during active ESP control. As the BSC remains unchanged, and only the velocity estimation is replaced by the fallback reference speed module, the application of the fallback ABS control can be based on the application of the complete system. Especially the parameter values of the hydraulic model and most of the application parameter values are valid too for the fallback ABS.

The last fallback stage is required for vehicles with a critical brake force distribution in combination with the EBD in case all sensors including some (but not all) WSSs fail. This fallback stage will keep the EBD of the vehicle at an uncritical value by limiting the brake pressure at the rear axle (as long as the number of available WSSs will allow this).

30.4 COMPONENTS



The components as chosen by the system definition are shown in Figure 30.64a, while Figure 30.64b shows them mounted in the car. The lateral accelerometer (i.e., the yaw rate sensor) should preferably be mounted close to the center of mass of the vehicle as this gives a good compromise in the phase shifts between the steering angle and the lateral acceleration at the front axle and that at the rear axle.

30.4.1 Sensors

30.4.1.1 Yaw Rate Sensor

The yaw rate sensor belongs to the class of vibrating gyros. Because of the importance of this sensor, there is much activity worldwide to develop low-cost precision sensors. The sensor used in the first ESP systems is described in [52]. The accuracy for the offset has to be better than ±2°/s and sensitivity errors have to be to less than ±5% over its life. It has a measuring range of ±100°/s, an externally toggled bipolar self-test function which causes a superimposed output of ±25°/s to the yaw velocity signal (Figure 30.59), and a reduced susceptibility to induced noise on the wiring and to radiated electromagnetic interferences. Figure 30.65 shows a low-cost micromachined sensor used as the successor of the first sensor mentioned earlier. For a detailed description of this sensor, see [53].

The yaw rate sensor is a twin sensor which combines two sensors. A micromachined yaw rate sensor element and a surface micromachined acceleration sensor element are integrated into one package. Its internal self-test capability switches, in case of a failure, the output into the out-of-range band of the signal so that internal defects can be detected by the ECU. The operating range of the acceleration signal is ±1.8 g. For improving the safety aspects, this design uses a background test for detecting internal defects too, which then switches the output in the out-of-range band of the signal.

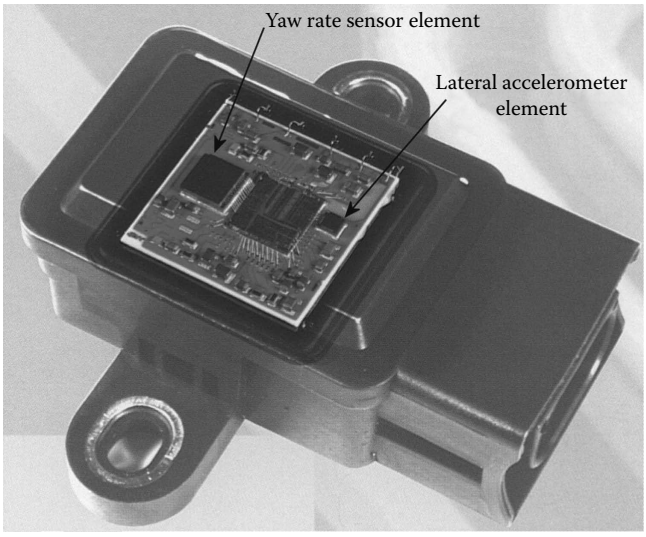

FIGURE 30.65 Yaw rate sensor with sensor hybrid shown on top.

Both outputs (yaw velocity and lateral acceleration) are analog and their values are obtained from the difference of the output signal with a +2.5 V reference voltage. The advantage of this method is that it improves the common mode rejection ratio of each signal path and therefore it reduces the susceptibility to various disturbances. A further step is the addition of a digital CAN interface which results in a further reduction of the amount of wiring and a further improvement in noise immunity.

The physical principle is the following (Figure 30.66). Two bulk-micromachined silicon masses are supported by leaf springs in a kind of a gimbal frame (side length 7 mm) and exited to oscillate by "Lorentz forces" at their natural frequency, typically of about 6 kHz. The oscillation of these two masses is in the antiphase mode and the mechanical coupling between these two masses by another pair of leaf springs is nearly one. The "gimbal" is supported by very weak springs to the environment so that the induced vibration from the vehicle is effectively isolated. On top of each of these masses, a surface micromachined accelerometer with open-loop signal processing is fixed to measure the Coriolis accelerations caused by the angular velocity of the sensor. The detection of internal defects can be signaled by switching the output into the out-of-range band of the signal. The offset stability is good and it is easy to compensate for temperature effects.

A similar accelerometer with closed-loop signal processing is used to measure the lateral acceleration of the vehicle (Figure 30.67) [53]. The accuracy for the offset has to be better than ± 0.075 g and sensitivity errors have to be less than ±7% over its life. A background test signal is continuously

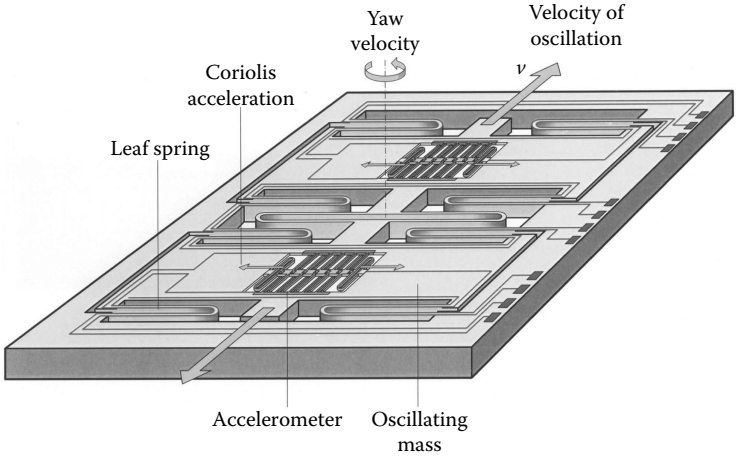

FIGURE 30.66 Yaw rate sensor element.

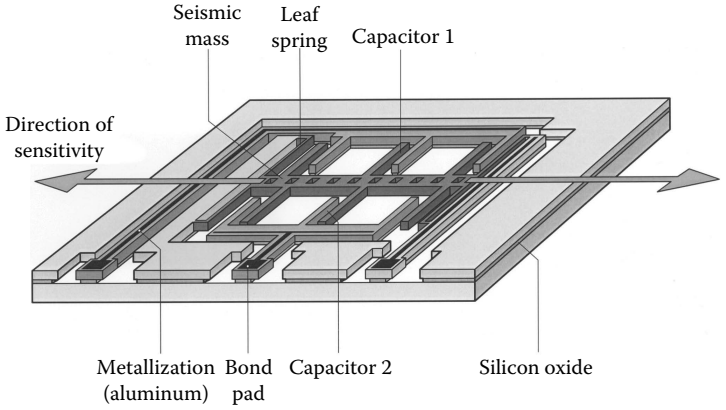

FIGURE 30.67 Accelerometer element used for the measurement of the Coriolis acceleration and the lateral acceleration.

fed into the signal-processing loop to detect internal defects and is then eliminated at the output to obtain a clean output signal. If this test signal differs by a certain amount, the output is switched into the out-of-range band of the signal.

The yaw rate sensor is supplied with nominal +12 V and therefore the outputs are not ratiometrical. Using a power supply regulator within the sensor improves the signal filtering also with respect to the increased power supply rejection ratio. ESP requires very high signal fidelity for these signals and therefore the common mode rejection ratio has to be large and the testability of these sensors becomes very important. This leads to a five-pin interface which is absolutely necessary to meet these high requirements. It allows reading the sensor output quasi-differential to compensate for transmission errors, to calibrate the A/D converter, and to enable the test mode. In total, signal path errors are reduced by a factor of two as compared to a ratiometrical three-wire interface. Digital interfaces using a CAN protocol are designed into the sensor. In this case, the susceptibility for conducted and radiated noise and corrosion and other problems with connectors is further reduced and the signal monitoring for inconsistent signal conditions is then much easier.

30.4.1.2 Steering Wheel Angle Sensor

The basic operating principle of the steering wheel angle sensor is the use of the anisotropic effect of a thin magnetic layer (AMR elements) [54]. Two of those elements are fixed to small gear wheels with different numbers of teeth and are driven by the steering column and their output signals are derived using a "nonius" principle to get a very high resolution. This special design also provides the absolute steering wheel angle position immediately after power up of the sensor so there is no need to have a sleep mode. Its operating range is ±720°. The overall accuracy has to be better than ±5° over its life. Figure 30.68 shows this sensor. The number of teeth of the small gear wheels is chosen in such a way that the difference in the rotation angle between the two can be used as a measure for the number of revolutions of the steering wheel. A microcontroller handles the four A/D converted output signals of the AMR elements, checks them if they are consistent, and converts them to the predefined CAN protocol. The susceptibility for conducted and radiated noise and corrosion and other problems with connectors is reduced and the signal monitoring for inconsistent signal conditions is then much easier. Its redundant signals and electronic paths and the implemented software concept allow a self-supervisory function on which the safety concept can rely. Internal defects are immediately sent via the CAN bus to the ECU. The CAN protocol has error detection and error correction capabilities. Therefore, the other sensors can be calibrated using this digital signal as a basis.

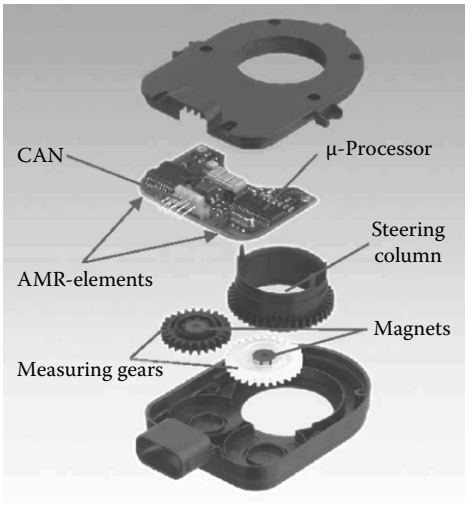

FIGURE 30.68 Exploded view of the steering wheel angle sensor.

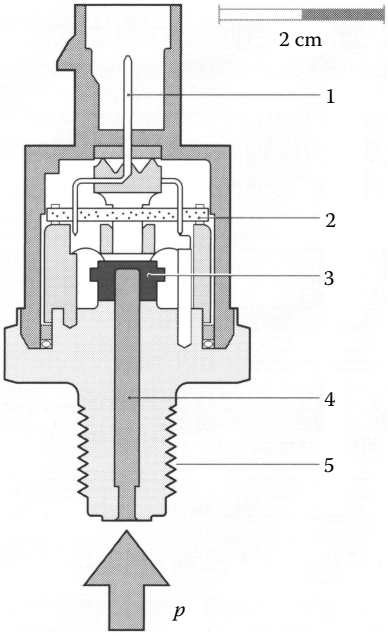

FIGURE 30.69 Cross section of the pressure sensor with (1) connector pins, (2) signal processing, (3) steel membrane with strain gages, (4) brake fluid bore, and (5) thread, p: brake fluid pressure.

30.4.1.3 Pressure Sensor

The pressure sensor has an operating range of 0–250 bar for measuring the pressure of the brake fluid either induced by the driver or by the precharge pump. The offset has to be less than ±3 bar and sensitivity errors have to be less than ±5% over its life. The sensor has been designed to include a background test which also allows the detection of internal defects that influence the offset and the sensitivity of the sensor. In case of an internal defect, the output of the sensor is switched into the out-of-range band of the signal. To ensure a correct function of this background test function, a power-up test sequence is initiated by the slew rate of the supply voltage at each power-up condition (Figure 30.60). This also allows detecting defects in the wiring harness and connectors between the sensor and the ECU.

The basic principle of this sensor is derived from the piezoresistive effect of a polysilicon layer designed as a strain gage, which is directly deposited on an electrically isolated membrane made of high-grade steel (Figure 30.69). The full bridge signal as the main signal path is amplified and compensated for temperature. The signal of one-half of the bridge is compared with a pressure-independent reference signal and the difference between these two signals is compensated for temperature and other effects and then amplified to show the same sensitivity as the signal of the main path. Thus, a test signal is derived to check the main signal for correctness in offset and sensitivity. If a deviation of a certain amount between these two signals occurs, the output is switched into the out-of-range band of the signal. This self-test function allows for the detection of sensitivity changes in the range of 5% or more and equivalent changes in the offset.

30.4.2 Actuators

30.4.2.1 Hydraulic Unit

The block diagram of a HU is shown in Figure 30.70. The unit is of the traction control type and is hydraulically closed using a self-priming recirculation pump (sRFP). For active pressure generation in the wheel brake cylinders, the active pressure valves, also called switch over valves, USV, are closed while the suction valves, HSV, are opened. The additional pressure-limiting function of the

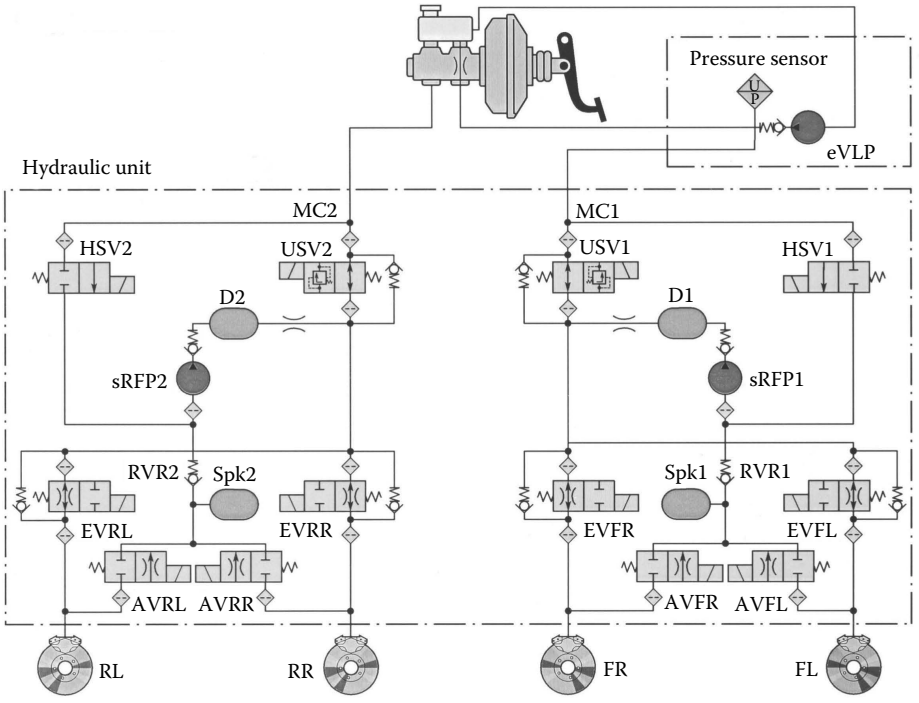

FIGURE 30.70 Hydraulic system of ESP with optional precharge pump.

USVs has a value which is chosen sufficiently high to reach locking pressure in each wheel brake cylinder at any maneuver. In order to limit the workload of the pump motor, the HSV is only opened if any of the EV in the corresponding brake circuit is open.

The suction valves ASV of the TCS–HU have to be replaced by the HSV in order to be able to open the valve also if the driver applies the brake. The HSV is a two-stage valve (Figure 30.71). In the first stage, a small seat in the valve is released. In the second stage, the larger seat is also released. If the driver applies the brake, the electromagnetic force of the HSV may not be strong enough for the anchor to release the larger seat also. However, during braking, it is sufficient to reach the first stage of the HSV only. For active braking, that is, if the driver does not apply the brake, the second stage must be opened. Since the driver does not apply the brake pedal, the electromagnetic force is large enough to release the large seat also. The design of the HSV allows it to release the small seat against MC pressures of up to 120 bar. This is sufficient, since at MC pressures above 120 bar all wheels are in the antilock braking mode.

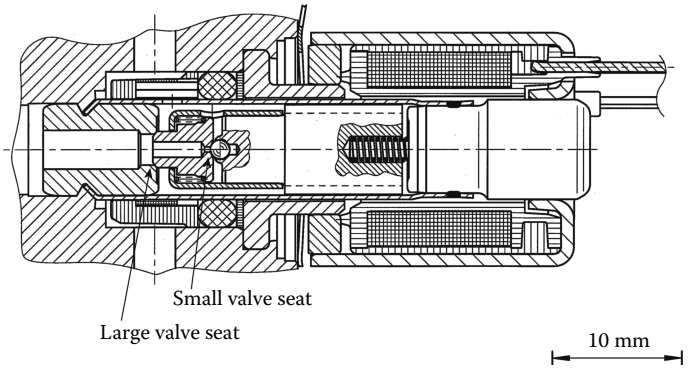

FIGURE 30.71 Cross section of the two-stage magnetic suction valve HSV.

30.4.2.2 Precharge Pump eVLP

The main reason for precharging the recirculation pump of the HU is the performance requirement of ESP at low ambient temperatures. Increasing viscosity of the brake fluid at lower temperatures together with the flow resistance of the brake fluid through the MC, the brake lines connecting the MC with the HU and the suction valves in the HU are the main reasons for the low efficiency of the sRFP. If a sRFP however, is capable of increasing the pressure in the wheel brakes fast enough by itself without precharging, then the precharge pump eVLP can be omitted. For most cars, precharging is not required. The precharge pump is of the gerotor type so that the fluid flow is almost continuous and there is no flow-restricting EV.

If the precharge pump is started, brake fluid flows from the reservoir through the precharge pump and the check valve into the push rod brake circuit. In the brake circuit, this fluid flow splits up and a part of the brake fluid flows through the brake MC back to the reservoir. The pressure in the brake circuit is determined by the fluid flow resistance from the brake MC back to the reservoir. This resistance is realized by a throttle bore in the MC whose diameter must be tuned together with the precharge pump delivery rate. The tuning must be such that the precharge pressure for the recirculation pump of the HU is sufficiently high (e.g., 15 bar) but not too high at low ambient pressures (otherwise the brake pedal is "hard" if the driver applies the brake during TCS operation). If the fluid flow passing through the MC back to the reservoir is reduced, then the brake circuit pressure is reduced as well. This occurs, for example, if the suction valve HSV is opened, and part of the fluid flow is led to the recirculation pump and eventually to the wheel brakes. Therefore, the precharge pump delivery rate must be clearly larger than that of the recirculation pump. Since the request for precharging is predominant at low temperatures, the precharge pump is designed for optimal delivery rate at low temperatures. During braking, the check valve prevents the brake fluid escaping from the push rod brake circuit through the precharge pump back to the reservoir.

Modern brake MCs have a floating piston which is not connected to the push rod piston. Forced by the pressure in the brake MC push rod circuit, the floating piston can therefore move away from its initial position. After the central valve of the floating piston has closed, the pressure in the floating piston brake circuit will increase to approximately the value of the push rod circuit if the floating piston friction is neglected. Thus, it is sufficient to connect the precharge pump to one brake circuit only. A failure in the precharge pump circuit (e.g., if the check valve leaks) will then not lead to a failure in the total brake system. Since the push rod circuit has a direct connection to the reservoir, pressure pulsations induced by the recirculation pump into the brake circuits are well damped.

30.4.3 Electronic Control Unit

The block diagram of the ECU is shown in Figure 30.72 and the nomenclature is shown at the end of this chapter. For safety reasons, the microprocessor is redundant similar to that with ABS and TCS and the cross-checking between the microprocessors is done as with the other systems (for cost reasons, modern systems use a different approach to check the proper function of the microprocessor). Also, critical signal paths are redundant to improve safety. For the voltage supply to the valves and to the pump motor, solid-state relays are used. The wheel velocity signals are output for use in other control units. The stabilized supply voltage of 5 V is required by, for example, the pressure sensor.

The ECU is mounted on the HU. This reduces cost, size, and wiring, and improves the reliability as compared with a separate ECU box. But since the HU is mounted with a bracket in the engine compartment, the ambient temperature of the ECU may be high (up to 120°C). The entire circuitry is therefore designed onto a ceramic substrate using the new small-scale hybrid technique. This substrate is directly attached to the HU. The coils of the valves are part of the ECU, so interconnection is very short and quite simple. This design results in small interferences

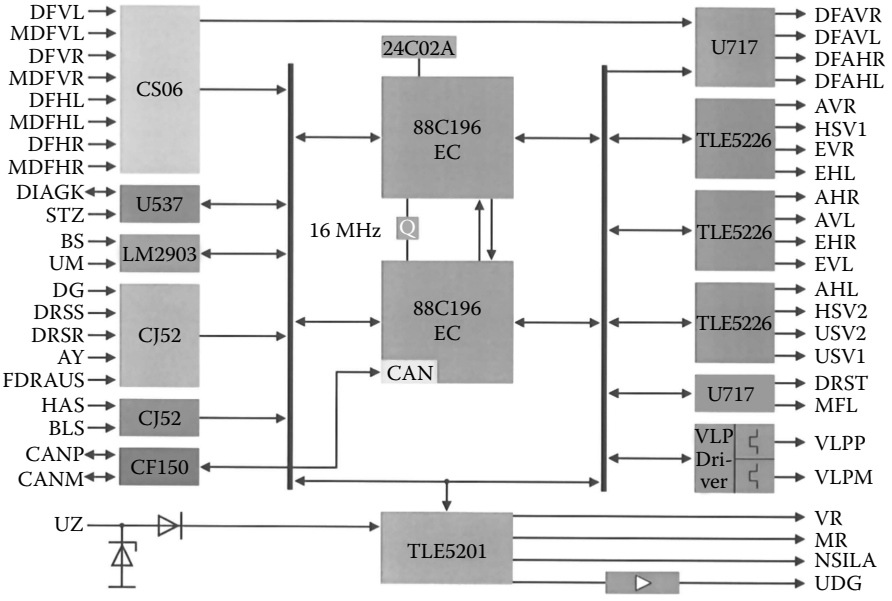

FIGURE 30.72 Block diagram of the ECU of ESP.

due to minor inductive coupling and therefore leads to an improved signal path performance and allows for pulse width-modulated stimulation of the valves and the pump motor. This results in the reduction of external wiring, which results in overall cost reduction. Each single signal path has been optimized concerning signal path errors and bandwidth aspect to achieve better overall accuracies for the sensor signals, which on the other hand also result in reduced sensor requirements.

A further step in reducing cost is achieved by the introduction of variant coding. Now it is possible to use the same ECU for different vehicles of the same platform and to choose the appropriate set of vehicle-dependent parameters like vehicle types, brake system, engine, and transmission. This results in fewer variants of ECUs and fewer spare parts in storage and also in more flexibility during the manufacturing process.

30.5 OUTLOOK

With the development of active four-wheel drive systems, active suspension systems, active rear wheel steering systems, and active brake and traction force distribution systems in the eighties of the last century, the desire for integration of these systems together with ABS and TCS followed [55–74]. In Europe, the goal was to improve the "vehicle safety to an unprecedented level" by using these systems in an integrated manner [65]. A summary is given in [74]. A drawback of this development was the immense cost and weight of those active systems to reach that level of safety. Only luxury cars could afford such high costs. With the introduction of ESP, the activities were virtually stopped since ESP already achieved a similar very high level of safety unknown up to that moment, but with significantly lower cost and with virtually no additional weight. Safety is thus not a privilege of luxury cars only but also of micro and compact cars.

New developments realize active front wheel steering systems and active antiroll bar systems which are not as expensive as the active systems of the eighties. Again the desire is to integrate these systems, however, now together with ESP [75–81]. Here, the approach of [76–78] is discussed.

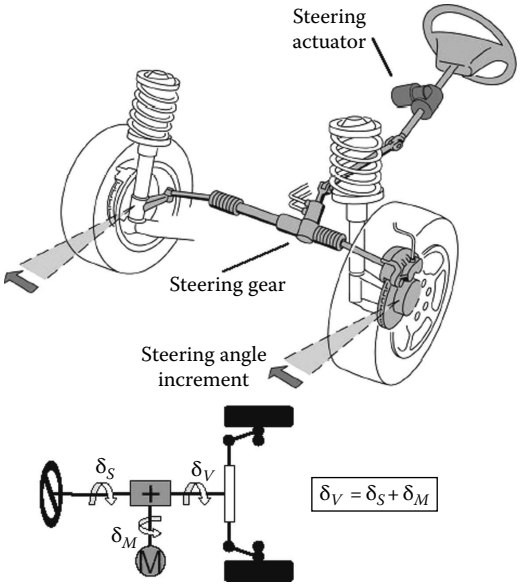

FIGURE 30.73 Active steering system.

If an active steering system is available, ESP can also use this system to control the handling behavior of the car, not only in limit situations but also during normal driving. Figure 30.73 shows the concept of a first realization of such a system with which ESP can modify the steering angle [82,84,85]. The system by itself performs several functions.

- Below a certain vehicle velocity, the steering transmission ratio is reduced to improve the handling of the vehicle and to improve maneuvering while parking in a slot.
- Compensation of the elasticity of the steering system and thus enhanced handling at higher velocities by feed forward control.
- Countersteering during split-μ braking, which reduces the steering load of the driver and which reduces the stopping distance because GMA (see ABS) is not required.
- Support of ESP by controlling the yaw moment of the vehicle through automatic steering. This feature is particular interesting since the steering angle corrections are very comfortable and the vehicle velocity is not influenced as when the yaw moment must be generated by brake and engine interventions. Moreover, the interventions are very fast so that the actuating signal can be kept small.

Another active system is shown in Figure 30.74, in which ESP can modify the normal force distribution on the wheels by control of special active antiroll bars as an active suspension [83,86]. The system itself performs several functions.

- Symmetric variation of the effective stiffnesses of the antiroll bars at the front and at the rear axle to reduce the roll angle while cornering.
- Asymmetric variation of the effective stiffnesses of the antiroll bars at the front and at the rear axle to influence the handling behavior of the vehicle in the direction of understeer or oversteer.
- Asymmetric variation of the antiroll bars at the front and at the rear axle to increase the normal, lateral, and longitudinal forces on the wheels and enhance the stopping distance during split-μ braking or reduce the yaw moment on the vehicle.

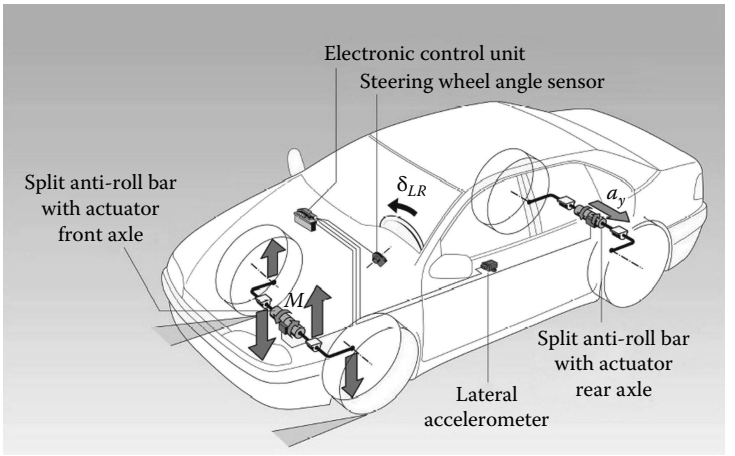

FIGURE 30.74 Active antiroll bar.

- Support of ESP by controlling the yaw moment of the vehicle through automatic variation of the effective stiffnesses of the antiroll bars on the front and on the rear axle. This feature is particular interesting since the antiroll bar corrections are, like the steering angle corrections, very comfortable and the vehicle velocity is not influenced as when the yaw moment must be generated by brake and engine interventions. However, in contrast with the steering angle corrections, the interventions by the active antiroll bars are relatively slow so that the actuating signal cannot be kept small by this feature alone.

Each of these systems can thus influence the yaw moment on the car. The question is now, how to implement the total yaw rate control (the term yaw rate control means the vehicle dynamics control). Early proposals were based on the observation of the different intervention bandwidths of the brake, engine, active steering, and active suspension actuators. Each actuator had its own yaw rate controller (Figure 30.75). The controller gains had to be tuned such that the interference between the interventions did not lead to undesirable or even unstable vehicle behavior. The charm of this approach is that to some extent the development of the controllers can be done independent of each other. Obviously, if the controller gains must be drastically reduced

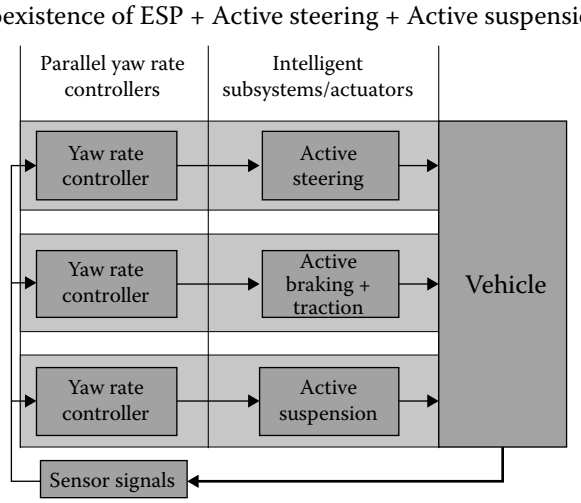

FIGURE 30.75 System integration using parallel yaw rate controllers.

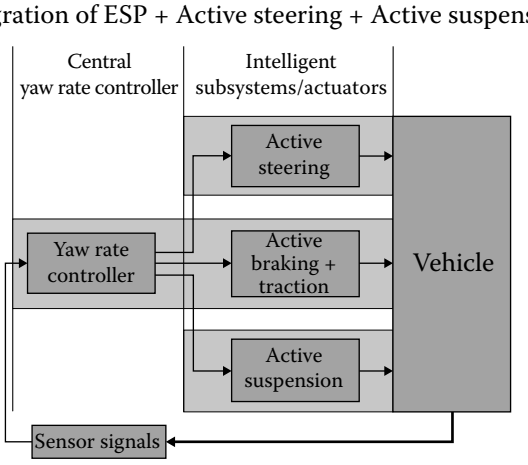

FIGURE 30.76 System integration using a central yaw rate controller.

to guarantee the peaceful coexistence of the controllers, important performance potential is lost. Identification, adaptation, and learning control are not feasible. Furthermore, the systems must exchange information. This can be seen from an intervention of the active suspension. If the active suspension modifies the behavior of the vehicle and changes the characteristic velocity, then ESP may intervene and compensate the modification in the vehicle behavior. The complexity of the control and the controller safety will increase rapidly with the number of systems and so does the development and application effort. The question of multiple sensors or inclusion of nonstandard sensors in the control and safety concepts must be solved also.

Later proposals use a central yaw rate controller which takes the different properties of the actuators in consideration (Figure 30.76). This is particularly important if the brake actuation is no more much slower than the steering actuation as is the case with an EHB where the brake interventions can be very fast. The superimposed central yaw rate control distributes the required yaw moment between the active systems and uses them as intelligent actuators. The idea is to extend the structure of the existing ESP in which the "intelligent subsystems" BSC and TSC determine their own target values of the controlled variable "slip" and where the vehicle dynamics controller determines the increments of the slip to adjust the yaw moment on the vehicle. Thus, the active steering controller and the active suspension controller must determine their target values by themselves while the vehicle dynamics controller is extended to also determine the increments of the steering angle and of the effective antiroll bar stiffnesses to adjust the yaw moment on the vehicle.

EHB and the new active systems can influence the handling behavior of the car also in situations in which the physical limit is not reached, for example, by a lateral brake force distribution in the case of EHB. If the passive car handling changes, for example, because of changes in the tire properties, then these systems can restore normal vehicle behavior by interventions which are not noticed by the driver. These systems therefore have the potential of making handling robust against parameter changes. However, in order to fully exploit the high speed of the interventions, the test cycle of the yaw velocity signal (Figure 30.59) must be avoided, which results in the requirement for redundant yaw velocity signals.

NOMENCLATURE

$\dot{\psi}$	yaw velocity
$\dot{x}_0$	velocity of the vehicle at the center of mass in x_0-direction
$\dot{y}_0$	velocity of the vehicle at the center of mass in y_0-direction
$\ddot{x}_0$	acceleration of the vehicle at the center of mass in x_0-direction
$\ddot{y}_0$	acceleration of the vehicle at the center of mass in y_0-direction

$\tilde{v}_y$	velocity of the vehicle at the center of mass in the lateral direction as obtained from the measurement equation
$\hat{v}_y$	velocity of the vehicle at the center of mass in the lateral direction as obtained from the Kalman filter equation
$\dot{\beta}$	slip angle velocity of the vehicle at the center of mass
$\dot{\psi}_M$	yaw velocity of the extended bicycle model
$\dot{v}_y$	time rate of change of the lateral velocity of the vehicle at the center of mass
$\dot{\dot{\psi}}$	yaw acceleration
$\dot{v}_{Whl}$	acceleration of the wheel
$\Delta\dot{\psi}$	difference between the nominal and the actual yaw velocity values
$\dot{v}_x$	time rate of change of the longitudinal velocity of the vehicle at the center of mass
$\dot{v}_{x,off}$	slope of the road in longitudinal direction of the vehicle
$\dot{v}_{x,off}$	time rate of change of the slope of the road in longitudinal direction of the vehicle
$\dot{\psi}_M$	yaw velocity of the extended bicycle model of the vehicle
$\Delta\dot{\psi}_{No}$	actuating signal of the yaw velocity of the vehicle
$\Delta\dot{\psi}_b$	compensation of the yaw velocity of the extended bicycle model for banked turns
$\dot{\psi}_{No}$	nominal yaw velocity
$\dot{\psi}_k$, $\dot{\psi}_{k+1}$	yaw velocity at sample time point k and $k + 1$ respectively
$+A$	acceleration threshold
$+a$	acceleration threshold
a	longitudinal distance from the front axle to the center of mass of the vehicle
A	bulk head area of the vehicle
$-a$	deceleration threshold
A_0, A_1, A_2	coefficients for the computation of the target wheel slip
A_{11}, A_{12}, A_{21}, A_{22}	time variable coefficients
a_{Whl}	acceleration of the wheel
a_x, a_y	acceleration in longitudinal resp. lateral direction of the vehicle at the center of mass
ay_{corr}	calibrated lateral acceleration signal
ay_{Mess}	measured lateral acceleration signal
ay_{off}	offset value of the measured lateral acceleration signal
ay_{ref}	lateral acceleration value computed from the reference value of the yaw velocity
b	half the track width
c	longitudinal distance from the rear axle to the center of mass of the vehicle
C_p	brake torque ratio
c_w	wind drag coefficient
C_α, C_λ	lateral resp. longitudinal tire stiffness
$C_{\alpha,F}$, $C_{\alpha,R}$	total lateral stiffness at the front and rear wheels respectively
D_T	sampling time of the brake slip controller
D_λ	dead zone for the drive slip difference between the driven wheels of one axle
$e_\Delta v$	actuating signal for the drive slip difference controller
F_1, …, F_4	lateral force from the wheel on the vehicle at wheel 1, …, 4
F_B	brake force from the road on the tire
F_b	braking force on the wheel at the brake pad
F_b^*	traction force increment due to braking another wheel
$F_{B,A}$	brake force from the road on the tire during the adaptation phase
F_{B1}, …, F_{B4}	brake force from the road on the tire for wheel number 1, …, 4
F_{BF}	stationary (filtered) brake force from the road on the tire
F_h	traction force from the road on the driven wheel at the high-friction road surface
F_l	traction force from the road on the driven wheel at the low-friction road surface
F_N	normal force from the road on the tire
F_R	resultant force from the road on the tire in the plane of the road

F_{R1}	resultant force from the road on the tire of wheel number 1 in the plane of the road
F_S	lateral force from the road on the tire
$F_{S,F}$	lateral force from the road on the tire at the front wheel of the bicycle model
$F_{S,R}$	lateral force from the road on the tire at the rear wheel of the bicycle model
F_{S1}, …, F_{S4}	side force from the road on the tire at wheel number 1, …, 4
F_x	longitudinal tire force
F_y	lateral tire force
f_ω	sensitivity change in the measured yaw velocity signal
I_{EVi}, I_{AVi}	currents for the inlet resp. outlet valves of the EHB system
I_{TR}	total transmission ratio of the drive and power trains
J_{Mot}	engine crankshaft moment of inertia
J_V	moment of inertia of the vehicle about the body fixed z-axis
J_{Whl}	moment of inertia of the wheel about its axis
K_p, K_d, K_i	gains for the PID brake slip controller
Lw_{corr}	calibrated steering wheel angle signal
Lw_{Mess}	measured steering wheel angle signal
Lw_{off}	offset value of the measured steering wheel angle signal
Lw_{ref}	steering wheel angle value computed from the reference value of the yaw velocity
m	lowest negative nominal torque on the driven wheels for MSR control
M_1	oversteering yaw moment
M_2	understeering yaw moment
M_{BR}	brake torque from the brake on the wheel
$M_{BR,A}$	brake torque from the brake on the wheel during the adaptation phase
M_{Ca}	torque of the cardan axle multiplied by the transmission ratio of the differential
M_{CaHalf}	drive torque on a driven wheel
M_{Dif}	difference in the brake torques between two driven wheels at one axle
M_{Dr}	output torque of the engine requested by the driver
M_{MOT}	engine output torque
M_{NoLock}	nominal brake torque difference for the control of the difference between the drive slips of the driven wheels of one axle
M_{NoMot}	nominal engine output torque for throttle control
M_{NoSPR}	nominal engine torque reduction by spark retard
M_R	torque from the road on the wheel
m_v	vehicle mass
M_{WhlNo}	nominal torque on the wheel
M_{WhlNo3}, M_{WhlNo4}	nominal torque on driven wheels 3 and 4, respectively
M_{YawNo}	nominal yaw moment
M_{Yw}, M_{yaw}	yaw moment
p_{Circ}	pressure in the brake circuit
p_{Whl}	pressure in the brake wheel cylinder
$p_{Whl,i}$	pressure in the brake wheel cylinder number i
p_{WhlNo}	nominal pressure in the brake wheel cylinder
p_{WhlNoi}	nominal pressure in brake wheel cylinder number i
R	wheel radius
R_T	radius of the turn
SUM	event-controlled integration
T	time length between adjacent sampling time points
t_1, t_2	start resp. end time of the increase in the pressure difference threshold between two brake wheel cylinders at one axle
t_{EVi}, t_{AVi}	stimulation times of the inlet resp. outlet valve of wheel number i
T_{iOFF}	time period during which the fuel injection is shut off of engine cylinder number i

u_1, u_2	forcing functions
$u_{1,k}$, $u_{2,k}$	forcing functions at sample time point k
U_{Mval}	stimulation time length of the inlet and outlet electromagnetic valves
v_{Ca}	average velocity of the driven wheels of one axle
v_{CH}	characteristic velocity
v_{Dif}	difference in the velocities between two driven wheels at one axle
v_i	calibrated wheel velocity signal
$v_{i,Mess}$	measured wheel velocity signal
v_{NoCa}	nominal average velocity of the driven wheels of one axle
v_{NoDif}	difference in the nominal wheel velocities of the driven wheels of one axle
v_{Ref}	reference velocity
v_V	velocity of the vehicle at the center of mass
v_{VWhl}	velocity of the wheel center
$v_{VWhl,F}$	velocity of the front wheel center of the bicycle model
$v_{VWhl,R}$	velocity of the rear wheel center of the bicycle model
v_{Whl}	velocity of the wheel
$v_{Whl,1}$, $v_{Whl,4}$	velocity of wheel number 1, …, 4
$v_{Whl,A}$	wheel velocity during the adaptation phase
v_{WhlFre}	free rolling wheel velocity
$v_{WhlFre3}$,$v_{WhlFre4}$	free rolling velocity of wheel number 3 resp. 4
v_{WhlNo3},v_{WhlNo4}	nominal velocity of wheel number 3 resp. 4
v_x	velocity of the vehicle in longitudinal direction at the center of mass
v_y	velocity of the vehicle in lateral direction at the center of mass
$v_{y,k}$, $v_{y,k+1}$	velocity of the vehicle center of mass in lateral direction at sample time points k and $k + 1$, respectively
x_1, x_2	parameters for the brake hydraulics simulation model
α	slip angle of the wheel
α_0	slip angle at the maximum of the μ-slip angle curve
α_F	slip angle of the front wheels
α_R	slip angle of the rear wheels
β	slip angle of the vehicle at the center of mass
$\beta\,(t)$	time history of the slip angle of the vehicle at the center of mass
β_0	initial value of the slip angle of the vehicle at the center of mass
β_M	slip angle of the extended bicycle model of the vehicle at the center of mass
ΔM_{NoLock}	reduction in the nominal brake torque difference for the control of the difference between the drive slips of the driven wheels of one axle determined by the vehicle dynamics controller
δ, δ_S, δ_{LR}	steering wheel angle
δ_A	Ackermann steering angle
Δa_{yb}	compensation of the lateral acceleration for banked turns
ΔD_λ	increment in the dead zone for the drive slip difference between the driven wheels of one axle determined by the vehicle dynamics controller
δ_M	steering wheel angle increment from active steering
ΔM_{Yw}	increment in the yaw moment
Δp_1	initial threshold in the pressure difference between two brake wheel cylinders at one axle
Δp_2	final threshold in the pressure difference between two brake wheel cylinders at one axle
δ_V	total steering wheel angle for active steering
δ_W	steering angle of the front wheels
$\Delta\beta$	difference between the nominal and the actual vehicle slip angle values
$\Delta\beta_{No}$	actuating signal of the slip angle of the vehicle
$\Delta\lambda$	increment in the wheel slip computed by the vehicle dynamics controller

$\Delta\lambda_1$	increment in the slip of wheel number 1
$\Delta\lambda_i$	increment in the slip at wheel number *i*
$\Delta\lambda_{MA}$	increment in the nominal average drive slip from the vehicle dynamics controller
$\Delta\lambda_T$	increment in the target slip for off-road conditions
$\Delta\omega$	difference between the calibrated and reference yaw velocity values
$\Delta\omega_{zul}$	failure threshold of the yaw velocity fault
λ	wheel slip
λ_0	slip value at the maximum of the μ-slip curve
λ_1	Slip threshold velocity
λ_A	slip during the adaptation phase
λ_i	slip of wheel number *i*
λ_{MA}	nominal average drive slip of the driven wheels of one axle
λ_{MAmin}	average drive slip of the driven wheels of one axle with maximum vehicle stability during the TCS function
λ_{MAT}	target average drive slip of the driven wheels of one axle
λ_{No}	nominal wheel slip
λ_{Noi}	nominal slip of wheel number *i*
λ_T	target slip
λ_{Ti}	target slip of wheel number *i*
λ_{WhlNo3}, λ_{WhlNo4}	nominal slip of wheel number 3 resp. 4
μ_A	coefficient of friction in longitudinal wheel direction during the adap tation phase between the tire and the road surface
μ_B	brake coefficient of friction between the tire and the road surface
μ_{BM}	coefficient of friction at the maximum of the μ-slip curve
μ_{BS}	coefficient of friction between the tire and the road of the locked wheel
μ_h	high value of the coefficient of friction of the road surface
μ_l	low value of the coefficient of friction of the road surface
μ_{Res}	coefficient of friction of the road surface computed from the longitudinal and lateral forces on the wheel
μ_S	lateral coefficient of friction between the tire and the road surface
ρ	mass density of air
ψ	yaw angle
ω_{ay}	yaw velocity value computed from the lateral acceleration value
ω_{corr}	calibrated yaw velocity value
ω_{Lw}	yaw velocity value computed from the steering wheel angle value
ω_{Mess}	uncalibrated yaw velocity value
ω_{off}	offset value of the measured yaw velocity signal
ω_R	rotational wheel velocity
ω_{R0}	free rolling rotational wheel velocity
ω_{ref}	reference value of the yaw velocity
ω_{streu}	influence of faults on the signals of the wheel velocities, lateral accel eration, and steering wheel angle on the fault in the reference value of the yaw velocity
ω_v	yaw velocity value computed from the wheel velocity values

ACRONYMS

ABS	antilock brake system
AC	alternating current
A/D	analog to digital converter
AMR	anisotropic magneto resistive
ASR	traction control system

ASV	suction valve
AV	outlet valve
AVHL	outlet valve rear left
AVHR	outlet valve rear right
AVVL	outlet valve front left
AVVR	outlet valve front right
AY	lateral acceleration sensor input
B	brake booster
BA	brake assistant
BC	brake wheel cylinder
BITE	build in test equipment
BLS	brake light switch
BS	brake switch
BSC	brake slip controller
CAN	controller area network
CANM	CAN bus ground
CANP	CAN bus signal
D1	damping chamber front
D2	damping chamber rear
DFAHL	wheel speed sensor output rear left
DFAHR	wheel speed sensor output rear right
DFAVL	wheel speed sensor output front left
DFAVR	wheel speed sensor output front right
DFHL	wheel speed sensor rear left
DFHR	wheel speed sensor rear right
DFVL	wheel speed sensor front left
DFVR	wheel speed sensor front right
DG	pressure sensor input
DIAGK	diagnostics input/output
DRSR	yaw rate sensor reference voltage
DRSS	yaw rate sensor signal
DRST	yaw rate sensor test signal
EBD	electronic brake force distribution
ECU	electronic control unit
EEPROM	electrically erasable programmable read only memory
EHB	electro hydraulic brake system
EM	electric motor for recirculation pump
EMS	electronic engine power control
ESP	electronic stability program
EV	inlet valve
EVHL	inlet valve rear left
EVHR	inlet valve rear right
eVLP	precharge pump new generation
EVVL	inlet valve front left
EVVR	inlet valve front right
FDR	electronic stability program
FDRAUS	ESP-ON/OFF-switch
FMEA	failure mode and effect analysis
FWD	front wheel drive
GMA	yaw moment gradient attenuation
HAS	hand brake switch

HBA	hydraulic brake assistant
HDC	hill descent control
HSV	high pressure suction valve
HU	hydraulic unit
M	electric motor
MC	brake master cylinder
MDFHL	wheel speed sensor rear left ground
MDFHR	wheel speed sensor rear right ground
MDFVL	wheel speed sensor front left ground
MDFVR	wheel speed sensor front right ground
MFL	multi function lamp
MR	pump motor relay
MSR	engine drag torque control
NSILA	SILA (inverted)
PATA	ESP-ON/OFF-signal input
PBA	pneumatic brake assistant
PCB	printed circuit board
PI	proportional-integral-type controller
PID	proportional-integral-differential-type controller
RAM	random access memory
RFP	recirculation pump
ROM	read only memory
ROM	roll over mitigation
RTA	wheel velocity fault compensation
RVR1	check valve front
RVR2	check valve rear
RWD	rear wheel drive
SL	select low
SN	brake fluid level signal input
Spk1	accumulator front
Spk2	accumulator rear
sRFP	self-priming recirculation pump
STZ	idle timer
SW	software
TCS	traction control system
TSC	traction slip controller
UDG	power supply of pressure sensor
UM	voltage from recirculation pump
USV	pressure limiting electromagnetic valve
UZ	power supply input
VDA	association of german vehicle manufacturers
VLPM	precharge pump ground
VLPP	precharge pump voltage
VR	valve relay
WSS	wheel speed sensor

31 Active and Semi-Active Suspension Control

Davor Hrovat

CONTENTS

31.1 Introduction 1180
31.2 Performance Index 1182
31.2.1 Ride Comfort 1182
31.2.1.1 RMS Acceleration-Based Ride Metric 1182
31.2.1.2 Inclusion of Jerk 1182
31.2.1.3 ISO-Based Ride Metric 1183
31.2.1.4 NASA-Based Ride Metric 1183
31.2.1.5 Appropriate Choice of Ride Metric 1184
31.2.2 Rattlespace Design Constraint 1184
31.2.3 Tire Deflection Handling Constraint 1184
31.2.4 Combined Performance Index 1185
31.3 Passive versus Semi-Active 1185
31.4 External Factors: Road Roughness Description 1186
31.5 Optimal Suspensions for Quarter-Car Models 1189
31.5.1 One-DOF Models 1189
31.5.1.1 Some Useful Facts: Certainty Equivalence Principle 1191
31.5.1.2 Optimal Structure and Key Characteristics: Skyhook Damping 1192
31.5.1.3 Jerk-Optimal Case: Fast Load Leveling 1192
31.5.2 Two-DOF Models 1193
31.5.2.1 Illustrative Example 1196
31.5.2.2 Comparison with Conventional Passive Suspension 1196
31.5.2.3 Comparison with 1 DOF 1197
31.5.2.4 Influence of Unsprung Mass 1200
31.5.2.5 Additional Characteristics: Invariant Points 1200
31.5.2.6 Dynamic Vibration Absorbers 1200
31.5.2.7 Optimal Quarter-Car Structure 1202
31.5.2.8 Additional Considerations 1204
31.6 Optimal Suspensions for Half-Car Models 1204

31.1 INTRODUCTION

Vehicle suspensions perform a number of important ride, handling, and overall vehicle agility and safety-related functions. They must support the vehicle sprung mass and secure the proper posture for both the vehicle and the driver. At the same time, they must provide effective isolation from the road roughness-induced disturbances.

It is desirable to maintain a proper vehicle posture in the presence of various inertial and external forces and moments caused by braking, turning, wind gust, and other events. For example, during braking and rapid accelerations in turns, a proper anti dive and anti squat/anti pitch suspension geometry and anti roll bar design is typically used to provide a good vehicle posture and control for most of current vehicles equipped with conventional, passive suspensions. This in turn can facilitate more comfortable and more "in-control" driver posture, leading to better handling and overall safer vehicle ride. This can be further enhanced with active suspensions discussed later.

There are many factors influencing ride comfort. These include road roughness, curvature, and undulation; seat configuration; vehicle interior, color, and spaciousness; noise, vibration, and harshness (NVH); or even odor and visual perception of surrounding scenery. The most relevant for ride studies is ground input disturbances caused by prevailing road roughness, which will also be the main focus of the present survey. Because of this, in a certain sense the ride design problem could be viewed as an equivalent filter design problem where one would attempt to eliminate the negative effects of vibrations caused by road roughness. At the same time it would be desirable to pass the low-frequency components of road inputs that are necessary to follow the terrain, while satisfying the given design and system-imposed constraints.

Conventional vehicle suspensions achieve the road-induced vibration isolation through passive means such as springs and dampers or shock absorbers. On the other hand, the active suspensions are characterized by a requirement that at least a portion of suspension force generation is provided through active power sources such as compressors and hydraulic pumps. Practical applications of active suspensions have been facilitated by maturing of microprocessors and associated electronics, which in turn also influenced actuator and sensor developments.

Some of the potential benefits of active suspensions were predicted decades ago by the first pioneer researchers. Indeed, the optimal control techniques that were "launched" with Sputnik and used in the aerospace industry since the 1950s and 1960s have also been applied to the study of active suspensions, starting from about the same period [1]. Early investigations [2–5] used the simplest possible, one-degree-of-freedom (1-DOF), quarter-car models. The resulting optimal suspension design problem fits naturally into the linear–quadratic–Gaussian (LQG) or, equivalently, the Wiener–Hopf setting [4]. It will be argued later that, despite their simplicity, these early contributions had a profound impact on the practical implementation some 15–20 years later, when the utilization of these theoretical results was made possible by the ever-increasing capacity of microcomputers in the automotive industry.

It should be pointed out that the design and synthesis of active suspensions can be approached from many avenues: modal analysis [6]; classical techniques, such as root locus and Bode and Nichols plots [7–9]; eigenvalue assignment [10]; Youla parameterization and linear fractional

transformation [11]; simulation using multibody dynamics computer models [12–15]; design of experiments [16]; bond graph modeling methodologies [17]; optimization—e.g., nonlinear programming and multicriteria optimization [18–20] and optimal control [2–5,21–24]; and, more recently, neural networks, fuzzy logic, evolution strategy, and learning automation [25–30]. While each of these approaches can bring some useful perspectives and insights, this chapter will focus on the applications of optimal control techniques and especially on the related work by the author and his colleagues at Ford. It will be demonstrated later that this constitutes a very natural approach revealing important global trends and insights such as the optimal system structure, performance potentials and trade-offs, and fundamental actuator and sensor requirements.

Specifically, it will be shown that with this approach even the simplest possible, 1-DOF linear vehicle models can produce very useful insights. For example, a straightforward application of the well-known linear–quadratic (LQ)-optimal control methodology that minimizes vehicle root-mean-square (rms) acceleration as a typical comfort measure will lead to the concept of "skyhook" damper introduced in Section 31.5.1. The latter has found many practical applications in the automotive industry, especially in the context of semi-active (SA) damping. Further introduction of an rms jerk term as an additional comfort measure leads to the concept of fast load leveling that offers additional practical advantages for active suspensions.

Introduction of one additional DOF representing the wheel-hop dynamics leads to the 2-DOF quarter-car model that was thoroughly investigated by a number of researchers resulting in a new insight, especially during the 1980s. For example, as it will be shown later in Section 31.5.2, the addition of the wheel-hop mode results in one more vehicle handling-related constraint and additional invariant points in related transfer functions (e.g. the transfer function between ground input displacement and sprung mass acceleration). In turn, this significantly reduces the potential benefits of active suspensions. Once the nature of this constraint is well understood, one way to recover a good portion of this lost performance is via structural changes using appropriate dynamic vibration absorbers.

Next, moving from 1D to 2D models, it will be possible to use the front wheels to preview the road disturbance that will eventually impact the rear wheels. This naturally leads to the concept of preview controls, which, as it will be shown in Section 31.6, can offer further significant benefits. Finally, moving to the full 3D models, it will be shown that under reasonable assumptions, many of these models can be further decomposed to simpler 1D and 2D counterparts.

It should be pointed out that for the earlier system-level, global study of potential benefits, it is quite appropriate to use simple, linear models, where the actuator dynamics are typically neglected. Again, the main objective is to establish what the best possible performance improvement is, that active suspension can supply under ideal conditions. Obviously, if these maximum possible potential improvements are not significant, then there is little incentive to further pursue a particular active setting all the way toward practical implementation. At the same time, these types of studies naturally lead to consideration of structural changes needed to achieve certain performance, that is, they facilitate outside-the-box thinking. Once the potential benefits have been established for a given active suspension configuration, it is then appropriate to start considering different actuation schemes that could deliver these projected benefits. At this stage, a careful consideration of actuator dynamics and design is necessary, since the actual process of delivering the projected benefits is by no means trivial in practice.

The earlier linear setting is quite appropriate for typical ride problems characterizing on-road vehicle operating at a given speed on typical roads with a prevailing roughness that excites relatively small motions of vehicle masses and suspension components. This situation changes for off-road operations and/or under occasional large bump or pothole excitations. In this case, nonlinear dynamic extensions need to be considered too. One such extension that naturally builds on the earlier linear studies will be given in Section 31.8.3.2. This will be followed by consideration of important practical issues and related topics.

The next three sections summarize the main ingredients needed to formulate the optimal suspension design problem to be considered in the rest of the chapter. The necessary infrastructure includes appropriate definitions for ride performance metric, active and passive suspensions, as well as the corresponding representation for road roughness, which acts as the main disturbance. The high-level active suspension design and investigation of performance potentials and trade-offs at the system level is addressed in the subsequent section, which also contains a brief description of related vehicle models.

31.2 PERFORMANCE INDEX

The ground vehicle suspension design is influenced by a number of often conflicting factors and attributes. Good vibration isolation is required to secure the occupants' ride comfort, whereas good posture and road holding is important for vehicle handling, which in general leads to enhanced safety and overall vehicle control and stability. Key design constraints are represented by maximum allowable relative displacements between the vehicle body and various unsprung mass components, including wheels, bump stops, and protruding parts of the steering mechanism. Additional constraints are imposed by the overall system robustness, reliability, weight, and cost requirements. Many of these factors will be discussed next and then combined in an overall performance index (PI) that will be used for most optimal control designs in later sections.

31.2.1 Ride Comfort

Due to its highly subjective nature, there are many different ways to quantify ride comfort (see Chapter 36), which is typically measured at the suitable sprung mass (or vehicle main mass) location such as the driver's seat or vehicle body center of mass (CM) or CG location. They vary in complexity from the simple rms and maximum vertical or heave acceleration metrics to frequency-weighted metrics and much more complex measures that combine contributions from different vehicle vibration modes. In the next few subsections, we will summarize the most relevant metrics and associated characteristics. Additional details and approaches can be found elsewhere in this handbook (see Chapter 36).

31.2.1.1 RMS Acceleration-Based Ride Metric

One of the simplest ride measures is based on calculations of rms values of vertical acceleration typically measured at the driver's or passengers' seat locations. In a related 1978 Ref. [31], the authors conducted a field study involving two different automobiles, 78 passengers, and 18 different road sections to conclude that "excellent correlation was found to exist between the subjective ride ratings and simple rms acceleration measurements at either the vehicle floorboard or the passenger/seat interface." The main result from this work is reproduced in Figure 31.1, which shows the correlation between the average or mean personal ratings and rms acceleration measured for combined vertical and lateral directions, where higher ratings imply better ride comfort. A similar correlation was obtained for vertical-only accelerations.

31.2.1.2 Inclusion of Jerk

Further refinements of the rms ride measure are possible through introduction of mean-square (ms) jerk, which is the derivative of the acceleration. Some authors [32–34] have advocated the inclusion of jerk as an additional comfort measure that amplifies the contribution from high-frequency disturbances, which are typically lumped under NVH. In Section 31.5.1.3, we will make use of this additional term to arrive at a very desirable basic optimal suspension structure.

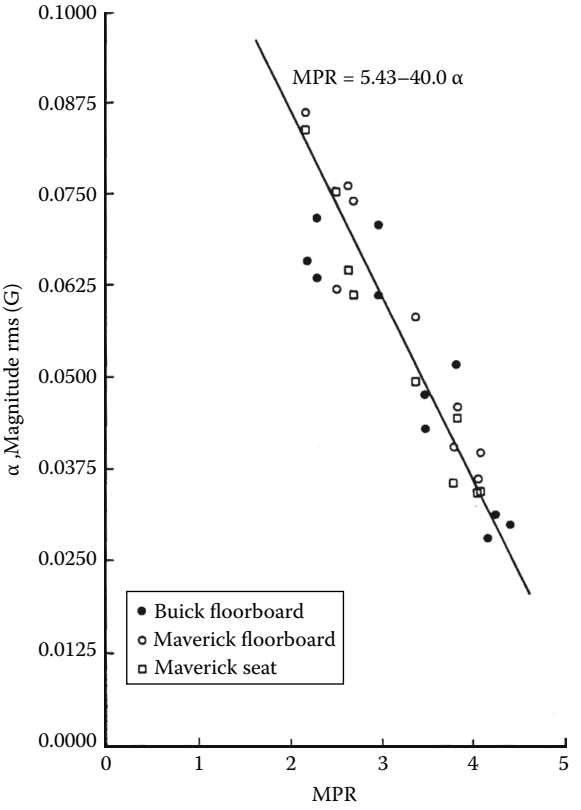

FIGURE 31.1 Experimental rms accelerations versus mean personal ratings and corresponding least squares curve fit [31].

31.2.1.3 ISO-Based Ride Metric

The rms (or ms) quantifiers do not reflect the frequency dependence of human sensitivity to vibrations. To account for this aspect of ride comfort, the International Organization for Standardization (ISO) has developed a standard ISO 2631, which also takes into account the length of time of human exposure to the vibrations [35]. This is represented through the plot of ride comfort boundaries as a function of third octave band center frequency. According to the earlier standard, the region of greatest human sensitivity to vertical vibration lies between 4 and 8 Hz, which roughly includes various resonances of human internal organs (see Section 36.2.2). Although developed primarily under the assumption of sinusoidal or periodic excitation, the standard also applies to the case of broadband vibrations, which are represented via rms values within prespecified one-third octave bands [36,37]. Similar considerations apply for vibration in the lateral direction with respect to the human body. Although not explicitly used here, the ISO-based metric could be easily incorporated in the proposed optimal control framework via an appropriate state space augmentation.

31.2.1.4 NASA-Based Ride Metric

The earlier measures are primarily based on decoupled tests, typically performed in only one direction at a time. A more comprehensive measure, which takes into account interdependency of various modes of vibrations, was developed by NASA, primarily for aerospace applications [38]. A similar measure was adapted and extended to automotive applications as summarized in [39], where the interdependence between heave, pitch, roll, and many other factors have been considered. This metric can be used for optimal suspension designs where vehicle models have many DOFs (in addition to the standard heave mode), as well as for more detailed vehicle evaluations of different suspension concepts and strategies.

31.2.1.5 Appropriate Choice of Ride Metric

Which of the earlier ride metric alternatives one should evoke will depend on the context of their usage. If the primary use is in the context of simple models, then the simple rms-based metric will suffice. On the other hand, if models with higher DOF are used, then the more complex measures such as the earlier NASA-based metric may be appropriate.

To date, there is a lack of comprehensive comparison among different ride comfort measures. An earlier comparison [31] between the simple ms measures and the more involved ISO standard 2631 was inconclusive; indeed, the correlations with ride ratings even resulted in a slight advantage for the simple rms metric. In view of this and in the interest of the simplicity of approach that is often needed to reveal the main trends, it is natural to start with the ms acceleration as a measure of ride comfort. This also matches the relatively simple models of relevant vehicle dynamics and the road input disturbances that will be discussed later. Once sufficient information has been obtained about the potential benefits at this simplified or idealized system level, it is appropriate to consider other, more detailed metrics—such as 2.1.3 and 2.1.4—along with corresponding increase in model and optimization process complexity and level of detail.

31.2.2 Rattlespace Design Constraint

Based on the previous section, if all that we wanted was to minimize the ms vertical acceleration of a sprung mass, then the solution would be conceptually trivial: just produce a constant suspension force equal to the sprung weight, and the acceleration in question will always be zero (note that while conceptually trivial, it is by no means trivial to actually implement even this simple strategy, as will be discussed elsewhere in this handbook—see Chapter 22). The problem with such a "solution" is that the affected vehicle would then need unrealistically large suspension strokes to negotiate large road irregularities and hills and valleys, that is, in effect the vehicle would have to transform in to a flying object! The fact that only a limited suspension stroke is available must be reflected by incorporating at least one additional constraint into the ride optimization problem.

This additional, design-related constraint can be represented as either a hard or soft constraint in the sense that is used in optimization theory. That is, the "soft" constraint is typically introduced via an integral penalty term thus allowing for occasional violation of the constraint. The "hard" constraint, on the other hand, is strictly enforced, typically via an explicit (in)equality. The hard constraint approach is more accurate, although even in this case there is no guarantee that comprehensive, accurate, optimal solutions can be found. Simply, it is practically impossible to predict all road irregularities that will be encountered throughout the life of a large production volume of vehicles. Because of this, and because of analytical convenience, it is more common to introduce a soft constraint in the form of ms suspension stroke or so-called rattlespace. The resulting PI to be optimized, then, typically consists of two terms:

- The ms acceleration, which is a measure of ride comfort
- The weighted ms rattlespace, which reflects design and packaging constraints

This simple, two-term PI will be used in the context of the simplest possible, 1-DOF quarter-car vehicle models, to be discussed in Section 31.5.1. A similar two-term PI can be and was also used for the 2-DOF, quarter-car models. However, the three-term PI incorporating vehicle handling constraint (to be introduced next) is more suitable in this case, since for many on-road vehicle operations, the handling constraint is more limiting (or "active") than its rattlespace counterpart.

31.2.3 Tire Deflection Handling Constraint

For slightly more complex, 2-DOF quarter-car models, it is possible to impose one additional, handling-related constraint. This pertains to tire wheel-hop dynamics, typically manifested as a relatively lightly damped mode at 10–12 Hz. This can result in considerable time variations of the

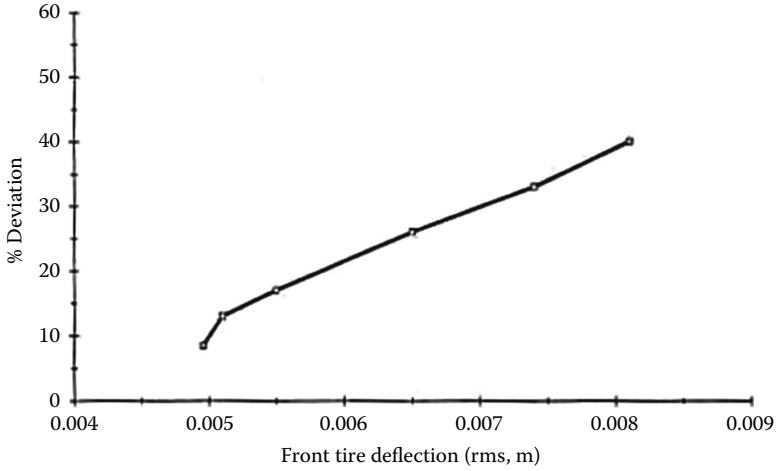

FIGURE 31.2 Percent change in path deviation versus change in tire deflection for the case of traversing a rough road with crosswind gust.

tire normal force around (quasi) static equilibrium, which in turn can lead to a loss of contact with the ground and reduced handling ability. The detrimental effect of tire force variation on vehicle handling comes in good part from the convex relationship between tire cornering forces (lateral forces) and normal forces, for a given tire slip angle (see Chapter 17). To investigate these effects, the following study was conducted [40]: A vehicle traveling at 100 km/h with a constant straight-ahead steering was subjected to a crosswind gust of 36 km/h on a rough road. Figure 31.2 shows the resulting lateral deviation in vehicle trajectory after 4 s that is plotted as a function of tire rms deflection around equilibrium. It can be seen that there is an almost linear relationship between the vehicle path deviation—an explicit handling metric—and the tire rms deflection, an implicit metric. Thus the latter can be used next to include the handling in a three-term PI representing vehicle ride, handling, and design/packaging requirements.

31.2.4 Combined Performance Index

In view of the preceding text, we can now formulate the final three-term PI as follows: (1) For ride comfort use the ms acceleration term; (2) for rattlespace constraint use the weighted ms rattlespace, which reflects design and packaging limitations; (3) and for handling limitations, use the weighted ms tire deflection. This three-term PI will be used in the context of 2-DOF quarter-car vehicle models, to be discussed in Section 31.5.2. As a final word of caution, it should be pointed out that some authors have attempted to use only a two-term PI consisting of the earlier ms ride and handling metrics. This leads to pathological situations resulting in infinite rattlespace requirements.

31.3 PASSIVE VERSUS SEMI-ACTIVE

Different suspensions satisfy the earlier mentioned ride, handling, and design requirements to differing degrees. Although significant improvements can result from a designer's ingenuity, on the average, suspension performance is mainly influenced by the type or class of suspension used. Here one distinguishes, in ascending order of improved performance, between passive, SA, and fully active suspensions. Passive suspensions are those found on most conventional vehicles. Roughly, they are characterized by the absence of external power sources, whereas the active suspensions require additional sources, such as compressors and pumps, to achieve superior ride and handling performance. The SA (or semi passive) suspensions [41] then fall in between passive and active, since they essentially act as time-varying dampers and thus offer potentially significant performance improvements while requiring relatively small or negligible external power supplements.

More precise definitions of active and passive suspensions were given in [42,43] following similar definitions of passivity and passive operators as used, for example, in electrical networks and mathematics. According to the latter, an operator P is passive if there exists some constant k such that the inner product

$$< Px \mid x >_T > k \tag{31.1}$$

where the inequality must hold for all final times T and all elements $x(\cdot)$ of an extended inner product space *He,* composed of all functions that do not have a finite escape time (i.e., do not "explode" in a finite time). If one associates x with the actuator velocity and Px with the corresponding force, then inequality (31.1) reflects a power dissipation requirement for passive actuators.

For the case of linear time-invariant dynamic systems, one can assume, without loss of generality, that the constant k equals 0. Moreover, in this case the passivity inequality (31.1) is equivalent to requiring that the associated transfer function matrix $P(s)$ be a Rational Positive Real (RPR) matrix. The RPR matrix $P(s)$ must satisfy the following three requirements [42,44]:

1. All elements of $P(\cdot)$ have poles in the left-hand side plane, that is, where $\mathrm{Re}[s] <= 0$.
2. The Hermitian matrix $P(j\omega) + P^*(j\omega)$ is positive semi-definite for all $\omega \in \Re$, with jω not a pole of any element of $P(\cdot)$.
3. If $j\omega_o$ is a pole of any element of $P(\cdot)$, it is at most a simple pole. In that case the residue matrix,

$$P_o = \lim_{s \to j\omega_o} (s - j\omega_o) P(s) \text{ in case } \omega_o \text{ is finite and}$$

$$P_\infty = \lim_{\omega \to \infty} P(j\omega)/j\omega \text{ in case } \omega_o \text{ is infinite, is positive semi definite Hermitian}$$

where P^* stands for the complex-conjugate transpose and the elements of P belong to the class of distributions or generalized functions. Note that the immittance matrix of a linear time-invariant, lumped, finite, and passive n-port is necessarily RPR. In this case, an alternative description of passivity can be obtained via the state-space approach, which leads to a Positive Real Lemma or, as is often called, "Kalman–Yakubovich Lemma." The resulting set of matrix equations is then equivalent to (1–3) in the earlier mentioned requirements and is sometimes preferred in the synthesis of passive networks.

The earlier definition was used to check the passivity of the relationship between optimal suspension forces and velocities for simple 1-DOF [43] and 2-DOF [45] vehicle models. Similar approach can be used to explicitly constraint the suspension synthesis to the subclass of passive structures or to constraint the amount of active energy spent by active suspensions with regenerative capabilities during given road-induced maneuvers. This offers some interesting and challenging future avenues of research.

31.4 EXTERNAL FACTORS: ROAD ROUGHNESS DESCRIPTION

There are two main sets of disturbances that affect vehicle ride and handling: one is caused by road roughness and the other by different forces and moments that originate in various inertial and aerodynamic loadings, as caused by braking, turning, and wind gusts, for example. The most relevant for ride studies are ground input disturbances caused by road roughness.

The road input disturbances can be described in many possible ways. Chiefly, they can be classified as shock or vibration. Shocks are discrete events of relatively short duration and high intensity, as, for example, caused by a pronounced bump or pothole on an otherwise smooth road. Vibrations, on the other hand, are characterized by prolonged and consistent excitations that are felt on "rough" roads. A well-designed suspension must perform adequately in a wide range of shock and vibration environments.

In the context of vibrations, the road roughness is typically specified as a random process of a given displacement power spectral density (p.s.d.). Typical measured spectral densities of various terrains from [46] are reproduced in Figure 31.3. An often used approximation of these road displacement p.s.d. curves is given in the form

$$S(\Omega) = A\Omega^n \tag{31.2}$$

where

Ω is the spatial frequency, typically in units of "radians per length"

A and n are appropriate constants

For the most commonly used case of $n = -2$, the corresponding line with the slope of -2 in log–log scale is shown in Figure 31.3 as well. With $n = -2$, the displacement spectra of Equation 31.2 imply a white-noise ground input *velocity,* which—when augmented by commonly evoked Gaussian assumption—conveniently matches the well-known, standard LQG assumptions for process noise. A procedure to construct and preprocess such a road sequence on a digital computer is given in [47].

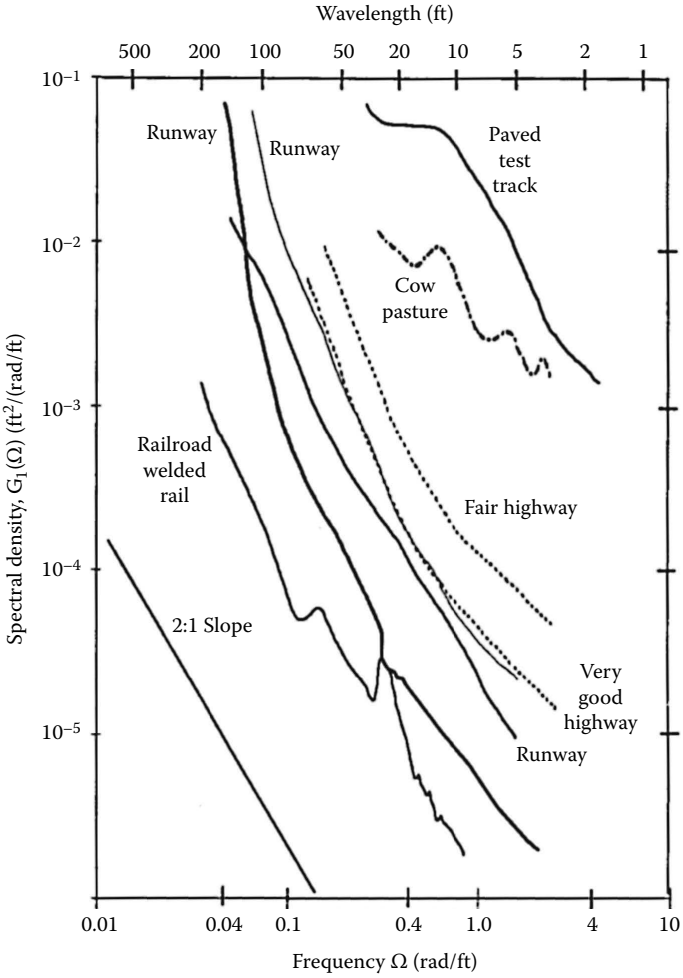

FIGURE 31.3 Power spectral density of various roads and terrains.

The simple expression (31.2) approximates various roads with different degrees of fidelity [39]. An example, the so-called Rochester Road section of low-speed track at the Ford Dearborn Proving Ground, is shown in Figure 31.4a, reproduced from [39]. Here, it can be seen that the standard white-noise velocity assumption, represented by the thick line, fits the data very well ($n = -2.02 \sim -2$), except possibly at the very low frequencies.

On the other hand, Figure 31.4b shows a different road section from [39]. This is the so-called section between broken road and Rochester Road that displays significant deviations, especially at low frequencies, from the fitted model of Equation 31.2, where $n = -1.99$. A better correlation with measured spectra in this case was obtained with the help of more complex, exponential fit [24]. Other variants of road description include various forms of processing of "raw" white-noise velocity spectra. This processing ranges from a simple, first-order filtering to third-order filtering used to capture possible strong oscillatory components in the spectra [39].

The extensions of these single-track models toward spatial road surfaces are described in [39] and references therein. The authors propose to consider a road model illustrated by Figure 31.5, where left and right track inputs are derived based on the road roughness at suitable points in between the

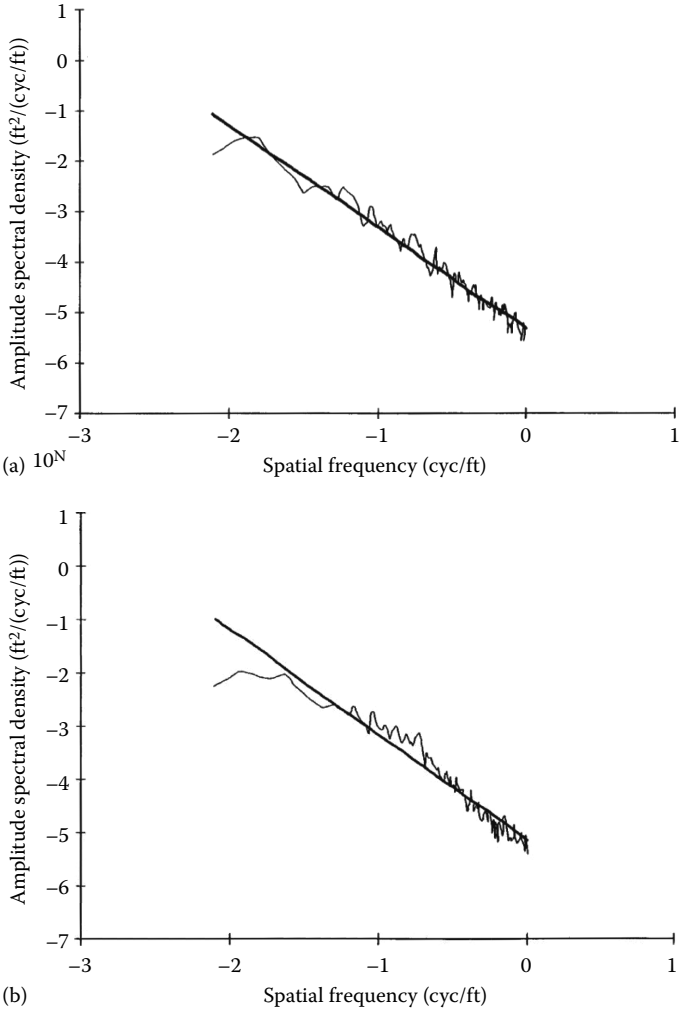

FIGURE 31.4 (a) Comparison of model given by Equation 31.2 with $n = -2.02$ and measured road roughness for "Rochester Road section." (b) Comparison of model given by Equation 31.2 with $n = -1.99$ and measured road roughness for "section between broken road and Rochester Road."

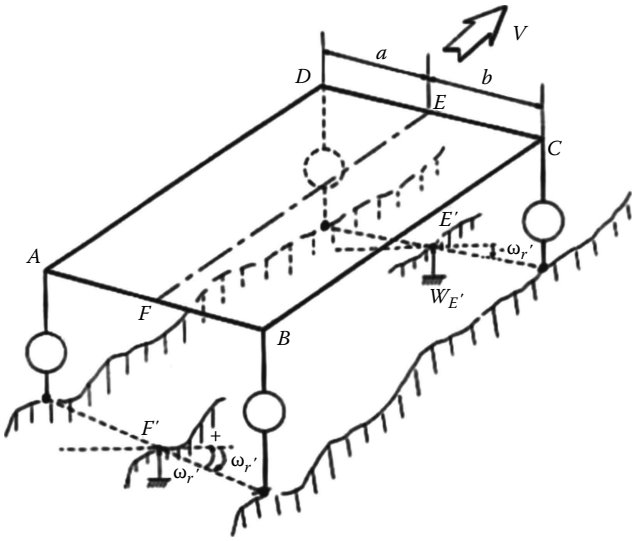

FIGURE 31.5 Road configuration for 3D vehicle model studies.

tracks, usually along the vehicle centerline represented by E' and F' in Figure 31.5. Also given in Figure 31.5 are the relevant expressions for wheel–road contact velocities as a function of vertical (W_E and W_F) and rotational (ω_E and ω_F) velocities at E and F. It is furthermore assumed that W_E and ω_E are (low-pass filtered) white-noise velocity processes and that W_F and ω_F are their delayed versions. The resulting, cross-correlated road input representation is suitable for 3D optimal control design and analysis and, as will be shown later, leads naturally to a particular form of decoupling and simplification of the corresponding full-car problem.

31.5 OPTIMAL SUSPENSIONS FOR QUARTER-CAR MODELS

This section reviews some of the many findings based on simple, quarter-car or "unicycle," 1D vehicle models. These have been the subject of many investigations during the past few decades. The most appropriate approach here is to start with the simplest possible, 1-DOF models, which, while neglecting the unsprung masses, still yield some very useful results, forming the bounds for limiting optimal performance of more complex, higher DOF models.

31.5.1 One-DOF Models

In view of Section 31.2, the optimal suspension design problem for the 1-DOF model of Figure 31.6 can be expressed as follows:

$$\text{Minimize}\left\{PI_1 = E\left(x_1^2 + ru^2\right)\right\} \tag{31.3}$$

subject to the state equations

$$\dot{x}_1 = x_2 - w \tag{31.4}$$

$$\dot{x}_2 = u \tag{31.5}$$

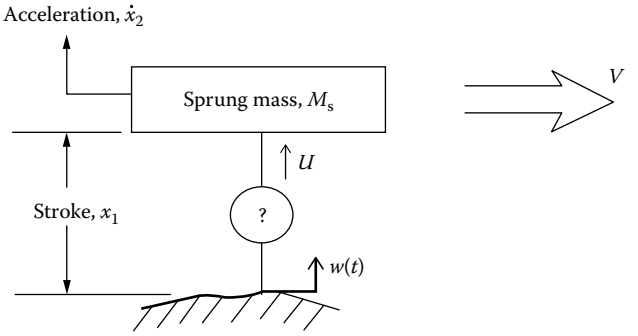

FIGURE 31.6 A 1-DOF model.

where the earlier expectation represents steady-state ms values. The states x_1 and x_2 from Figure 31.6 represent rattlespace (suspension deflection with respect to equilibrium) and vehicle vertical velocity with respect to an "inertial" ground—in practice, a low-frequency "smooth" component of road inputs. We assume that both states are measurable and available for control; other cases are discussed in 31.8.2. The rattlespace constraint on x_1 is introduced in the PI (31.3) to reflect a limited suspension stroke capability. As discussed in Section 31.4, the ground input velocity w due to road roughness effects is typically modeled as a white-noise, Gaussian process specified via

$$E[w(t)] = 0 \tag{31.6}$$

$$E[w(t_1)\,w(t_2)] = 2\pi W\delta(t_1 - t_2) \tag{31.7}$$

where $\delta(\cdot)$ stands for the impulse or Dirac delta function and W is the two-sided road velocity power spectral density (see [47]),

$$W = AV$$

where

A is the road roughness factor
V is the vehicle forward velocity

The optimal suspension design problem then consists of minimizing the PI (31.3), which penalizes excessive suspension stroke and sprung mass acceleration u, subject to the state Equations 31.4 and 31.5. The acceleration is a convenient control variable in the present setting, and it amounts to normalizing the original control force U from Figure 31.6 with respect to the sprung mass m. The weighting parameter r in Equation 31.3 acts as a "tuning knob," so that larger r results in smaller accelerations, that is, improved ride comfort, and increased suspension stroke requirements.

For the present second-order system, the LQ-optimal solution can be calculated analytically ([24]) from the associated Riccati equation to yield the optimal control acceleration:

$$u_{LQ} = -r^{-1/2}x_1 - \sqrt{2}r^{-1/4}x_2 \tag{31.8}$$

The corresponding optimal trade-off curve is shown as a solid line in Figure 31.7. Both the rms acceleration and rattlespace have been conveniently normalized with respect to road/speed characteristics, so that $\tilde{x}_1 = x_{1,rms}/\sqrt{2\pi AV}$. Note in particular that traveling on rough roads, and/or at high speeds, implies *smaller* normalized rattlespace and larger normalized accelerations. The solid

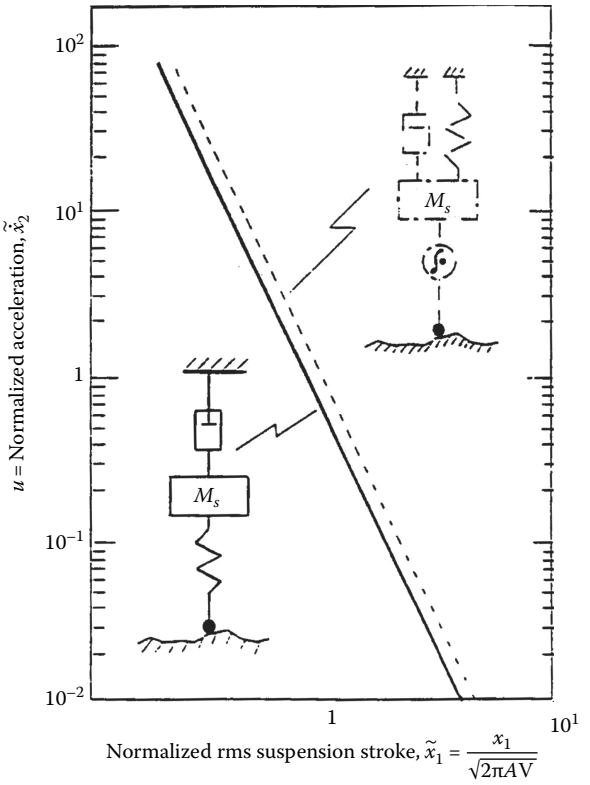

FIGURE 31.7 Optimal performance trade-offs for 1-DOF model with PI_1 (solid line) and PI_2 (dashed line).

straight line in Figure 31.7 is parameterized by the weighting parameter r and has a slope of −3 on the log–log scale, which implies that each 10% increase in allowed rattlespace results in ~30% decrease in rms acceleration. Larger values of r result in softer suspensions, with smaller accelerations and larger rattlespace requirements.

31.5.1.1 Some Useful Facts: Certainty Equivalence Principle

Note that the assumptions in Section 31.4 imply that all response variables are Gaussian. This makes it possible to calculate the probability that the suspension stroke and other variables of interest will remain within certain bounds around the equilibrium. For example, evoking the standard results for Gaussian or normal distributions, it can be concluded that the variation of these variables around their equilibria will exceed three times their corresponding rms values during only 0.3% of ride time. It should also be remarked that, because of the central limit theorem [24], similar conclusions apply for non-Gaussian road sequences. This was also observed by a number of researchers (e.g., [39,48]) based on measured road data.

While the earlier problem could be also addressed via optimal filtering [24], one of the advantages of the LQ approach is that it also applies to linear, time-varying systems, and there are many well-developed numerical techniques for its solution in the most general multi-input–multi-output (MIMO) setting. Moreover, one can evoke the certainty equivalence principle (CEP) [24], which states that the optimal controller for the original stochastic problem coincides with the solution of an equivalent deterministic problem, obtained by replacing all random variables by their expected values. In the present case, it can be shown [49] that the deterministic problem amounts to replacing the white-noise ground velocity by an equivalent step in ground displacement, that is, by an impulse in ground velocity. Alternately, the ground step can be replaced by an equivalent nonzero state (rattlespace in the case of 1-DOF model) initial condition, which occurs when dealing with optimal shock isolation during,

for example, an airplane landing. The main point is that with the "one shot" LQ approach, one can solve two problems: one is the stochastic, vibration isolation problem with the PI given as in Equation 31.3, and the other is the corresponding deterministic or shock isolation problem [49].

31.5.1.2 Optimal Structure and Key Characteristics: Skyhook Damping

The optimal suspension structure can be deduced directly from the LQ problem formulation knowing that the LQ-optimal control is a linear function of states. It consists of a linear spring placed between the vehicle body and the road and a so-called skyhook damper [2,41] placed between the vehicle sprung mass and an inertial, smooth ground. This is illustrated by a schematic shown on the left side of Figure 31.7. Note that the optimal structure can be predetermined even before pursuing any actual (numerical) solution of the problem. The same can be said about equivalent nonlinear problems, where the skyhook damper would now be characterized by a nonlinear force description. Since an absolutely smooth inertial ground is in practice not available from a moving vehicle, the actual suspension will have to be placed between the vehicle and the road, which in effect acts as a "moving ground." It can then be shown, using the previously discussed definition of passive systems, that the LQ-optimal suspension for the stochastic case is necessarily an active device, for any value of the weighting parameter r [43].

In addition, it follows from Equation 31.8 that the optimal closed-loop system is mildly oscillatory with a favorable damping ratio of ~0.7. To put this in proper perspective, it should be pointed out that the corresponding ratios of typical conventional passive suspensions are around 0.2–0.3. As will be shown in Section 31.5.2.2, this range of values is close to optimal for the passive case: smaller values would amplify the body resonance, whereas larger values would increase disturbance force transmissibility from road through the damper. This is where the skyhook dampers fundamentally differ from their passive counterparts: by emulating a contact with the hypothetical, smooth, inertial ground, the optimal algorithm facilitates much larger damping rates leading to a well-damped body mode with no negative transmissibility-related side effects. The net effect is a dramatic improvement in ride and handling for road/steering excitation frequencies around the body modes. For example, the dynamic sag due to body roll in turns can be two to three times smaller with the optimal active suspension of the same stiffness as its passive counterpart [24]. Thus, even though the handling per se was not taken into account in the earlier optimization, the resulting optimal structure nevertheless offers significant handling benefits. While the present observations are based on the simple 1-DOF model, most of the facts also apply to the full 3D setting. For example, the optimal damping ratio of 0.7 applies for the key rigid body modes (heave, pitch, and roll) characterizing the dominant, sprung mass mode of oscillations (see Section 31.7).

31.5.1.3 Jerk-Optimal Case: Fast Load Leveling

Since there is evidence that the jerk, as well as acceleration, is important for ride comfort (see Section 31.2.1), it is appropriate to consider extending the earlier 1-DOF model by including the sprung mass jerk, $\dot{u}$ (the derivative of acceleration u) as an additional comfort measure in the PI of Equation 31.2. Following [49,50], we define

$$PI_2 = E\left(x_1^2 + r_1 u^2 + r_2 \dot{u}^2\right) \tag{31.9}$$

The problem can next be transformed into a more standard, LQR form by defining the sprung mass acceleration u as an additional third state and the sprung mass jerk, $\dot{u}$, as the new control input. There are now two tuning parameters, r_1 and r_2, which weigh ms acceleration and jerk, respectively.

As shown in the earlier references, it is still possible to obtain the analytical solution for the resulting third-order LQR problem. The optimal structure in this case is shown with dashed lines in Figure 31.7. In addition to a skyhook damper, this structure includes a skyhook spring and a load leveling device that operates on the integral of suspension deflection. This configuration in fact has some desirable characteristics.

The load leveling secures zero steady offset in the case of external load disturbances caused by vehicle weight changes and inertial forces in turns or during braking, for example. Being fully integrated in the LQR synthesis process, this load leveling action can be relatively fast, with settling times of the order of 1–3 s [49,50], as opposed to more conventional slow-acting load levelers requiring dozens of seconds to settle. While the fast load leveling facilitates load disturbance rejection and good tracking of low-frequency components of the road, the skyhook damper and spring minimize transmissibility of road-induced disturbances.

The corresponding optimal ride performance is represented by the dashed line in Figure 31.7, which applies for the extreme case when $r_1 = 0$. This results in minimal possible jerk for a given rattlespace. Even in this extreme case, there is a relatively modest, about 10%, increase in rattlespace requirements for the same level of rms accelerations [50]. At the same time, while the optimal damping ratio of 0.7 is now reduced to 0.5, it is still substantially above the typical passive values of 0.2–0.3.

On the other hand, at the other extreme where $r_2 = 0$, for the "standard" 1-DOF case, the rms jerk is theoretically infinite or—taking into account the wheel-hop and other neglected dynamics—very large. This implies that substantial reduction in jerk will be obtained with the new jerk-optimal structure. In practice, this means that the high-frequency, NVH isolation of the proposed jerk-optimal suspension will be much superior to the one achievable with the standard structure.

The basis for this improved low-pass filtering is in the fact that the conventional spring in the standard configuration has been replaced by an integrator and a skyhook spring, both reducing the transmission at high frequencies. The improved high-frequency filtering in this case also leads to less stringent desired force bandwidth requirements. This is a favorable consideration for narrow bandwidth or "slow-acting" active suspension actuators, which offer a promising approach to practical production implementation of active suspensions.

In summary, the application of optimal control technique to a single, 1-DOF, quarter-car or "unicycle" model has resulted in fundamental insights about the optimal suspension structure and performance potentials. This includes the concept of a skyhook damper, which has found applications in most of the SA and active suspensions in production or under research and development. Although the simple model neglects the wheel-hop mode, the earlier principal isolation structure is still near optimal and, as needed, can be augmented by a damper in parallel with the active actuator. Typically, this configuration is often used in practice to control the 2-DOF case. It can be shown [24] that this strategy is usually not far from optimal. Inclusion of jerk as an additional ride metric leads to the concept of fast load leveling and associated integral control, which can also be extended to more complex model settings. To this end one could also explicitly include the integral term(s) by appropriately augmenting the state-space vehicle model formulation [51].

31.5.2 Two-DOF Models

A typical 2-DOF model structure including wheel-hop dynamics is shown in Figure 31.8a, along with its 1-DOF active (Figure 31.8b) and 2-DOF passive (Figure 31.8c) counterparts. The related model equations are given in Chapter 22 on related advanced suspension hardware. This allows for inclusion of a handling measure in the PI in the form

$$PI_3 = E\left(r_1 x_1^2 + r_2 x_3^2 + u^2\right) \tag{31.10}$$

where x_1 and x_3 are the states representing tire and suspension deflection as per Figure 31.8. As elaborated in Section 31.2.3, the tire deflection is an indication of road-holding ability, in the sense that smaller tire deflections lead to better vehicle handling characteristics. Since this term in Equation 31.10 represents an additional "soft" constraint, it is to be expected that this will lead to deterioration in performance as measured by rms acceleration and rattlespace.

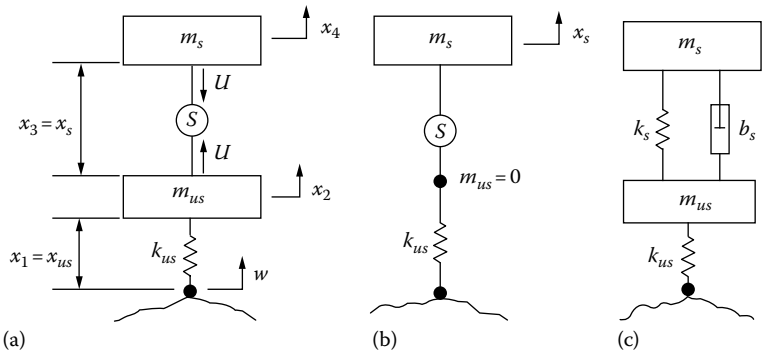

FIGURE 31.8 (a) A 2-DOF vehicle model with active suspension *S*, (b) corresponding limiting case when $m_{us} = 0$, (c) 2-DOF model with conventional passive suspension.

The earlier four-state LQ problem was solved numerically [24], and the results of the corresponding global study for various r_1 and r_2 combinations are shown in Figures 31.9a and b [57] in the form of "carpet" plots of normalized rms acceleration versus suspension and tire deflections, respectively. Here, the ratio of sprung-to-unsprung mass was $\rho = 10$, and the unsprung natural frequency was $\omega_{us} = 10 \times 2\pi$ rad/s. The PI weights r_1 and r_2 serve as "tuning" knobs controlling the optimal trade-off between acceleration, suspension stroke (design constraint), and tire deflection (handling constraint).

From Figure 31.9b it follows that reducing r_1 while keeping r_2 constant results in increased tire deflection and decreased sprung mass acceleration. On the other hand, Figure 31.9a shows that reduction of r_2 while keeping r_1 constant leads to increased suspension deflection and decreased accelerations. In the extreme case of $r_2 = 0$, the problem becomes a degenerate one where extremely large suspension deflections are possible since the suspension force is not a function of suspension deflection and thus cannot give static support for the vehicle weight. Indeed, Figure 31.9 shows that there is no incentive to increase r_1/r_2 above ~1000, since then the acceleration and tire deflection remain practically constant, while the suspension deflection increases significantly. Similar problems do not occur if only $r_1 = 0$, and this case can be used for preliminary suspension design. As a rule of thumb, $r_1/r_2 \sim 10$ leads to reasonable results. In addition, the area of relatively large normalized accelerations (above say 50) in Figure 31.9a and b corresponds to very large disturbance levels typical for off-road operations, whereas the area of small normalized acclerations is characteristic of very smooth roads and/or low vehicle speeds.

When these considerations are taken into account, it becomes evident that most optimal designs of practical interest for automotive applications will fall within the shaded area in Figure 31.9a and b, with normalized accelerations between 10 and 50 $s^{-3/2}$. This is consistent with corresponding passive results discussed in Section 31.5.2.2 later. Also, based on most vehicle/road data for on-road operations, it is to be expected that the tire deflection constraint will trigger first, that is, become active before the rattlespace does. This means that in most cases, the graph from Figure 31.9b should be checked first, and when the tire handling constraint there is satisfied, there is a good chance that the rattlespace constraint will be satisfied too. Finally, note that no control design, linear or nonlinear, can fall below the $r_1 = 10^{-2} \sim 0$ line in Figure 31.9a and $r_2 = 10^{-3} \sim 0$ line in Figure 31.9b. Typical usage of the global performance plots is best shown through an illustrative example.

Similar solutions can also be obtained using linear matrix inequality (LMI)-based approaches [52–54], although one should be aware of occasional incorrect claims that this type of methods outperform the earlier carpet plots in their native H_2 metric. A desirable feature of the LMI-type controllers is that they can incorporate the (slowly) time-varying parameters, such as changes in vehicle sprung mass. Related methods here include the linear parameter-varying (LPV) techniques [53,55]

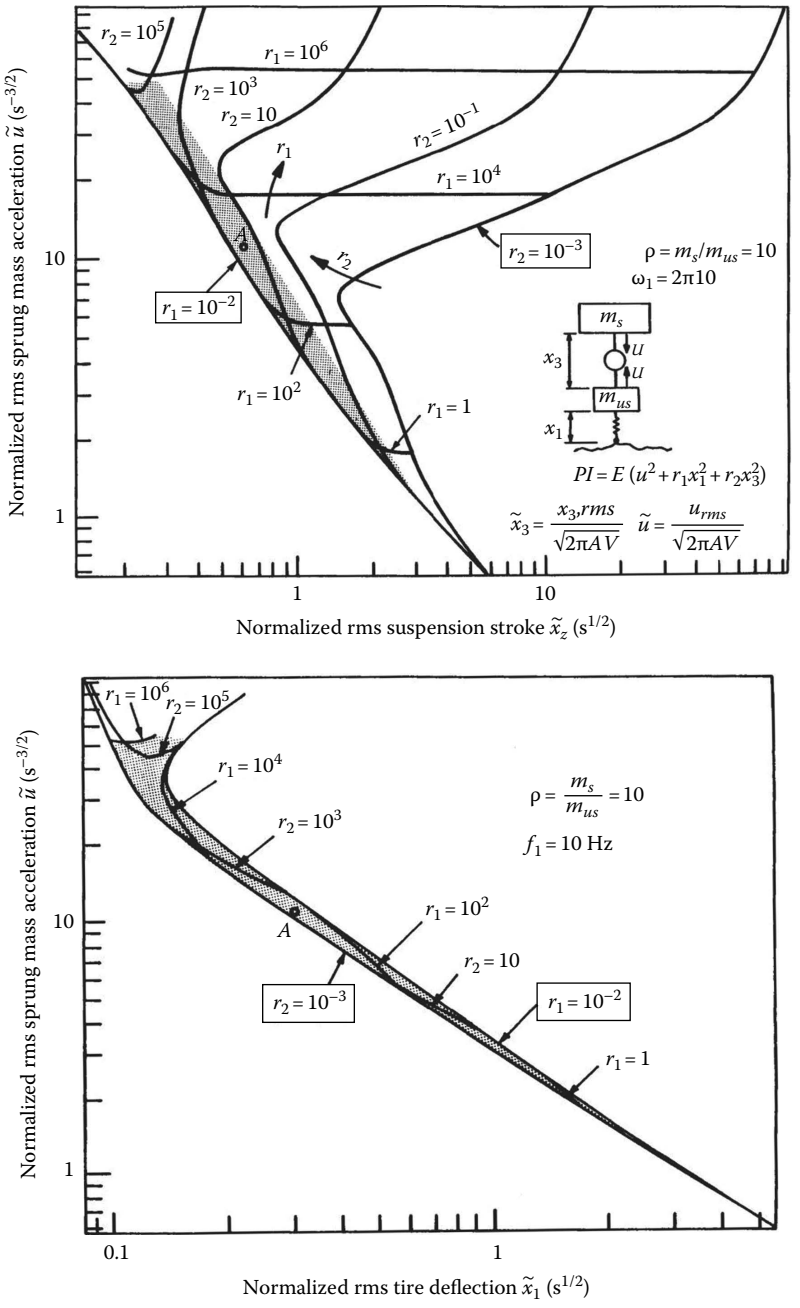

FIGURE 31.9 (a) Optimal normalized rms acceleration versus normalized rms suspension stroke for 2-DOF model. (b) Optimal normalized rms acceleration versus normalized rms tire deflection for 2-DOF model.

that explicitly include possible slowly varying system parameters, such as road roughness and vehicle speed variations with results similar to [56]. In general, there are many publications that essentially repeat original results obtained in the 1980s and early 1990s [24] but with different techniques and approaches, which could be attributed to the "waterbed" effect where any improvement in one area (e.g., ride) is reflected through corresponding loss of performance in other, complementary areas (e.g., handling and/or design/rattlespace requirements).

31.5.2.1 Illustrative Example

Assume that for a particular vehicle $\rho = 10$ and $\omega_{us} = 2\pi \times 10$ rad/s. The road is described by a road roughness coefficient $A = 1.6 \times 10^{-5}$ ft (4.9×10^{-6} m) that corresponds to a medium-quality road. The vehicle is traversing this road at a speed of $V = 80$ ft/s (88.5 km/h). The tire deflection from equilibrium should be below 1 inch (2.54 cm) 99.7% of the time so that x_{1rms}<1/3 in. = 0.847 cm and $\tilde{x}_1 = x_{1,rms}/\sqrt{2\pi AV} < 0.3\ s^{1/2}$. From Figure 31.9b the minimum possible normalized rms acceleration is $\tilde{u} = 10\ s^{-3/2} = 10\ s^{-3/2}$. Accepting $\tilde{u} = 10.9\ s^{-3/2}$ results in 3% g rms acceleration and tuning parameters $r_1 = 1100$ and $r_2 = 100$ shown as design A. Using these values for r_1 and r_2 in Figure 31.9a reveals a normalized rms secondary suspension deflection of $x_3 = 0.605\ s^{1/2}$ that insures that the suspension deflection will remain within ± 2 in. (5.08 cm) of the static value 99.7% of the time. With $r_1 = 1000$ and $r_2 = 100$ the optimal control gains are $k_1 = -6.084$, $k_2 = 0.548$, $k_3 = -10.0$, and $k_4 = -4.438$, and the closed-loop eigenvalues are $e_{1,2} = -2.20 \pm j2.26$ and $e_{3,4} = -2.75 \pm j62.9$. The first set of oscillatory eigenvalues corresponds to the vehicle heave mode with a natural frequency of 0.5 Hz and damping ratio of ≈0.7. The second set corresponds to the wheel-hop mode with a resonant frequency of 10 Hz and relatively small damping ratio of 4.4%. Whether or not this small amount of damping is of consequence will depend on the particular hardware implementation, which may include a combination of active and passive means to improve closed-loop robustness. Also, in practice, an excessively soft suspension setting may require load leveling to keep the suspension static or steady-state deflection in the neighborhood of zero or nominal value.

31.5.2.2 Comparison with Conventional Passive Suspension

At this stage, it is instructive to compare the earlier active suspension results with corresponding passive case. For this purpose consider Figure 31.10 from Hrovat [24], which displays normalized rms acceleration versus tire deflection for active and passive suspensions. For simplicity, the optimal active suspension performance is shown via the limiting curves $r_1 \sim 0$ and $r_2 \sim 0$ only, which are representative of the main trends. Here, the design points with lower accelerations and higher tire deflections are characterized by softer, lower-frequency body modes and less damped wheel-hop modes.

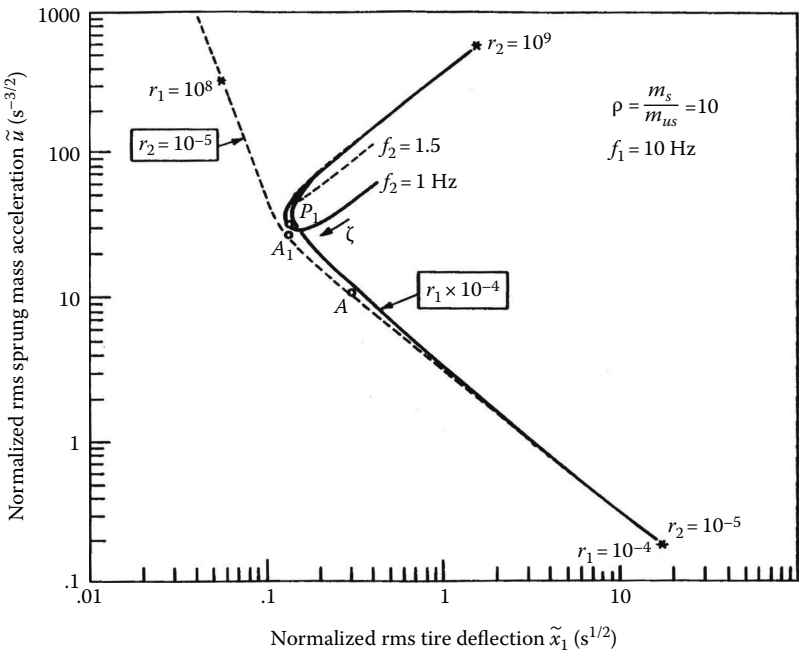

FIGURE 31.10 Comparison between conventional passive suspension and optimal active suspension.

The passive performance trade-offs correspond to vehicles characterized by a structure shown in Figure 31.8c, with heave mode resonant frequencies f_2 between 1 and 1.5 Hz, and damping ratios, ζ, between 0.02 and 1. A typical passive suspension setting is shown as point P_1, where $f_2 = 1$ Hz and $\zeta = 0.3$. As can be seen from Figure 31.10, this amount of damping is near optimal in terms of ride and handling compromise for the passive case. These values are within the range typically found in most of today's vehicles, which have evolved through many iterations primarily based on intuition and decades of experience.

The performance of an optimal active suspension with the *same* amount of wheel hop is shown in Figure 31.10 as point A_1. Comparing P_1 and A_1, it can be seen that in this case the active suspension results in only 11% lower rms acceleration levels. However, it can also be seen that for some other road/speed operating conditions (to the right of A_1), there is a potential for substantial ride improvement with active suspensions compared with their passive counterparts. Indeed, as shown in Figure 31.10, for passive suspensions almost any deviation in operating conditions from P_1 will result in degradation of performance. On the other hand, for active suspensions, either handling or ride can be improved by choosing the tuning parameters r_1 and r_2 such that the resulting operation settles either to the left or to the right of A_1, respectively. For example, by relaxing the wheel-hop requirements, the acceleration for design case A treated in the earlier illustrative example is 67% smaller than the one at P_1—see Figure 31.10.

Different attributes of the performance at three operating points of interest (A, A_1, and P_1) can also be seen from associated Bode plots shown in Figures 31.11a through c. From Figure 31.11c, it can be seen that the main difference between the active suspension A_1 and corresponding passive counterpart P_1 occurs at the sprung mass mode around 1 Hz, where the active suspension brings much more damping through the aforementioned "skyhook" effect. The active suspension A results in further significant reduction of the acceleration levels (except at the wheel-hop invariant point of 10 Hz—see 31.5.2.5 in the following text), but at the same time it deteriorates handling and rattlespace requirements due to a large, poorly damped resonant peak around the wheel-hop frequency around 10 Hz. It can also be shown [24] that, unlike their passive counterparts, the LQ-optimal suspensions can result in a nonzero DC gain between the rattlespace and road velocity input. This may not be too detrimental in practice, since it is possible to use high-pass filters to eliminate the very low-frequency components of the ground input signals resulting from hills and extended road grades.

Based on the earlier results and observations, it can be concluded that the full advantage of active suspensions stems from possible *adaptive* tuning (or gain scheduling) of controller parameters, depending on the driving condition [24,56]. For example, if the steering wheel position or lateral acceleration sensors indicate operation on a straight section of a road, where handling is less critical, then it may be possible to relax the wheel-hop constraint. The exact amount of wheel hop that could be tolerated under different driving conditions should be predetermined through appropriate vehicle tests.

31.5.2.3 Comparison with 1 DOF

Let us now place the earlier 2-DOF, quarter-car results in proper perspective with respect to their 1-DOF counterparts. For this purpose we will first introduce a new, modified 1-DOF model, which will facilitate comparisons with 2-DOF systems. The new 1-DOF model, shown in Figure 31.8b, corresponds to a special, limiting 2-DOF case, where the unsprung mass is reduced to zero (note that, as shown in [57], the optimal performance improves as the unsprung mass decreases (see 31.5.2.4 in the following text)). The optimal suspension control problem for this special case has been analytically solved with the help of appropriately defined states [57]. The resulting optimal trade-off curves are shown in Figure 31.12, for the limiting cases when $r_1 = 10^{-4}$ and $r_2 = 10^{-5}$ in the PI of Equation 31.9.

Note from Figure 31.12a that for normalized rms suspension strokes, $\tilde{x}_3$, above roughly 0.3, this new 1-DOF performance is similar to the traditional one. However, for $\tilde{x}_3$ below 0.3 the new 1-DOF

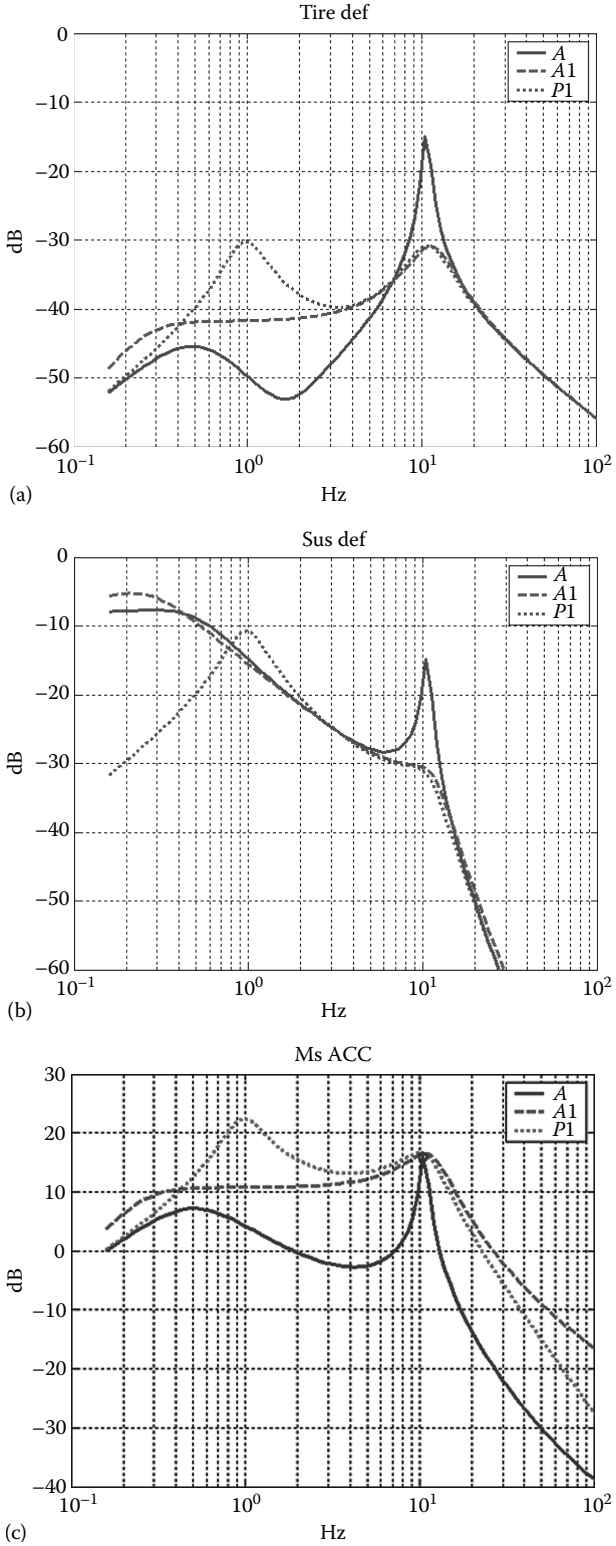

FIGURE 31.11 (a) Bode plots of tire deflection, (b) rattlespace, (c) sprung mass acceleration versus ground velocity for associated operating points A, A_1, and P of Figure 31.10.

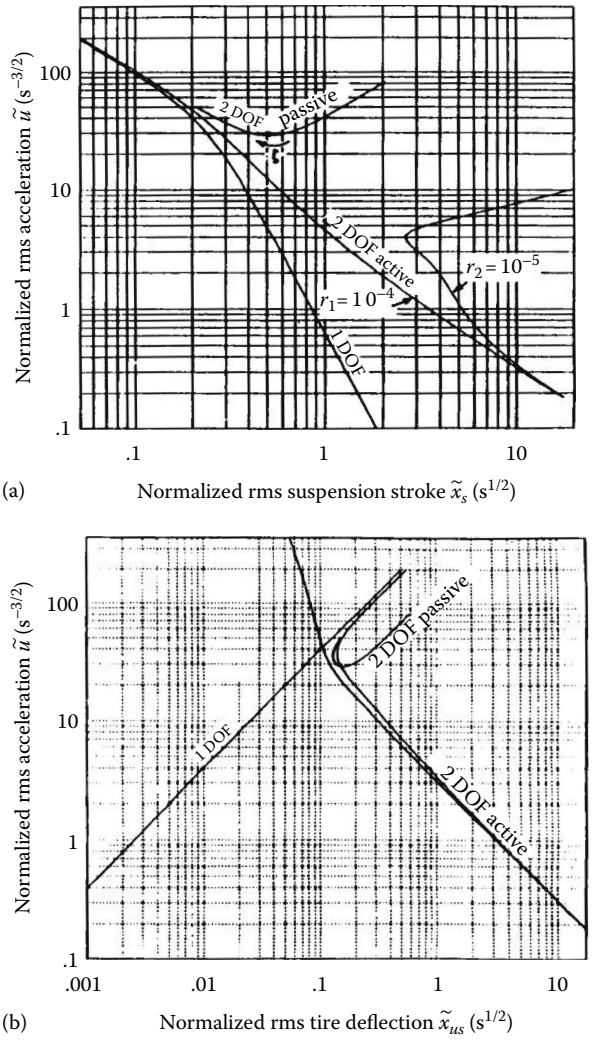

FIGURE 31.12 Comparison, in particular, (a) suspension stroke and (b) tire deflection, between conventional passive suspension, optimal 2-DOF suspension, and optimal limiting case where *mus* = 0.

curve is deflected toward smaller acceleration values. This is due to the gradual stiffening of the (secondary) suspension, so that more and more of the overall deflection is now being taken by the (primary) tire spring. Of course, the overall deflection is still larger than in the traditional optimal 1-DOF case.

Also displayed in Figure 31.12 are the corresponding limiting performance curves for typical 2-DOF passive and optimal active suspensions. It can be seen that while the optimal active suspensions for 2-DOF systems can still significantly outperform passive ones, they fall short of the optimal 1-DOF performance. For example, at a normalized rms suspension stroke of 0.6 $s^{1/2}$, the 1-DOF case results in a normalized rms acceleration of 3 $s^{-3/2}$, whereas the 2-DOF results in 10.9 $s^{-3/2}$, a 263% increase. The main reason for this deterioration stems from the conflicting requirements imposed on the active actuator of Figure 31.8a: it should simultaneously provide small sprung mass acceleration (for comfortable ride) and a considerable amount of unsprung mass damping needed to reduce the wheel hop (for good handling). It is easier to satisfy these conflicting requirements for smaller unsprung mass, which gives an additional incentive for reducing the unsprung weight through the use of, for example, aluminum wheels and lightweight, composite materials. The best

performance within the present single-actuator 2-DOF structure of Figure 31.8a is then obtained when $m_{us} = 0$, as shown in Figures 31.12a and b.

31.5.2.4 Influence of Unsprung Mass

The preceding discussions already indicated that in the context of the 2-DOF quarter-car problem, it is advantageous to reduce the unsprung mass or—more specifically—to reduce the ratio of the unsprung-to-sprung masses. A more detailed study to that effect has been documented in [57]. One of the main conclusions of this study is that for the case when the total vehicle mass is kept constant, every 10% reduction in unsprung mass contributes to 6% reduction in rms sprung mass acceleration, for the same level of wheel hop. For active suspension vehicles, this gives an added incentive for reduction of unsprung weight through the usage of lightweight materials and appropriate design changes.

31.5.2.5 Additional Characteristics: Invariant Points

Using the earlier 2-DOF case, it was possible to point out the limitations imposed by introduction of the additional DOF and associated handling (i.e., tire deflection) constraint. Additional insight can be derived from the fact that for certain transmission paths, there are frequencies where the associated transfer functions are constant or invariant. One such invariant point exists at the wheel-hop resonance of

$$\omega_1 = \sqrt{\frac{k_{us}}{m_{us}}} \tag{31.11}$$

in the case of a transfer function between sprung mass acceleration and road input velocity [7]. This can be seen from Figure 31.11c, which illustrates that in the immediate vicinity of the wheel-hop resonant frequency, all acceleration transfer function levels are about the same, independent of the suspension type (active or passive) and parameters. One additional invariant point [58] exists for the transfer function between rattlespace and road input velocity at the intermediate frequency

$$\omega_2 = \sqrt{\frac{k_{us}}{(m_s + m_{us})}} \tag{31.12}$$

which corresponds to the case when the two masses, m_s and m_{us}, are riding locked together on the tire with stiffness k_{us}. This invariant point can be seen on Bode plots in Figure 31.11b. It should be pointed out that introduction of tire damping eliminates the earlier invariants [24], although, since in practice the amount of tire damping is typically small, the knowledge about the earlier invariant points is useful and insightful information.

31.5.2.6 Dynamic Vibration Absorbers

The previous two sections show some fundamental limitations of active suspensions when applied to a standard 2-DOF, quarter-car structure. Chiefly, one of the main constraints of such a structure is that one and the same suspension force must address two conflicting requirements: on one hand, it must be small enough to provide for a comfortable ride, while at the same time it should also be large enough to provide adequate wheel-hop damping for improved vehicle handling. This limits maximum achievable performance for the given structure, so that any further improvements are only possible through *fundamental structural* or design changes. One possible solution here can be found in the form of a dynamic vibration absorber or tuned mass damper [24,59], attached to the unsprung mass as shown in Figure 31.13.

Dynamic absorbers (DAs) are often used to contain pronounced and lightly damped oscillations. Typical applications of DA range from electric hair clippers [60] to tuned mass dampers

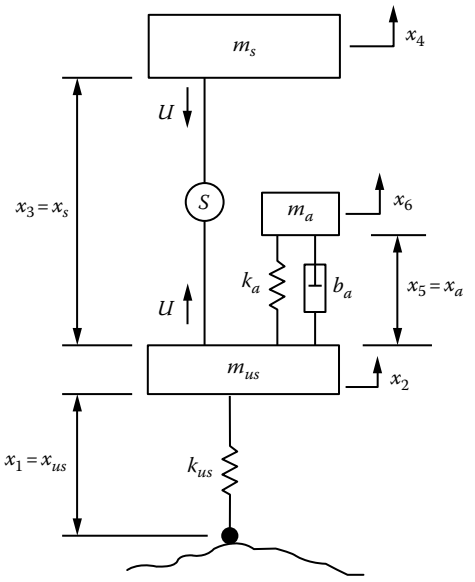

FIGURE 31.13 Two-DOF vehicle model with DA.

for structural control of tall buildings [61]. In automotive applications, DAs have often been used, sometimes as afterthoughts, to reduce unforeseen and undesirable vibrations. However, apparently there has been only one production application of DA with the aim of improving ride comfort. This is the case of the well-known French subcompact Citroen 2CV, first introduced in 1949. The 2CV was legendary for having superior ride for a car of its size.

A global study of the potential benefits of DA in the context of active suspensions was reported in [59]. Both passive and active DA concepts have been considered in this study. The resulting plots of limiting performance trade-offs with an added passive DA are shown in Figure 31.14, where the traces marked "2 DOF + DA" correspond to optimal 2-DOF controller gains with an appended DA with the mass equal to 10% of the unsprung mass, natural frequency $\omega_a = \omega_{us} = 2\pi \times 10$ r/s, and a damping ratio $\zeta = 0.2$. Comparing the 2 DOF + DA case with the optimal 2-DOF and 1-DOF trade-offs in Figure 31.14a, it can be seen that the DA can contribute to substantial improvements in performance, especially for $\tilde{x}_s > 0.2$ s$^{1/2}$.

As an example, consider again operations at point *A* from Figures 31.9 and 31.10, which had an unsprung mass damping ratio of only 4.4%. As indicated earlier in 31.5.2.1, this small amount of damping can be inadequate, and some way of increasing it would be highly desirable. Here we propose to use an appropriately tuned DA. The addition of such DA results in a performance at A′ in Figure 31.14, where acceleration, rattlespace, and tire deflection have all been reduced, while at the same time the wheel-hop damping ratio increased to 16%. Further substantial reduction in acceleration results for point *A″*, which has the same suspension stroke requirements and lower tire deflection than *A*.

This clearly illustrates that the addition of DA has significant potential for improved ride and handling performance of active suspensions. Their main drawback is the added weight and packaging requirements, which represent a real design and development challenge that must be resolved prior to their possible widespread usage. One step in this direction might be the recently advertised Bose active suspension [62]. It seems to incorporate the DA (or so-called damper mass [62]) integrated in the wheel assembly in an apparently efficient way [63]. Additional vehicle objective and subjective tests and evaluations are needed to fully ascertain the effectiveness of this particular suspension. Finally, further performance benefits are possible with the help of various forms of active DAs and unsprung mass actuators as investigated in [59].

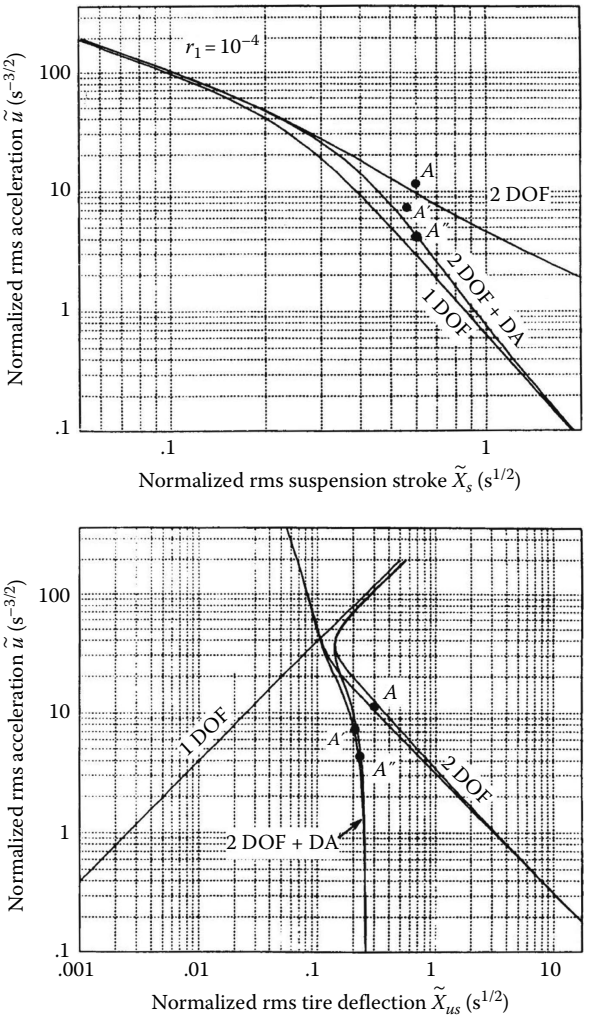

FIGURE 31.14 Comparison between optimal 2-DOF suspension ($\rho = 10$, $\omega_{us} = 2\pi \cdot 10$ s^{-1}), a suboptimal 2 DOF + DA suspension ($\rho_a = \rho$, $\omega_a = \omega_{us}$, $\varsigma_a = 0.2$), and optimal limiting case when $m_{us} = 0$, $r_1 = 10^{-4}$, and $r_2 = 10^{-5}$.

31.5.2.7 Optimal Quarter-Car Structure

In the preceding section, we have seen that changing the quarter-car structure via (tuned) DA can substantially improve the performance of active suspension vehicles. At this point, it is appropriate to ask what is the best possible quarter-car structure that would result in an absolute minimum for PI_3 of Equation 31.9. For this purpose, we introduce the suspension configuration from Hrovat [59], shown in Figure 31.15a. Unlike the conventional 2-DOF structure from Figure 31.8a, the proposed configuration is not constrained by the requirement of equal sprung and unsprung forces, U_s and U_{us}. This implies that such a two-control configuration is very flexible and powerful—sort of a "dream team" of quarter-car suspension structures. For example, the unsprung control force U_{us} can be used to alter both the effective unsprung mass and tire stiffness and damping without negatively affecting the sprung mass acceleration that is controlled via the sprung mass force U_s. While this is conceptually simple and elegant, practical implementation of this intriguing "dream team" concept is by no means trivial. For start, it is practically not possible to find an inertial ground from a moving vehicle. (Similar effect can be realized via reaction jets, but this, as of

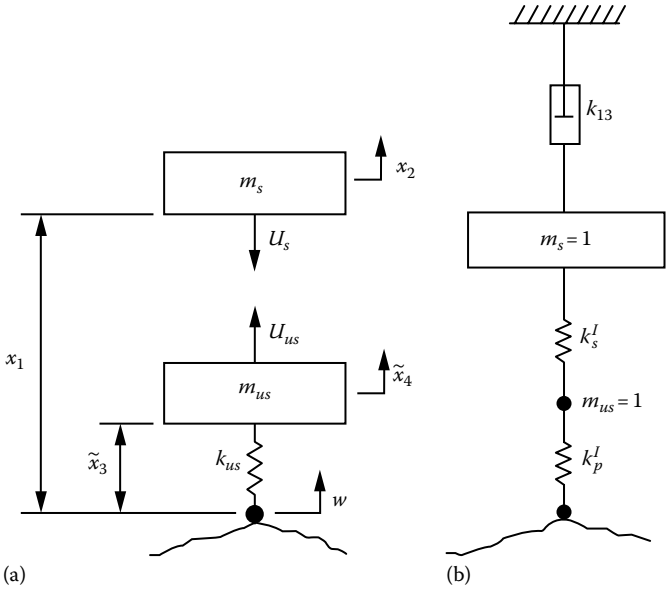

FIGURE 31.15 (a) Two-DOF vehicle model with active suspension capable of producing independent forces U_s and U_{us}. (b) Singular optimal incremental suspensions structure.

now, is not practical.) An approximation can be obtained via active dynamic vibration absorbers discussed in the previous section. Another practical consideration relates to the required unsprung force production bandwidth, which can be quite large and challenging.

As shown by Hrovat [59], the earlier inquiry into the best possible 2-DOF quarter-car performance leads to a singular optimal control problem characterized by a lack of penalty on the unsprung actuator force. This is known as a "partially cheap optimal control problem." In this context the cheap, unsprung control primarily serves as a structure optimizer: it can effectively reduce or eliminate the unsprung inertia and add or substitute additional inertia, compliance, and damping as needed to minimize PI_3.

The solution to the earlier optimization problem was obtained in [59] by transforming the aforementioned cheap control problem into an equivalent singular perturbation setting, as discussed in [24] and references therein. The resulting optimal structure is shown in Figure 31.15b. With the hindsight from Hrovat [59], this simple structure can be explained as follows: The sprung mass control U_s is used to contain the slow body-related mode in accordance with an appropriately modified, "standard" 1-DOF optimal control law with the damping ratio of 0.7. The cheap and fast control U_{us} accomplishes two tasks. In effect, it completely eliminates the unsprung mass and adjusts the primary and secondary incremental stiffnesses so that the unsprung motion can instantaneously adapt to the best possible configuration for a given set of performance weights, r_1 and r_2.

The presence of two independent control forces, U_s and U_{us}, causes the new 1-DOF optimal structure of Figure 31.15b to substantially differ from the previously discussed 1-DOF configuration of Figure 31.8b, since the latter cannot alter the primary suspension stiffness. As such the new 1-DOF optimal structure serves as a benchmark of the best possible PI_3 performance that can be obtained with 2-DOF, quarter-car models. For an illustrative example introduced in [59], this limiting case resulted in normalized rms sprung mass acceleration of only 1.17 $s^{-3/2}$, with normalized rms tire and suspension deflections of 0.23 and 0.6 $s^{1/2}$, respectively (to fully appreciate this performance, consider Figure 31.14). This example illustrates that further substantial ride and handling improvements are possible with high-performance, active, and SA unsprung mass actuators. While in some cases this superior performance may not be practical due to packaging, weight, and cost constraints, it serves as an absolute reference against which any practical implementation can be compared.

31.5.2.8 Additional Considerations

The 2-DOF models used thus far have been developed under the assumption of zero tire or wheel-hop mode damping. This is a standard assumption, supported by the fact that the unsprung damping is usually very small. However, it is of interest to mention that the results of a global numerical study [57] demonstrated that even a tire damping ratio of only 2% can significantly improve the shape of the limiting optimal curves, which become much closer to the optimal 1-DOF curves in Figure 31.14. It was also shown there that even in this case, the DA still offers tangible benefits, which are, of course, somewhat less dramatic than before. Since in practice the tire damping can vary from a few percent at low speeds to near zero at high speeds, we should have the earlier results in mind when evaluating different passive and active suspension concepts.

It should be noted that, due to a natural separation between the slow body mode and the fast wheel-hop mode, it is possible to use *singular perturbation* theory to partition the problem into an equivalent slow 1-DOF system and a fast wheel-hop-associated subsystem [64,65]. This also creates a link with and further justification for 1-DOF studies.

In typical practical implementations, there will already be some sort of passive suspension in place to minimize active energy requirements and secure "limp-home" capability in case of active actuator failure. The active suspension then acts in tandem with its passive counterpart and as such may also enhance the overall system robustness since the added structural damping results in better damped zeros for the associated force-tracking task (see Section 22.3.3). Reference [66] considers simultaneous optimization of both active force and passive suspension parameters. A PI similar to Equation 31.9 was used with an additional term proportional to the square of active actuator force as a rough approximation of the corresponding energy requirements (e.g., in the case of electrohydraulic actuators without regeneration capabilities). The corresponding simulation results show potential for additional benefits especially in terms of energy consumption as reflected in this expended PI metric.

Finally, one could parallel the 1-DOF case and introduce *jerk* as an additional ride term in PI_3, Equation 31.9. For an overview of related applications for 2-DOF, quarter-car systems, consult [24] and references therein. In the case of 1-DOF systems, the jerk-optimal LQR solution lead to in practice very attractive structure composed of a skyhook damper and spring and *an integrator* operating on rattlespace error (deviation from equilibrium) in the manner of a fast load leveler. A similar integrator could be a priori imposed to the corresponding 2-DOF case leading to an LQ-optimal solution. As in the more conventional 2-DOF case, the jerk-augmented performance can be further improved via tuned dynamic vibration absorbers and other structural means—see [24] and references therein.

In summary, the optimal active suspensions for 2-DOF quarter-car models without tire damping result in significant loss of performance with respect to their 1-DOF counterparts. Nevertheless, such an optimal 2-DOF system can still substantially outperform the conventional passive suspensions due to the *inherent adaptive* capabilities of active suspensions, which can adapt to different road roughness levels and vehicle operating conditions. Further improvements are possible through a reduction of the unsprung mass and through structural changes aimed at independently controlling the wheel-hop mode in a manner that would not negatively impact the quality of the isolation of the sprung mass vibration. Ultimate quarter-car suspension would include an active unsprung mass actuator that would result in the most favorable structure and superior performance.

31.6 OPTIMAL SUSPENSIONS FOR HALF-CAR MODELS

There are a number of publications (e.g., [67,68]) investigating optimal and suboptimal ride characteristics of half-car, 2D vehicle models, which include both sprung mass heave and pitch modes as shown in Figure 31.16. Most of the past work was based on numerical analysis, which was used to evaluate optimal active suspension performance at a (usually) single operational point.

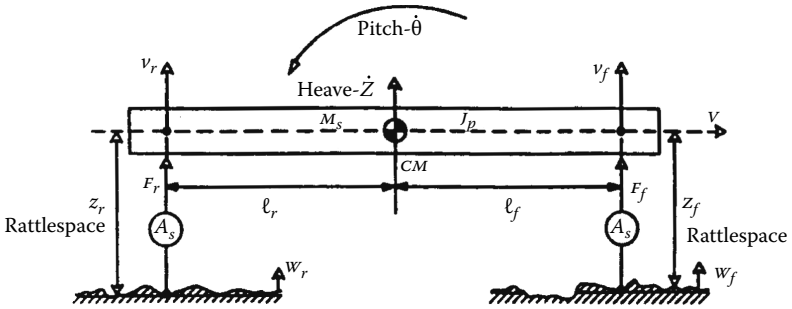

FIGURE 31.16 Half-car 2-DOF model.

This was extended in Krtolica and Hrovat [69], which developed a global analytical solution for the optimal suspension control problem minimizing

$$PI_4 = E\left(r_1\ddot{z}^2 + r_2\ddot{\theta}^2 + r_3 z_f{}^2 + r_4 z_r{}^2\right) \tag{31.13}$$

subject to 2-DOF, fourth-order system state equations describing vehicle heave and pitch dynamics as per Figure 31.16. In Equation 31.13 the first two terms penalize excessive heave and pitch accelerations, $\ddot{z}$ and $\ddot{\theta}$, respectively, while the last two terms penalize excessive front and rear suspension deflections, z_f and z_r.

As a by-product of the analytical solution, it was possible to establish a number of properties characterizing the resulting LQ-optimal suspension. For example, as in the simple 1-DOF quarter-car case discussed in Section 31.5.1, the optimal half-car suspension is also characterized by a favorable damping ratio of 0.7. The preceding reference by Krtolica and Hrovat [69] also contains necessary and sufficient conditions for decoupling of the original 2-DOF, half-car problem into two 1-DOF, quarter-car subproblems. These conditions are

$$M_s \cdot l_f \cdot l_r = J_p \tag{31.14}$$

$$r_1 \cdot l_f \cdot l_r = r_2 \tag{31.15}$$

where

M_s and J_p are vehicle mass and the pitch moment of inertia about the CM
l_f and l_r are the front and rear distances from the CM (cf. Figure 31.16)

The first condition, Equation 31.11, depends on vehicle physical parameters and is approximately (within 20%) satisfied by most vehicles. The second condition, Equation 31.12, can be satisfied by appropriately choosing the weighting parameters r_1 and r_2, which often results in a reasonable compromise between the pitch and heave aspects of a ride.

The same conditions also apply for the 4-DOF, half-car model that includes unsprung masses as per Figure 31.17a. The result is two decoupled 2-DOF, quarter-car models shown in Figure 31.17b. Note that the 2D, half-car model introduces one qualitatively new aspect—consideration of the front wheels as a convenient mechanism to preview the road ahead of the rear wheels. This anticipatory information can further improve the ride/handling trade-offs, above and beyond the optimal quarter-car trade-offs of Figures 31.9a and b.

Global performance potentials with preview applied to simple 1-DOF quarter-car models were investigated in Bender [4] and Tomizuka [70]. Hrovat [71] introduces an equivalent delayed-system formulation to develop similar results for 2-DOF, quarter-car, discrete-time models applicable to the configuration of Figure 31.17b. The related global performance plots are reproduced in Figure 31.18, where the solid lines represent the limiting curves without the preview. The optimal performance curves with preview times t_r up to 1 s are shown as dashed lines.

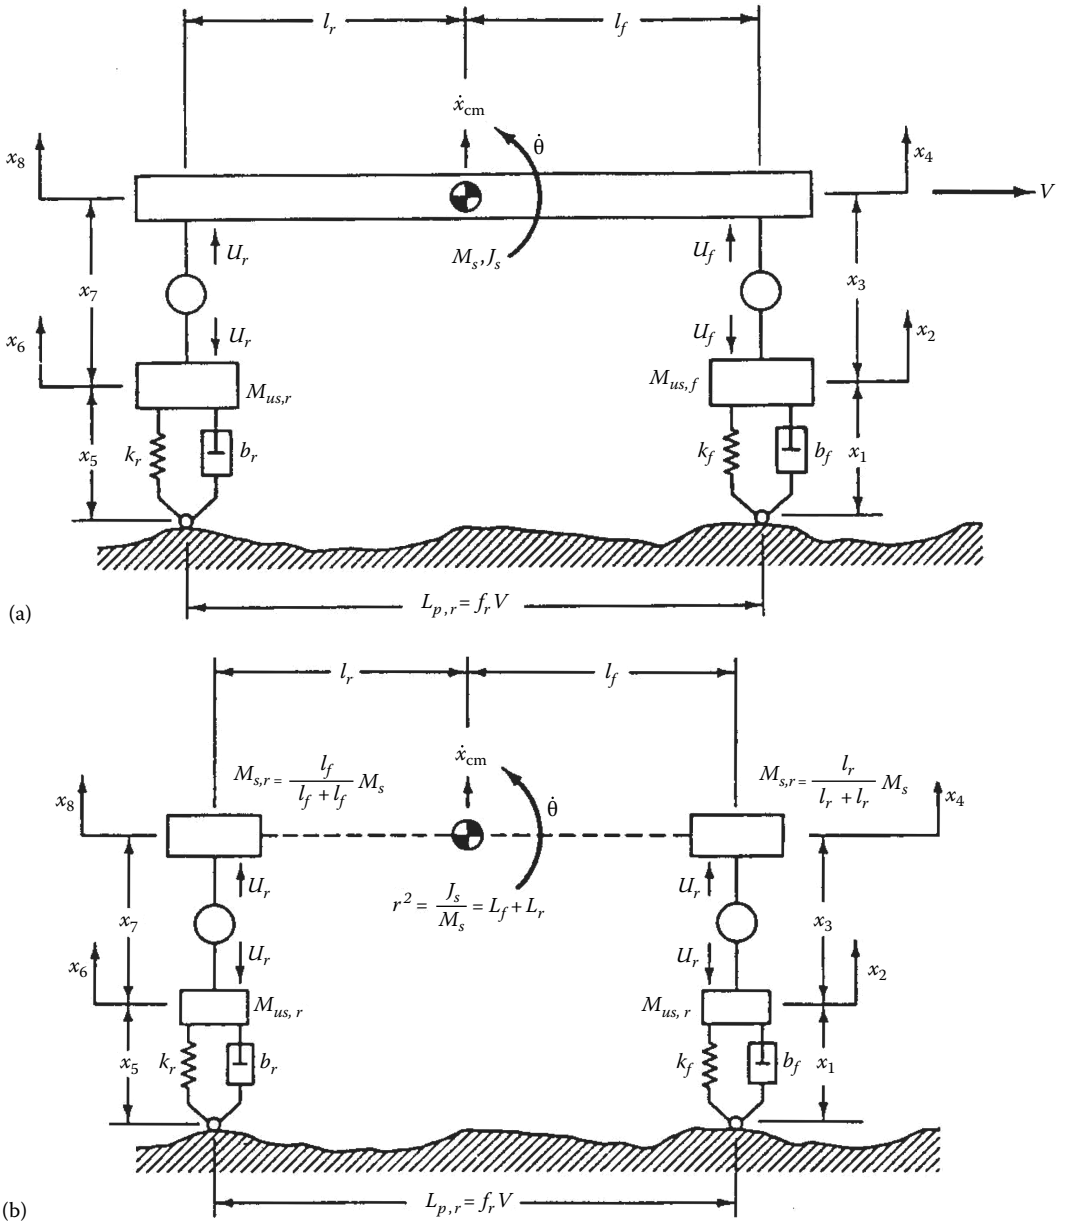

FIGURE 31.17 (a) Half-car, 4-DOF vehicle model. (b) Corresponding decoupled model consisting of two quarter-car 2-DOF subsystems.

From Figure 31.18a it can be seen that for normalized suspension deflections below about 0.6 $s^{1/2}$, preview information of up to 1 s can reduce the accelerations by approximately 50%–70%. Similarly, Figure 31.18b shows that even a relatively small amount of preview of only 50 ms can significantly reduce the tire deflection for normalized accelerations above circa 15 $s^{-3/2}$. For example, at normalized accelerations of 20 $s^{-3/2}$, the tire deflection can be reduced by about 30% with 50 ms of preview. Since in practice the most useful previews will probably be limited to below about 0.3 s, it can be concluded that preview information will probably be most useful for normalized accelerations above approximately 10 $s^{-3/2}$.

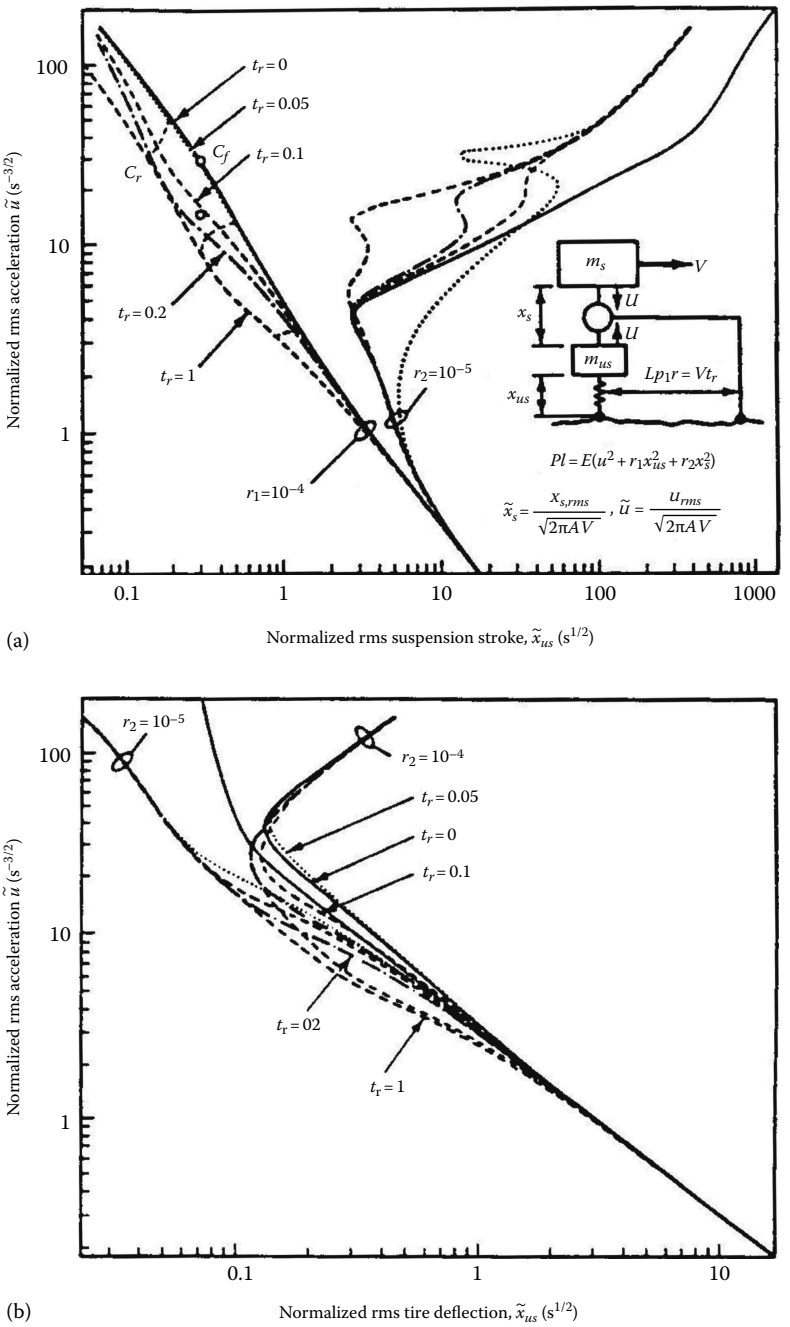

FIGURE 31.18 Optimal suspension performance for 2-DOF model with different preview times t_r, and ρ = 10, $\omega_{us} = 2\pi \cdot 10$ s^{-1}.

Moreover, one can now use the earlier plots to adapt different control gains for the front and rear suspensions, while satisfying tire and suspension deflection constraints. This is illustrated in Figure 31.18a with the help of design points C_f and C_r, for the front and rear control settings. Here both suspension units are subjected to the same stroke constraint, while the rear unit can benefit from 0.11 s of preview, which corresponds to a vehicle with a wheelbase of 2.75 m traversing a fair-to-medium road at a speed of 88.5 kph (further details about this example can be found in [71]). The result is a

considerable improvement in both heave and pitch aspects of the ride. Obviously, if a suitable sensor were available, then the performance could be further improved with the road preview ahead of the front wheels. Corresponding additional benefits could be again estimated with the help of Figure 31.18.

As in the quarter-car case, it is now possible to consider jerk-optimal suspensions for half-car models [72] and, also, the usage of singular perturbation theory to exploit the two-time scale separation between body and wheel-hop modes [64,73]. In addition, with the half-car structure it is possible to exploit the spatial separation between the front and rear of the vehicle. This was first done in [64], where the authors essentially neglected the cross-coupling between the front and rear PI terms corresponding to the fast, wheel-hop dynamics. The resulting hierarchical control structure consisted of a slow mode similar to the one from Figure 31.16 (with a set of tire springs as per Figure 31.8b) and a decoupled set of fast control modes used to contain the front and rear wheel hops. However, as shown by [65], for the particular data used in [64], the decoupling conditions (31.11) and (31.12) are almost satisfied anyway, so that even a simple set of two fully decoupled front and rear quarter-car models yields a performance close to optimal. It is only when strongly coupled data are used that one can start to appreciate the proposed spatial and temporal separation.

A comprehensive analysis of the 2D preview case in the continuous-time domain was performed by Hac [74]; the corresponding analytical solutions were similar to their limiting discrete-time counterparts from [71]. The performance potentials of front wheel preview have been further investigated in [75] and those of the slow-active suspensions in [76,77], where it was concluded that "0.033 s of preview is of little use, although 0.1 s is very useful." An attempt to apply the preview to a nonlinear 2D truck model has been discussed in [78], along with the corresponding power requirements. Finally, an analytical application of decentralized control concepts to active vehicle suspensions with preview is given in [79].

31.7 OPTIMAL SUSPENSIONS FOR FULL-CAR MODELS

In this section we will briefly survey some past and recent full-car, 3D results and place them in a proper perspective with respect to previously discussed half-car and quarter-car counterparts. Some of the earlier investigations of the optimal 3D suspensions can be found in [80–82], where numerical solutions of the corresponding LQ problem were obtained for a few specific operational road/speed conditions. On the other hand, complete analytical solution of the 2D case [69] facilitated similar analytical extensions [83] toward the full 3D structure shown in Figure 31.19. The corresponding

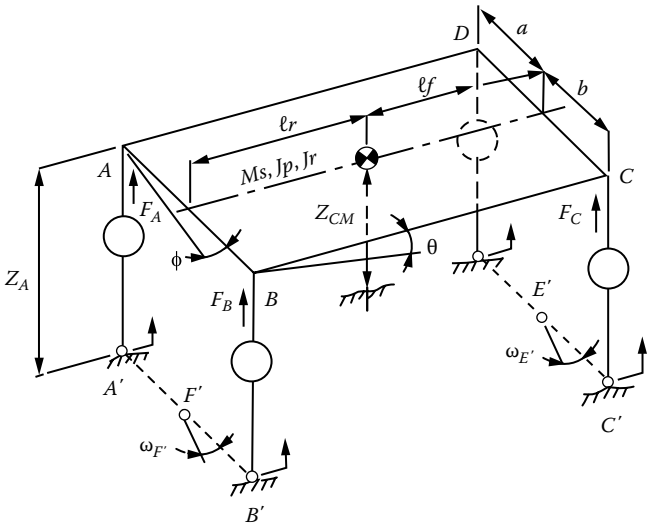

FIGURE 31.19 A 3D-vehicle model schematic.

optimization problem was formulated by mimicking the basic quarter-car and half-car performance requirements, Equations 31.8 and 31.9, so that the full-car PI now becomes

$$PI_5 = E\left(q_A z_A{}^2 + q_B z_B{}^2 + q_C z_C{}^2 + q_D z_D{}^2 + r_1 \ddot{z}_{cm}{}^2 + r_2 \ddot{\Theta}^2 + r_3 \ddot{\Phi}^2\right) \tag{31.16}$$

where the first four terms penalize excessive steady-state suspension deflection at the four corners (cf. Figure 31.19), while the last three serve as a measure of ride discomfort with respect to vehicle heave, pitch, and roll acceleration, respectively.

The analytical solution of the earlier seventh-order system was found with the help of a two-layered partitioning [83]. In the first step, the original seventh-order system was partitioned into a sixth-order, tricycle structure shown in Figure 31.20 and an additional "odd" state. The second step constituted further partitioning of the sixth-order Riccati equation, corresponding to the earlier tricycle model, into two third-order subsystems, which could then be solved analytically. The analytical solution of the sixth-order system was next merged with the additional seventh state shown in Figure 31.21. This additional state reflects the fact that the road elevations are not necessarily coplanar at the four tire–road interfaces.

The solution to the seventh-order LQ problem was completed by transforming the earlier seven states into a more practical set of states: three sprung mass velocities for heave, pitch, and

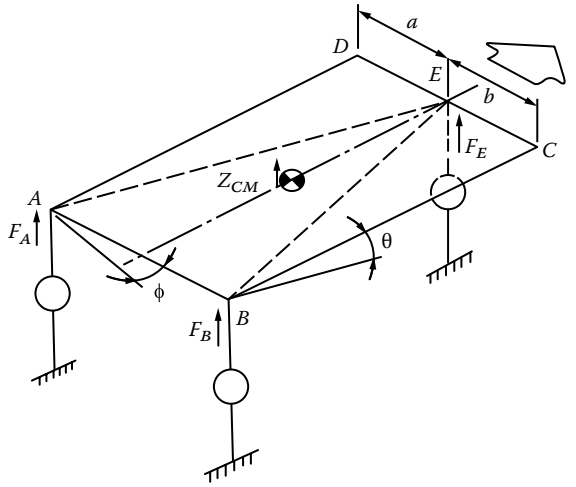

FIGURE 31.20 Equivalent "tricycle" configuration.

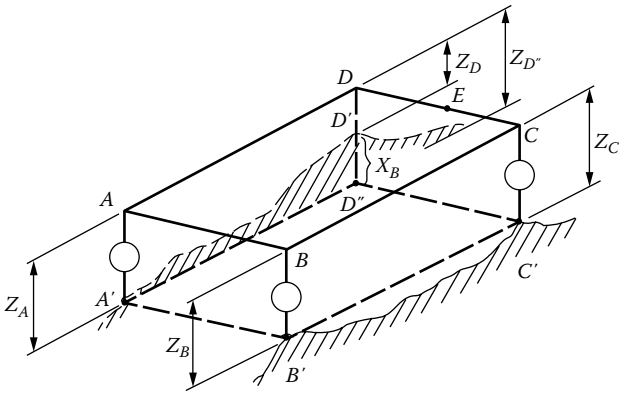

FIGURE 31.21 Introduction of additional state.

roll modes and four corner suspension deflections. Once the analytical solution to the full-car optimal suspension problem was found, it was possible to establish a number of related properties characterizing the optimal structure. For example, it was shown that all three optimal body modes have the highly desirable damping ratio of 0.7 that is achieved via "skyhook" damping. This holds for any set of PI_5 weights in Equation 31.16 and can be extended to even more general performance indices.

Under the following mild conditions, the original 3D problem can be decoupled into simpler pitch + heave and roll subproblems (see Figure 31.22)

$$a = b, \quad q_A = q_B, \quad q_C = q_D \tag{31.17}$$

where a and b are the lateral distances from the CM in Figure 31.19. It is also assumed that the ground roughness has been modeled according to a spatial road surface description from [84,85], which, as discussed in [39], conveniently facilitates the earlier decoupling. Moreover, if the previously established conditions (31.11) and (31.12) hold, then the pitch + heave dynamics can be further decoupled into front and rear quarter-car submodels as shown in Figure 31.22. In this way the original 3D problem is transformed into the much simpler, quarter-car models for which there is a wealth of results available, as discussed in previous sections. It should also be pointed out that, similar to the 2D case, it is now possible to consider 3D two-time scale and hierarchical control schemes, effects of flexible modes, preview, and different jerk-optimal PI augmentations.

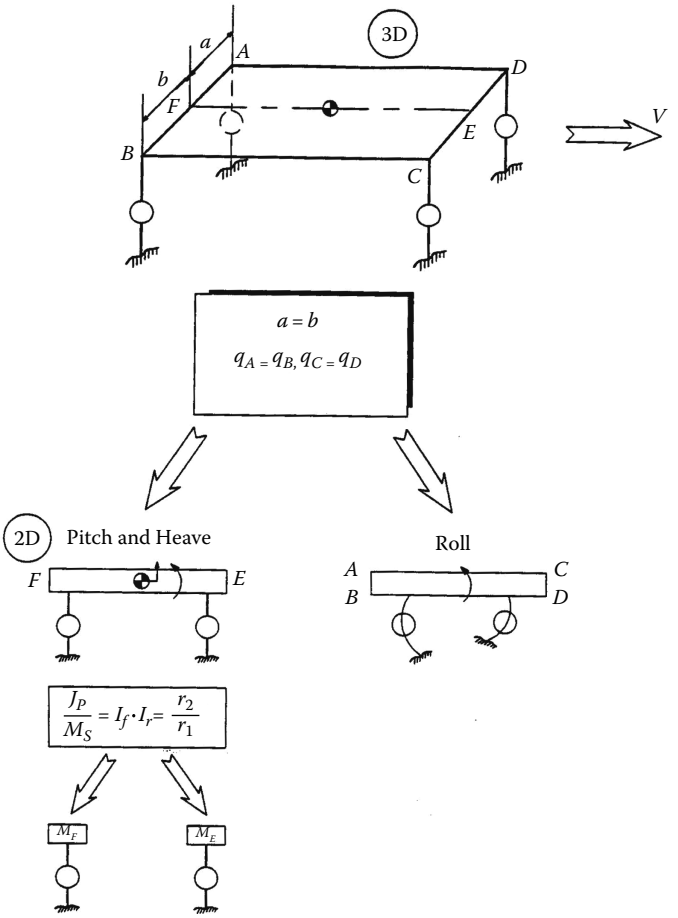

FIGURE 31.22 Front–rear–roll decomposition.

31.8 RELATED TOPICS

The preceding sections presented in a systematic fashion the fundamental characteristics of active suspensions. This was needed to establish key performance potentials and inherent limitations of different vehicle-suspension system models. A systematic way of presenting the results starting from the simplest possible and yet still relevant models is highly recommended since it leads to obtaining the fundamental insight, which can very easily be obscured by unnecessary details and case-to-case varying hardware specifics. The objective of this section is to briefly discuss developments in important areas that are directly or indirectly related to, or naturally follow after, these fundamental considerations.

31.8.1 Semi-Active Suspensions

The SA suspension concept was introduced in the early 1970s [41,86,87] in the form of variable, controllable damping. In this section we will somewhat loosely refer to "semi-active" as any essentially passive suspension concept, where a relatively small amount of external energy is used to improve the performance.

31.8.1.1 On–Off Semi-Active Damping

Since their introduction, SA dampers have been considered for diverse applications ranging from trains [88] to tractors and other off-road vehicles [89] to high-speed air-cushion vehicles [90,91] and military tanks [92]. Production applications of some very rudimentary SA concepts started in the early 1980s (see [24] of Chapter 22), with the introduction of the first variable damping shock absorbers. These variable dampers typically changed the damping from soft to firm and vice versa, through a manual or slow adaptive control and as such represented a very elementary form of the SA damping. The corresponding ride and handling performance improvements were marginal and sometimes even imperceptible, although some subsequent, more matured implementations show promise, especially in adapting to increased handling demands.

A somewhat more sophisticated and more demanding approach (in terms of implementation) is the so-called "on–off" SA strategy, which was first proposed in [90]. Simply stated, it switches the damper off, that is, creates a low or near-zero force, whenever the sprung and unsprung masses move in the same direction and the unsprung mass has a larger velocity. In any other situation the damper is set to "on" state, which produces large damper forces. The main idea of such a strategy was to reduce the sprung mass acceleration and motion, which was successfully demonstrated in early simulation and experimental studies [90,91,93,94]. However, care must be taken to prevent and smooth out too aggressive on–off switching, which may result in excessive jerks. This and similar refinements are a normal and necessary part of development from a relatively simple concept phase to actual production implementation.

During the recent years there has been considerable interest in the on–off SA concept in the industry. As a result, there appeared further improvements and refinements of the concept [95–98]. This is emerging as the first bona fide SA concept to see production [99,100].

31.8.1.2 Continuously Variable Semi-Active Damping

The original continuously variable SA modulation policy [41,86,87] is more challenging to implement than the earlier simple on–off concept, but at the same time it offers further performance improvement opportunities. It requires that the SA actuator continuously reproduces the (1-DOF LQ-optimal) skyhook damping force whenever this is possible in view of the passivity constraint. When this is not possible, the damper is simply turned off (here care should be exercised to avoid discontinuous-force switching that can lead to excessive jerk). The continuously variable SA policy was subsequently extended to 2-DOF, quarter-car, and more complex models, with simultaneous possible limiting of the damper maximum force leading to so-called "clipped" SA control [42,89,101–103].

While the clipped SA policy is in general not optimal [104,105], based on experience and prior results, it can be said that for most cases of practical significance, it is very close to optimal [102]. In its most basic form, the SA control problem can be cast in either linear state-space equation setup with nonlinear

constraints on SA damper forces or bilinear [42] with relatively simple inequality constraint on control variable—in this case SA actuator damping. It is also possible to represent the SA suspension design problem in the model predictive control (MPC)—hybrid control setting [105] with passivity-induced constraint as a natural switching parameter. Different (sub)optimal results are obtained depending on control horizon length and other MPC parameters. For control horizon of only one step in the future, the optimal control in this case coincides with the earlier clipped SA control [105].

Further improvements of the SA concept were also investigated through hardware modifications and extensions [106,107]. Usage of electrorheological (ER) and magnetorheological (MR) fluids has been proposed as a hardware alternative for the more conventional, variable-orifice hydraulic dampers [108,109]. From a practical standpoint, the MR concept appears especially promising for suspension and other vibration isolation applications (e.g., engine mounts), since it can operate on vehicle battery voltage, whereas the ER concept is based on high-voltage electric fields. There were also attempts to design the SA controllers using genetic algorithm [110], internal model control [111], dynamic programming [112], frequency-selective skyhook damping [113], neural networks [114], sliding mode controller [115], and preview control [116–120]. Actual production hardware and/or close-to-production hardware implementations are described in [99,100,113,121] and more recently in [122,123]. Additional related details and information can be found in Chapter 22 on advanced suspension hardware considerations.

31.8.1.3 Semi-active Spring

The concept of an incrementally SA spring, realized by means of on and off switching of additional gas spring accumulators, was introduced by [124]. This is a promising practical complement to SA damping, since, based on discussions in Section 31.5.2, both the suspension damping and stiffness should change to optimally adapt to different road/speed conditions. This can also be seen in Figure 31.23 reproduced from [125], which illustrates the performance of adaptive "passive" suspensions with the sprung mass natural frequency varying from 0.5 to 2 Hz and the corresponding damping ratio ζ ranging from 0 to 1. Clearly, the suspension stiffness has a significant influence on ride quality so that, similar to the fully active case, softer suspensions lead to more comfortable rides at the expense of increased suspension stroke requirements. Figure 31.23 also shows the corresponding optimal active boundaries. It can be seen that even such an idealized adaptive "passive" suspension cannot fully match the performance of the optimal active counterpart.

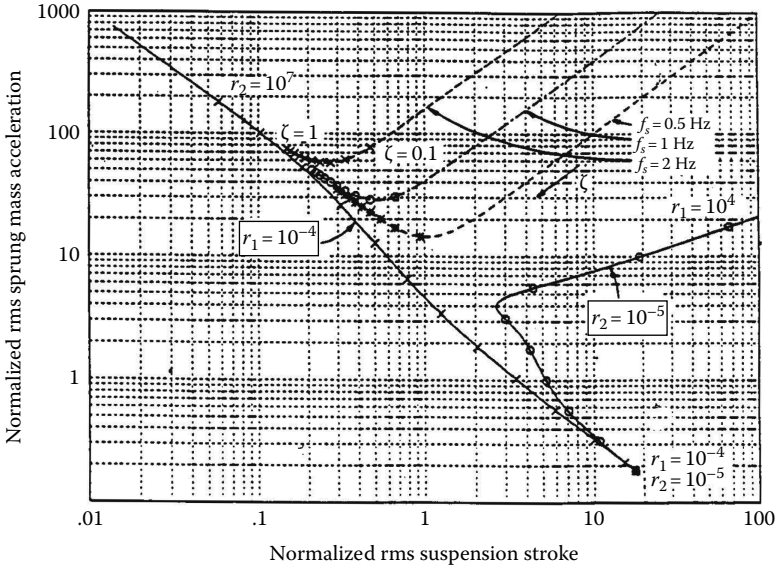

FIGURE 31.23 Comparison between quarter-car, 2-DOF models for passive suspension with f_s = [0.5, 1, 1.5] Hz, ζ = [0.1, 0.2, …, 1] and active suspension with $r_1 = 10^{-4}$ and $r_2 = 10^{-5}$.

31.8.2 State Estimation and Closed-Loop System Robustness

The underlying assumption in the preceding section has been that all the states are exactly known, which then gave us the best possible performance. In practice, some of the states may not be easily accessible. For the simple, quarter-car model, typical measurements may include sprung mass acceleration and suspension deflection, whereas the tire deflection is difficult to measure. Fortunately, the latter can often be neglected in the feedback control law without significant loss of performance, although there are operations when this cannot be done [24].

Based on the earlier measurements, it is possible to estimate the full-state vector using, for example, the Kalman filter in the context of the LQG methodology [126–129]. While such systems may reduce sensor requirements, it is important to remember that they typically lead to degradation in performance. For some realistic examples of systems using a single, rattlespace deflection measurement as in [127], it was shown [129] that such LQG policy can increase the LQ cost by more than 80%.

In addition, the LQG controller (with state observers or Kalman filters) is in general less robust with respect to modeling errors than the corresponding full-state counterpart. For a "typical" set of control gains, the gain margin of the suspension stroke-based LQG regulator can be only 0.2 dB, with the phase margin of 18° [129]. The corresponding LQ margins were ∞ dB and 100°. It should be pointed out that for a "softer" gain setting, even the full-state LQ regulator resulted in a small gain margin of only 1.5 dB and a phase margin of 33°. This is the consequence of a particular quarter-car structure, which included a parallel passive spring to (partially) support the vehicle. This additional spring leads to nonzero weightings on cross-terms between states and control in the PI, for which the "standard" LQ guarantees of ∝ gain margin and at least 60° of phase margin do not apply.

The preceding text indicates that it is important to consider closed-loop system robustness with respect to unmeasured states, structural changes (e.g., the introduction of a parallel supporting spring), as well as parametric uncertainties and, to a lesser degree, uncertainties due to sensor and actuator dynamics. To address various forms of uncertainties, a number of recently developed and computerized robust control techniques can be considered, with the ones based on frequency domain analysis being especially popular [130–132].

In particular, [132] investigated potential applications of H_∞ optimization in the context of a system-level active suspension design. It was found that, based on a performance mimicking Equation 31.10, the resulting controller introduced too much damping in the wheel-hop mode, since the H_∞ technique tends to minimize the peaks in the frequency-response curves. As might have been expected from the previous discussions, excessive damping will in general lead to deterioration of ride comfort performance. One of the potential benefits of H_∞-based approaches is for robustness analysis and enhancement. Especially promising here is the μ synthesis and analysis [133] that has already been applied to a number of automotive areas starting from, for example, [134], but it still has not been fully exploited in the context of active suspension design. Additional benefits are also possible by combining H_2 and H_∞ metrics [135]. For a full utilization of this mixed setting, one should leverage the H_∞ part for simultaneous optimization of a combined ride/handling/robustness trade-off.

31.8.3 Nonlinear Suspension Systems and Controls

Primary focus thus far was on optimal control methods applicable to linear vehicle models that are of course only approximately valid since the real vehicle system is necessarily nonlinear. For many operations, however, the linear system approximation is appropriate. This is also supported by experimental validations as discussed in [24]. However, there are situations that amplify the nonlinear effects. One example is created by discrete-event disturbances, such as single bumps or potholes, which can cause suspension bottoming—a highly nonlinear phenomenon. Another example is the always present dry friction, which may cause the suspension to lock on very smooth roads. The vehicle then essentially rides on tires. The present section gives a brief overview of different approaches to the nonlinear vehicle-suspension system design problem.

31.8.3.1 Nonlinear Control Design through Optimization

The nonlinear effects of suspension bottoming and the like were treated in [136] based on an approach that is similar in spirit to the optimal SA approach [102] discussed in 31.6.1. As was the case with [102], the method from [136] is computationally intensive, especially for higher-order vehicle models. However, with continuous improvements in computer processing power, this will be less of an issue in the future. Encouraged by favorable results with discrete disturbance responses, reference [136] argues for superiority of nonlinear over LQ-adaptive suspension algorithms. However, one could also present the reverse argument, especially if the full potentials of the adaptive strategies are taken into account [24].

Instead of competing alternatives, the two approaches can be viewed as complementing ingredients of an overall optimized suspension strategy. In this context, the LQ-optimal adaptive or gain-scheduling controls would be used for most driving situations with nonlinear policies being activated during excessive discrete-event disturbances and other special circumstances. An approach that would naturally blend the two is presented next.

31.8.3.2 Nonlinear Controls as an Extension of LQ Controls

From previous sections we know that the LQ setting offers a very attractive alternative and natural setting for solving the optimal or "best possible" active suspension design problem at the highest system level. This leads to fundamental results in terms of key limitations and potential benefits of such suspensions. However, one of the potential weaknesses of the LQ approach is that the actual hard constraints—such as rattlespace and tire deflection constraints—are approximated by their soft counterparts in the context of a quadratic penalty within an LQ PI. This leads to possibly more conservative results, especially when all suspension motion is confined to well within the allocated constraints.

To alleviate the above problem, Ref. [137] introduces additional quartic penalty terms for the earlier soft penalty constraints. This increases the penalty for excursions approaching the allowable space limits while at the same time reducing the same penalties for motions close to nominal, that is, close to static equilibrium. The resulting control law is summarized in Appendix 31.A. It has a desirable property that its linear term gains are identical to the well-known LQ gains ("downward compatibility"), thus recovering the LQ performance for relatively small motions, caused by relatively small road disturbances based on typical random road roughness characteristics. At the same time, the nonlinear control terms—in this case of a cubic variety—take care of excessive motions that can occur during encounters with sudden large bumps or potholes.

Illustrative examples in [137] show benefits of such a nonlinear suspension. In the case of a bump response, an effective "electronic tunable bumper" is providing additional flexibility in the tradeoffs between improved ride (lower acceleration levels) and allowable suspension and tire deflection. For random roads, there is a similar flexibility in terms of fundamental performance plots, which mimic Figure 31.9a and b in Section 31.5, but now for the nonlinear case [137]. This time the magnitude of road-induced roughness also alters these normalized plots, so that as the road disturbance increases the normalized rms tire deflection becomes smaller with simultaneous increase in the heave acceleration levels. This way, the nonlinear controller has some of the characteristics of its linear counterparts with gain scheduling. Of course, it is also possible to combine the earlier nonlinear controller with gain scheduling, which will inherit some additional desirable properties. The nonlinear portion will contain sudden large bumps and also offers some moderate adaptation to changes in prevailing road conditions. The gain-scheduling portion will then be used to accommodate or adapt to large changes in the prevailing road conditions.

31.8.3.3 Other Approaches to Nonlinear Suspension Control

There are many other nonlinear control-based approaches to active and SA suspension design. This includes sliding modes [138], adaptive controls [157], neural nets [26], feedback linearization [138],

and MPCs and hybrid controls [105,139], among others. In particular, reference [140] uses feedback linearization with backstepping for suboptimal active suspension design. It borrows some of the rationale from the earlier-mentioned decade-old optimization-based approaches, including a consideration of ride comfort versus rattlespace trade-offs, and adaptation to varying road roughness characteristics [141]. The centerpiece of this approach consists of an interesting albeit somewhat ad hoc nonlinear filter, which is less intuitive and straightforward to design than the optimization-based approaches. For example, [140] focuses on comfort versus rattlespace trade-offs, and it is not clear how easily one could incorporate the other important trade-offs such as the trade-off between handling (tire deflection) and ride comfort. Also, since there are no reported experimental results, it is not clear how robust this approach would be to parameter and system dynamics uncertainties and inaccuracies.

One of the most promising approaches to future advanced suspension design involves MPCs with their recent extensions in the form of hybrid controls [142–144]. The MPC control consists of using an appropriate plant model along with hard state, output and control constraints, which are in turn used to calculate optimal controls for an appropriate PI (typically in a quadratic or H_2 form) that spreads through a finite time horizon. Once the optimal control sequence has been found, only the first member of this sequence is actually implemented and the whole process of optimization then repeated. By implementing only the first step, one is in effect trying to contain unpredicted disturbances and model inaccuracies. As such, MPC is a very plausible and intuitively appealing approach that in a sense mimics control exerted by many living beings. At the same time, it is a natural extension of the earlier LQ optimization.

MPC controls have been successfully used for many years in the process industry, where update rates are relatively slow (of the order of seconds, minutes, or even hours), thus allowing for the earlier optimization to be performed on line. With ongoing progress in microprocessor infrastructure and MPC theory, it is now possible to consider other areas of application—such as aerospace and automotive—where control update rates are much faster (of the order of milliseconds). A prominent facilitator here was provided by development of the so-called explicit MPC methodology [145,146], where one performs all key optimizations off-line and stores the results in tables from where then actual controls are obtained by on line data entries based on plant states and various (measured disturbance and reference) inputs. The method was further extended to include nonlinear and hybrid systems, where the PI is now typically in the L_1 form and various nonlinearities and switching logic are represented by piecewise affine (PWA) functions [144].

Recent MPC/hybrid applications in the automotive industry include idle speed control [147], direct injection and stratified engine controls [148], transmission controls [149], traction control (TC) [150], and advanced active [139] and SA suspension control [105]. In particular, [139] is one of the first to effectively use and implement the MPC methodology in the context of active suspensions. The authors consider a quarter-car suspension model with road preview. The quadratic PI is similar to the earlier standard formulation (31.10) with an additional soft penalty on control force and a hard penalty on suspension travel or rattlespace. Also, a gain-scheduling type of road adaptation somewhat similar to [141] was used to facilitate easier satisfaction of the rattlespace hard constraint. The authors use more or less prevalent and most of the time preferable outer–inner loop approach based on the desired force generation and tracking (see Chapter 22, Section 22.3.3). The MPC optimization was performed on line in a laboratory half-car test rig, where the MPC (outer) loop was updated at a 10 ms rate. The resulting MPC-optimal force was then used as a reference signal for a sliding mode-based inner-loop controller implemented with an electrohydraulic setup operating at a 1 ms rate. The experimental results for smooth roads show similar benefits as for the standard LQ case from Section 31.5.2, whereas for harsh road profiles significant additional benefits resulted with MPC where rattlespace hard constraint prevents hitting the bump stops.

We conclude that, as a result of the substantial ongoing theoretical advances in the areas of nonlinear, model predictive, hybrid, and adaptive controls (cf., e.g., [144,151–155]), it is expected that the future will see increased applications of these and similar techniques in advanced suspension design.

Some early results in these directions have been mentioned earlier; additional attempts can be found in [156–159,141] and others.

31.8.4 Practical Considerations

The most direct way to actually implement the earlier optimal control-based suspension strategies is to use an inner-loop force control configuration. In this case, the outer/higher level provides the optimal desired or commanded force for the inner-loop, force-tracking control. This approach also applies in other cases, when the desired force can be generated via other control methods (e.g., classical and backstepping), which are not necessarily based on an explicit optimization. In practice, the active actuator should be supplemented by a more traditional passive counterpart consisting of spring and shock absorber or damper, typically geometrically in parallel with the active device. Of course, every practical active suspension implementation will also have an in-series compliance. In the case of the so-called narrow or low-bandwidth suspensions, this compliance is intentionally inserted to improve high-frequency isolation and reduce bandwidth requirements. (additional details can be seen in Chapter 22). They should work in tandem with the active device to deliver the desired force while at the same time minimizing the required energy expenditure (see Section 31.5.2.8). In addition, this approach leads to more robust and easier force-tracking implementation, since the presence of additional (passive) damping results in better preconditioning of the related system zeros that typically limit the inner-loop, force control performance (see Section 22.3.3). It also provides for a limp-home capability in case of active actuator failure.

For practical implementation, it is sometimes preferable to simplify the optimal strategies, thus leading to simpler software implementations at the expense of hopefully only slightly degraded performance. For example, in the case of quarter-car models, the full-state LQ-optimal regulator can be simplified to a three-term controller structure consisting of secondary suspension spring and damper (for body support and wheel-hop damping) and a skyhook-like damper for improved sprung mass damping and isolation. This is a suboptimal policy since it neglects tire deflection feedback. In many cases the effects of such an approximation are insignificant.

A similar approximation was used in quarter-car laboratory experiments with a wide-bandwidth electrohydraulic suspension leading to the results shown in Figure 31.24, where control gains have

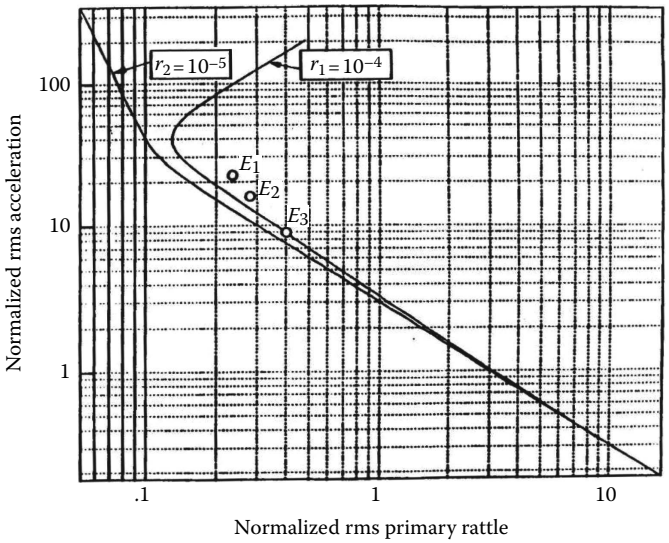

FIGURE 31.24 Optimal performance boundaries for $r_1 = 10^{-4}$ and $r_2 = 10^{-5}$ and experimental results E_1, E_2, E_3, for a quarter-car setup with an active suspension ($\rho = 12.5$, $\omega_{us} = 2\pi \cdot 12$ s^{-1}).

been adapted to the assumed varying road conditions ([24]). The comparison with superimposed optimal 2-DOF curves shows that, although not optimal, the experimental results follow the desired trends and are relatively close to the best possible performance. This gives credence to the underlying optimal analysis and proposed adaptive concepts.

More about practical aspects of advanced suspension design and implementation can be found in Chapter 22. This chapter contains description and comparison of different approaches based on force and displacement inner loops. The chapter also discusses related hardware concepts and actuator issues as well as challenges associated with different practical realizations. Additional information can be found in [160].

31.8.5 Other Aspects

Traditionally, the main focus of active and SA suspension control was on applications dealing with models limited to rigid body dynamics only. This includes vehicle heave, pitch, and roll modes. A consideration of some flexible mode effects can be found in [68,161].

It is believed that the earlier optimal control and robustness results provide a solid base for fault-tolerant control design, which typically constitutes the next important step in developing a product. This includes the generation of suitable dynamic models needed for system diagnostics and failure accommodation strategies.

While all these aspects are extremely important and must be addressed prior to production, they are beyond the scope of this chapter. The interested reader is referred to ongoing research publications in this dynamic field.

In addition to fault analysis and accommodation, the areas of fuzzy logic and neural network control applications can also benefit from the earlier optimal control findings. This includes the choice of proper input variables and overall control policy that, at least to a first degree, may mimic the LQ-optimal logic. Due to their practical and intuitive appeal, these techniques, and especially fuzzy logic, may provide an efficient mechanism to bring the more structured control approaches "home"—in the production car suspensions, power trains, brakes, and other devices.

The present emphasis was on optimal control applications to the design of advanced automotive suspensions, although many conclusions apply in general to other transportation areas. For more specific overviews of results pertinent to other areas, consult the following papers and references therein: commercial vehicle applications [162,163], rail vehicle dynamics [164–166], magnetically suspended vehicles [164,167,168], off-road and military vehicles [169], race cars [170], surface-effect ships [171], and other vehicles.

It should be mentioned that active suspensions can be integrated with other advanced vehicle subsystems into more effective, overall integrated and interactive vehicle control systems, which can significantly improve many vehicle functions especially with respect to vehicle stability in safety-critical emergency maneuvers.. References [172–176] combine active and SA suspensions with four-wheel steer (4WS), antilock braking (ABS), TC, and four-wheel drive (4WD) to achieve superior performance, handling control, ride comfort, and overall vehicle safety during acceleration/braking on straight-line driving as well as, in turns, on dry or slippery roads.

An example of using SA damping to improve vehicle handling and control on a rough slippery road is provided in [177]. Here both decentralized and coordinated controls between the SA damping and dynamic stability control have been investigated. It was found that the coordinated controls offer additional significant benefits in this case in terms of vehicle handling and safety. Present trend toward increased integration and interaction will continue to accelerate. This in turn will lead to increased prospects for future production introductions of active and SA suspensions. Their increased usage will facilitate superior and new functions that will impact many aspects of vehicle performance, comfort, and safety.

ACKNOWLEDGMENTS

Help from my Ford Research colleagues Dr. Jahan Asgari, Mr. Mike Fodor, and especially Dr. H. Eric Tseng is gratefully acknowledged. In addition, Dr. Niklas Karlsson contributed with an appendix on relevant nonlinear suboptimal controls.

31.A APPENDIX: NONLINEAR SUBOPTIMAL CONTROL

Consider the cost function

$$J = \frac{1}{2}\int_0^\infty \left(x^T Q x + u^T R u + \varepsilon f(x) \right) dt \tag{31.A.1}$$

where $\varepsilon f(x)$is a fourth-order polynomial in the state x, subject to

$$\dot{x} = Ax + Bu + \Gamma w \tag{31.A.2}$$

The solution to (31.A.1) and (31.A.2) was first derived in [137]; a more thorough presentation together with some important stability results is available in [178].

Here follows a step-by-step scheme for computing a suboptimal controller $u_{subopt}(x)$ to (31.A.1) and (31.A.2). The optimal controller can be expressed as

$$u_{opt} = -R^{-1}B^T \left(Px + \sum_{k=1}^{\infty} \varepsilon^k g^{(k)}(x) \right)$$

The suboptimal controller, on the other hand, is defined as

$$u_{subopt} = -R^{-1}B^T \left(Px + \varepsilon g^{(1)}(x) \right)$$

To compute u_{subopt}, the matrix P is first obtained as the stabilizing solution of the following Riccati equation:

$$PA + A^T P - PBR^{-1}B^T P + Q = 0$$

It can then be shown that $g^{(1)}$ is the solution to the linear equation

$$\frac{\partial g^{(1)}}{\partial x}(A - BR^{-1}B^T P)x + (A^T - PBR^{-1}B^T)g^{(1)}(x) = -\frac{1}{2}\left(\frac{\partial f}{\partial x} \right)^T \tag{31.A.3}$$

with the boundary condition $\lim_{t\to\infty} g^{(1)}(x,t) = 0$. Since $f(x)$ is a fourth-order polynomial in the state x, it is clear by inspection of Equation 3 that $g^{(1)}$ is a vector of polynomials of order three. Assume the state has dimension four. The function $g^{(1)}$ can then be written as

$$g^{(1)}(x) = \sum_{i=1}^{4}\sum_{j=1}^{4}\sum_{k=1}^{4} \begin{bmatrix} G^1_{ijk} x_i x_j x_k \\ G^2_{ijk} x_i x_j x_k \\ G^3_{ijk} x_i x_j x_k \\ G^4_{ijk} x_i x_j x_k \end{bmatrix}$$

Similarly, $f(x)$ can be written as the sum

$$f(x) = \sum_{i=1}^{4}\sum_{j=1}^{4}\sum_{k=1}^{4}\sum_{l=1}^{4} F_{ijkl}x_i x_j x_k x_l$$

Now, define the vectors ξ and η from the coefficients of $f(x)$ and $g^{(1)}$ as follows:

$$\xi = \left[G^1_{111}, G^2_{111}, G^3_{111}, G^4_{111}, G^1_{112}, \ldots, G^4_{112}, G^1_{114}, \ldots, G^1_{444}, \ldots, G^4_{444} \right] \in \Re^{256}$$

and

$$\eta = 2 \cdot \left[F_{1111}, \ldots, F_{1114}, F_{1121}, \ldots, F_{1124}, F_{1131}, \ldots, F_{4441}, \ldots, F_{4444} \right] \in \Re^{256}$$

The sought for vector ξ is obtained as the solution to

$$\hat{S}\xi = \eta,$$

where $\hat{S} = S^T \oplus S^T \oplus S^T \oplus S^T \in \Re^{256\times 256}$ and $S = A - BB^T P$. The symbol $\oplus$ denotes the Kronecker sum operator, defined by $S^T \oplus S^T = (I_4 \otimes S^T) + (S^T \otimes I_4)$.

A more general case is discussed in [178], where it is also shown that the suboptimal controller u_{subopt} under certain conditions guarantees a stable closed-loop system.

Example

Consider, for example, the active control of the quarter car described in Section 31.5.2. The dynamics is described by the matrices

$$A = \begin{bmatrix} 0 & 1 & 0 & 0 \\ -(20\pi)^2 & 0 & 0 & 0 \\ 0 & -1 & 0 & 1 \\ 0 & 0 & 0 & 0 \end{bmatrix}, \quad B = \begin{bmatrix} 0 \\ 10 \\ 0 \\ -1 \end{bmatrix}, \quad \text{and} \quad \Gamma = \begin{bmatrix} -1 \\ 0 \\ 0 \\ 0 \end{bmatrix}$$

Furthermore, let the cost function be

$$J = \frac{1}{2}\int_0^\infty \left(x^T Q x + u^2 + \varepsilon f(x) \right) dt \quad \text{where } Q = \begin{bmatrix} 1100 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 100 & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix},$$

$f(x) = 12{,}375{,}000 \cdot x_1^4 + 1{,}125{,}000 \cdot x_3^4$ and $\varepsilon = 0.25$. Note that the quartic terms penalize x_1 (the tire deflection) and x_3 (the suspension deflection) to the fourth order. This choice of $f(x)$ corresponds to a vector η where the only nonzero elements are $F_{1111} = 12{,}375{,}000$ and $F_{3333} = 1{,}125{,}000$.

The suboptimal controller is obtained as

$$u = ax_1 + bx_2 + cx_3 + dx_4 + \sum_{i=1}^{4}\sum_{j=1}^{4}\sum_{k=1}^{4} D_{ijk}x_i x_j x_k,$$

where $a = 6.0842$, $b = -0.5478$, $c = 10.0$, $d = 4.4375$ and where the coefficients D_{ijk} are given in the following table:

ijk	D_{ijk}	*ijk*	D_{ijk}	*ijk*	D_{ijk}	*ijk*	D_{ijk}
111	$1.16 \cdot 10^{4}$	123	$-4.80 \cdot 10^{2}$	222	$-1.43 \cdot 10^{-1}$	244	-3.35
112	$-7.95 \cdot 10^{2}$	124	$-2.86 \cdot 10^{1}$	233	2.78	333	$1.41 \cdot 10^{4}$
113	$4.06 \cdot 10^{4}$	133	$3.57 \cdot 10^{4}$	224	$2.74 \cdot 10^{-1}$	334	$6.07 \cdot 10^{3}$
114	$5.70 \cdot 10^{3}$	134	$1.02 \cdot 10^{4}$	233	$-2.75 \cdot 10^{2}$	344	$1.19 \cdot 10^{3}$
122	$-3.34 \cdot 10^{-1}$	144	$9.84 \cdot 10^{2}$	234	$-4.53 \cdot 10^{1}$	444	$9.03 \cdot 10^{1}$

32.1 INTRODUCTION

Vehicle motion controls in longitudinal, lateral, and vertical directions were to be controlled independently by traction/braking, steering, and suspension controls, respectively, in the past; however, in the recent 10–15 years, attentions are focused on integration of these controls to control vehicle horizontal motions, above all the vehicle lateral motion. We can call these recent years "integrated control era." In the early stage of the earlier-mentioned 10–15 years, the integration or system combination of vehicle motion control has been reviewed in [1] in which the integration possibilities of chassis and TCS then available are dealt with. There, integration is understood as functional or hardware integration or as functional and hardware integration.

Also in [2], a study is presented dealing with the synergism coming from the integration of such controlled systems which are designed for improving dynamic behavior of road vehicles. Several combinations of suspension, torque, and/or steering controls are presented and the idea is laid behind that integrated control is a combination of more than two controlled systems to offer synergistic effects on performance improvement in vehicle lateral dynamics.

Understanding the integrated control in this article is almost the same as in the earlier [1] and [2]. Control integration from the viewpoint of performance improvement of vehicle lateral dynamics by multiple hardware combinations that eventually result in the integral use of the tire forces will be dealt with here. So in other words, integrated control could be said as a reasonable use of the tire forces with several hardware and at the same time offering performance benefit of vehicle lateral motion.

It is interesting to see which areas are likely to be beneficial in a "g–g diagram" for respective system integrations in a conceptual diagram as shown in Figure 32.1 [3] which was also published in the early stage of the recent 10–15 years. The circular limit of longitudinal and lateral accelerations corresponds to tire friction circle for each tire and it is reasonable to regard the integrated vehicle control as the integral use of the tire forces.

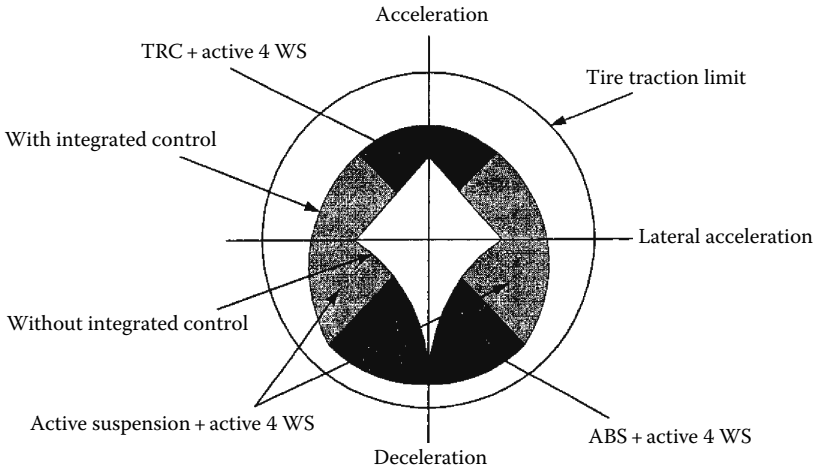

FIGURE 32.1 A concept of integrated control.

One of the important points in integrated control is a control integration methodology. Recently the author of [4] considers the scope, methodologies, and architectures for the design and development of interacting control systems in road vehicles laying an emphasis on the role of control system architecture, the resulting flow of control information, and the implications for control system design. It gives us broad review of current practice in integrated vehicle control to be referred once and so the earlier points will not be considered in any detail in this chapter.

32.2 VEHICLE CHASSIS CONTROL

Vehicle chassis control is generally meant to control vehicle lateral, vertical, and longitudinal motions in order to improve handling performance and safety, ride comfort, and traction/braking performance. These controls have basically been depending on steering controls, traction/braking controls, and suspension control, respectively. Our main interest here is the research and development of chassis controls for improving vehicle handling performance and active safety.

Since the 1980s, one of the most common chassis controls for the improvement of handling performance is rear-wheel steering (RWS). The RWS control depends on tire lateral force which is proportional to the steer angle, a control command, in a range where the lateral acceleration is small. In this range, the control law can rather easily be introduced by using two-degree-of-freedom linear vehicle model. However, in higher lateral acceleration, the lateral force is not necessarily proportional to the steer angle due to its saturation property to sideslip angle. The lateral force also becomes strongly dependent on the tire vertical load and the longitudinal force as well, so that the control law becomes rather sensitive to the vehicle motion and its environmental conditions [5].

In the recent 10–15 years, a so-called direct yaw moment control (DYC) is becoming one of the most promising means of chassis control. In DYC a vehicle motion is controlled by a yaw moment that is actively generated by the intentional distribution of the tire longitudinal forces between right and left (transversal split control of traction/braking). Some types of DYC are already installed in real cars in the market. One of the major advantages of this control method is that the tire longitudinal force has basically no feedback from the vehicle lateral motion as long as it is within the limit of the tire capacity due to the vertical load. One may think that the controlled longitudinal forces also have some effects of lateral motion, for example, effects of sideslip angle; however, it is not correct. A reason is as follows: A control command of the longitudinal force is normally a brake pressure or a traction torque which is directly an input torque to a spinning motion of a wheel.

The wheel spinning motion is independent from the vehicle lateral motion. So, the wheel longitudinal slip reaches some value at which the tire longitudinal force is balanced to the input torque, whatever a tire sideslip is, so far as the vertical load is large enough to produce the longitudinal force. This is a very important point in an intentional use of tire longitudinal forces for controlling vehicle lateral motion. Therefore, a precise yaw moment, required to control the vehicle lateral motion, can be developed and the vehicle motion with the control becomes more robust to fluctuation in the vehicle running condition and its environment [5,6]. Of course it should be noticed that the tire lateral force has the effect of the longitudinal force even though it is determined independently from the lateral force.

Though front-wheel active steer (FWS) has the same shortcoming aspects as RWS, recently FWS is also becoming one of the effective tools of the active chassis control together with developments of the steer-by-wire systems. However, the control command of both FWS and RWS is not the lateral force but the steering angle; therefore, the lateral forces generated by FWS and RWS have less accuracy and will be more susceptible to the vehicle motion because the tire lateral force has a nonlinear relationship to the sideslip angle and the vertical load. In contrast, as it is mentioned earlier, the yaw moment produced by DYC will be more precise; on the other hand, it cannot directly control the lateral motion since it does not use any lateral force directly for the control [6].

For these reasons, it is possible to realize more effective chassis control by integration or coordination of FWS, RWS, and DYC to compensate the drawback of each control. Roll moment distribution control (RDC) in an active suspension is also considered to be one of the tools to control the vehicle motion. A controlled four wheel drive (4WD) with differential control is one of the tools of chassis control as well. Of course, there are some other promising chassis controls than FWS, RWS, DYC, RDC, and controlled 4 WD such as antilock brake system (ABS) and traction control system (TCS). Since these controls are aiming at not controlling the vehicle motion directly but controlling the tire performance as a component control, they are not necessarily regarded as a control device for the strategic integrated vehicle motion controls but possible to accomplish their aims by stand-alone use; however, the drawbacks of ABS and TCS can be compensated by FWS, RWS, DYC, etc.

Since any general definition of "integrated control" is not established yet, the term is used here for combination or coordination/cooperation of two or three chassis controls for the vehicle handling and active safety, some of which are sometimes possible to be called multivariable control. Anyhow, it is obvious that any chassis control aiming at improving vehicle handling performance must rely on the tire lateral force and that the tire longitudinal force can also be used for the chassis control. These two forces each rely upon the vertical load and are interdependent. This relationship makes the vehicle dynamic characteristics very complex and nonlinear, and also it is no exaggeration to say that nonlinear characteristics of vehicle dynamics and its loss of stability can be due to nonlinear tire characteristics. Thus comprehensive study and deep understanding of tire and vehicle dynamics are required to develop more effective chassis control strategies as the integrated controls. It is desirable for the combination or coordination/cooperation of two or three chassis controls to compensate for the drawback of each stand-alone control due to nonlinear tire and vehicle characteristics.

32.3 FEATURE OF INDIVIDUAL CONTROL

Before going into detailed descriptions of the integrated controls, confirming the distinctive feature of typical chassis controls especially FWS, RWS, and DYC that are possible to be introduced into and compose promising integrated controls will be informative.

The vehicle response transfer functions calculated with a linear two-degree-of-freedom vehicle model of sideslip and yaw rate, to FWS, RWS, and DYC that will be produced by tire longitudinal forces, respectively, are shown in the Table 32.1. From this calculation, it is possible to understand the

basic nature of each control. It is understood that almost the same yaw rate response is available to any of the FWS, RWS, and DYC and there is no problem to control yaw rate by any of the FWS, RWS, and DYC. The sideslip response transfer function to FWS input has a positive zero; therefore, it is somehow difficult to have an exact model following control of sideslip angle by FWS. The DYC may not be suitable to control the lateral motion or acceleration, because there is a big delay in the lateral acceleration response to DYC input and also, from the practical point of view, the response gain to the moment input is very small compared with the responses to steer inputs, so impractically large input moment would be required for the control. Since the lateral acceleration transfer function to RWS has a positive zero, it is hard to have an exact lateral acceleration model following control by RWS.

There has been a detailed comparison between the effects of DYC and RWS [7–9]. Theoretically speaking, as long as the vehicle motion is considered in a form of two-degree-of-freedom vehicle plane model and the discussion is limited in model following controls of sideslip angle and yaw rate, the same control result is possible by DYC as is possible by RWS. For example, since both transfer functions of sideslip angle and yaw rate to yaw moment as well as to RWS have no positive zero, it is possible to introduce control laws of a sideslip angle or a yaw rate model following control by both DYC and RWS, respectively, just applying an inverse method. Even though it is

certain that RWS and DYC are possible to give us the same vehicle handling response, DYC is not necessarily suitable for the zero sideslip control. If the vehicle sideslip is made zero by the yaw moment produced by the tire longitudinal forces, the sideslip angle of rear wheels becomes smaller and the lateral force cannot sufficiently be generated at the rear wheels. In this case, the front wheels must take care of the lateral force to be balanced with the centrifugal force. Therefore, it will cause imbalance in the duty forces between the front and rear wheels that results in lowering the limitation of the vehicle motion.

The advantage of DYC is proved by the vehicle response to more severe steering input such as on a slippery road or severe lane change with braking. The vehicle motion with DYC still remains stable to such a severe maneuvering, while the vehicle motion with RWS starts spinning out. This is presumably due to the fact that the steering command from RWS control law cannot further generate sufficient lateral force of the rear wheels to control the vehicle motion to prevent the spin. Thus, the effect of DYC compared with that of RWS is more notable in the nonlinear range close to its limit. As long as the motion control depends only on the tire lateral force like RWS, there is a limit, because of the saturation characteristics, to the motion control with a large sideslip and lateral force. We can see that DYC has higher ability and is more effective even in such a near saturation region. Let's imagine a tire friction circle. At a near top or a bottom of the circle where the lateral force (vertical axis) is almost saturated, the margin of the longitudinal force (horizontal axis) is rather larger than that of the lateral force. At that region, using longitudinal force is more reasonable than using lateral force for the vehicle motion control.

The earlier characteristics are proved by using the so-called β-method [10,11] that is based on the relationships of restoring yaw moment to sideslip angle. This is a method to evaluate the vehicle dynamic characteristics by restoring yaw moment produced by sideslip motion of the vehicle. The restoring yaw moment decreases with braking and its excessive reduction makes the vehicle oversteer and causes vehicle spin. The moment increases with acceleration and excessive increase makes the vehicle too much understeer. The method compares how much an improvement can be made by the yaw moment produced by the tire longitudinal forces, that is, DYC and the rear tire lateral forces, that is, RWS, on the deterioration of yaw moment characteristics caused by the acceleration and deceleration. As a result, it is apparent that DYC is more effective and covers a wider range of the sideslip angle. Also the author of [12] has illustrated the effectiveness of DYC by using the moment method proposed by Milliken [13], that is, the relationship of yaw moment generated by tires against the lateral acceleration. He shows the result of the measurement of yaw moment generated against the vehicle lateral acceleration for vehicles equipped with DYC and with RWS using a flat belt-type test machine. The results show that the vehicle with DYC maintains its control up to higher lateral acceleration range.

32.4 INTEGRATED CONTROLS

32.4.1 Integration of ABS/TCS and Steering Control

As is described in Section 32.2, ABS and TCS are not necessarily regarded as a control device for the strategic integrated vehicle motion controls; however, the ill effects of ABS and TCS on vehicle yaw motion can be compensated by FWS, RWS, etc., and [2] deal with the synergism of the combination of ABS with yaw-controlled four wheel steering (4WS). Though ABS can provide to avoid the wheel lock and maintain the tire ability to produce the lateral force during braking, all the wheels of the vehicle cannot be controlled individually because the difference of tire longitudinal forces between right and left especially during braking on μ-split road surface impairs the directional stability. Therefore, the wheels are controlled dependently which results in a longer stopping distance. [2] shows that the combined use of the yaw-controlled 4 WS with the individually controlled ABS can give us shorter stopping distance as well as higher directional stability.

32.4.2 Integration of Front and Rear Steer Controls

As an extension of RWS, there is a concept of the integration of front and rear steer controls. By this combined use of the controls, as there are two control variables, it is obvious that the exact model following control of, for example, sideslip/lateral acceleration and yaw rate simultaneously is possible; however, there is a common shortcoming in FWS and RWS and so much effect of the integration may not be expected.

There is a trial to apply a model matching control by linear quadratic (LQ) method for integrating FWS and RWS controls [14]. In this concept of the controls, the vehicle model used to introduce the control is linear and there is no intentional consideration to solve the problems due to tire nonlinear characteristics, however, the effects of the integrated control that is eventually extended to nonlinear region are found. The control concept can be stated as a simultaneous use of two controls (multivariable variable control) for the model matching control of sideslip and yaw motions.

In order to intentionally cope with the problem due to tire nonlinear characteristics, there is an application of two-degree-of-freedom/H-infinity control to the synthesis of integrated controller of FWS and RWS though the vehicle model used is a two-degree-of-freedom linear one [15]. The controller consists of a feed-forward part and feedback one. Basically feed-forward controller is designed for the vehicle to follow the model responses of lateral acceleration and yaw rate. The feedback controller is designed to improve the robustness of the system against changes in vehicle dynamics presumably due to nonlinear tire characteristics, applying the H-infinity control system design. The frequency responses of an experimental vehicle with the integrated control on a wet road are shown in Figure 32.2. Even maneuvering on a wet road surface, the responses of the vehicle agree with those of the reference model over wide frequency range. Of course the vehicle response characteristics are significantly improved by the integrated control compared with the vehicle without the integrated control. This is recognized in the shape of the frequency response in Figure 32.2 that is very close to the reference model response and fairly far from the well-known lateral acceleration and yaw rate frequency response curves of the conventional vehicle even under wet conditions (Figure 32.2).

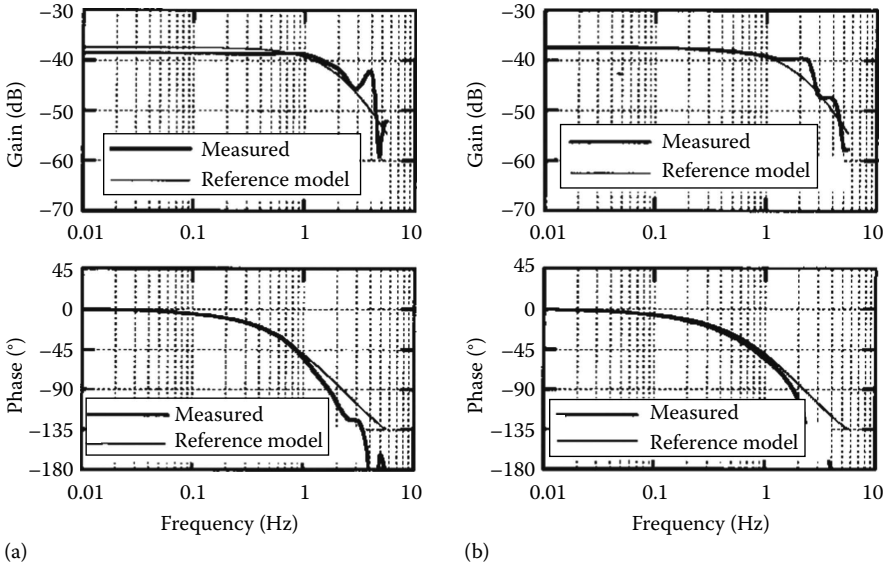

FIGURE 32.2 Integration effects of front and rear active steers by two-degree-of-freedom/H-infinity control. (a) Lateral acceleration and (b) yaw rate. (From Horiuchi, S. et al., *Vehicle Syst. Dynamics*, 25, 275, 1996.)

32.4.3 Integration of Rear Wheel Steer and Front/Rear Torque Distribution of 4 WD

Though the longitudinal force of the tire gives the indirect but significant effects on the tire lateral force, a torque distribution control by differential control of 4 WD cannot directly produce the tire lateral forces. Even an arbitrary yaw moment cannot be produced just by the differential controls. So the control cannot be used for any response model following control and there are few examples of integral use of the control with the other controls.

Even so, there is an application of nonlinear robust control to introducing the integrated control of RWS and torque distribution of 4 WD [16,17]. The control is based on a "two-degree-of-freedom" control system. The feed-forward part is composed only of RWS by solving the linear inverse problem to follow the yaw rate model response. The objective of the feedback part is to stabilize the vehicle in nonlinear regions and is therefore based primarily upon 4 WD control because the effect of the longitudinal force controlled by 4 WD torque distribution on tire characteristics itself is quite significant in nonlinear region. The RWS is also used in the feedback compensator in the linear region. A simple nonlinear tire model, in which the saturation property of the lateral force to sideslip angle and the effects of the longitudinal force on reducing the lateral force of the tire are considered, is used in introducing the feedback control. A strict linearization method is adopted otherwise; as the provided vehicle model is nonlinear, it is impossible to apply a linear control theory to determine the rear wheel steer angle and the front/rear torque distribution ratio. The feed-forward control part of the rear wheel steer in both [16] and [17] is designed to follow a given yaw rate on one hand; H-infinity control in [16] and μ-synthesis in [17] are used to design the feedback compensator, respectively. The effects of the integrated control are prominent as is expected especially in tire nonlinear regions.

32.5 INTEGRATION OF STEER CONTROL WITH ACTIVE SUSPENSION/RDC

A primary objective of active suspension is to improve ride comfort and it does not directly produce lateral forces so that it cannot be used alone to intentionally control the vehicle lateral motion or cannot necessarily be regarded as a strategic device for an integration control with other controls. Nonetheless, there is an example to deal with the synergism between active suspension and 4 WS in a straight running on irregular profile surface roads. Though it is just the combined use, effects are significant. Details are presented in [2] and will not be presented in any detail here.

A balance of the front/rear roll stiffness has a significant effect on vehicle understeer/oversteer characteristics depending on the transversal load transfer during circular turning which reduces the sum of the lateral forces of right and left wheels due to nonlinear relation of tire lateral force to vertical load. Hence, the RDC in active suspension or roll stiffness distribution control, RDC, is regarded as one of the tools for the chassis control; however, the RDC cannot directly produce tire lateral force so that the control cannot be used for any type of model following control as is for a conventional type of controlled 4 WD, and so there are few examples of integral use of the control with the other controls.

There is an example of just an intentionally combined use of RDC with RWS [18]. It is obvious that any type of RWS is inevitable to have the limit due to saturation property of the rear tire that causes the deterioration of the vehicle stability because the rear wheels of the vehicle with RWS must have higher tire work load. Depending upon an intuitive understanding that reducing the roll moment distribution at the rear axle is expected to mitigate this condition, the RDC is used aiming at compensating the drawback of the vehicle with RWS. The roll moment distribution in this example is controlled referring a spin or a drift level measured by the sideslip velocities at front and rear ends of the vehicle. If the driver's will is to increase the yaw rate and the vehicle motion has a tendency toward drift—front sideslip velocity is larger than rear one—then the roll moment is distributed to the rear. If the driver's will is to reduce the yaw rate and the tendency of the vehicle motion is toward spinning—rear sideslip velocity is larger

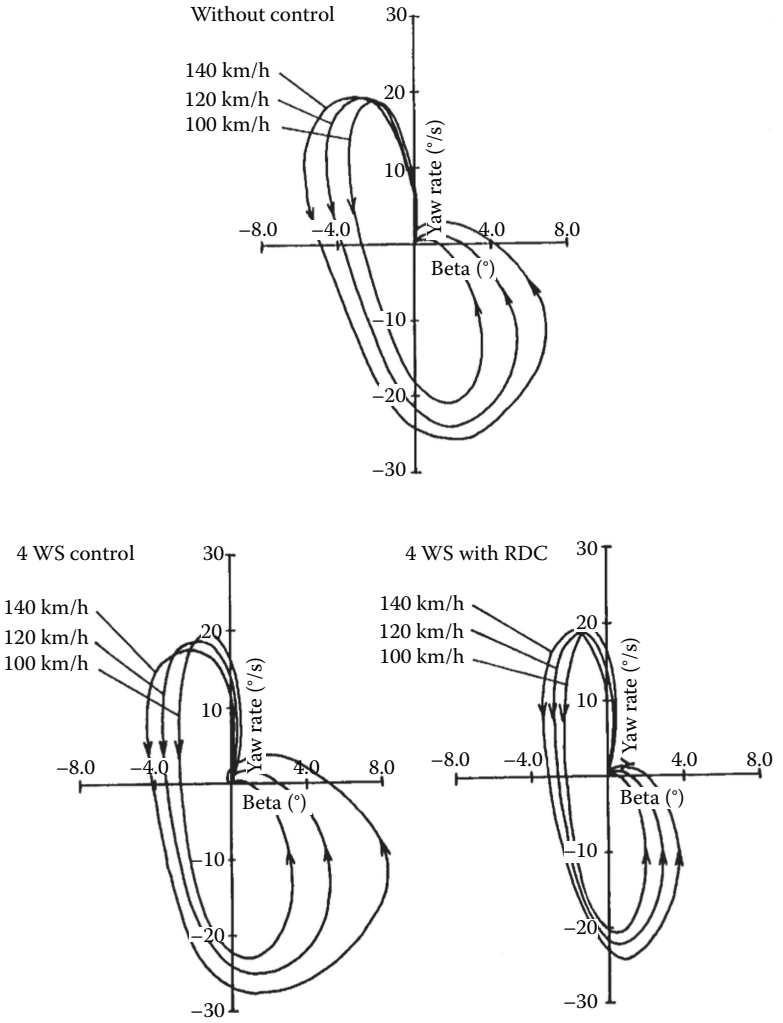

FIGURE 32.3 Effects of the integration of RDC and 4 WS. (From Abe, M., *JSAE Rev.*, 12(3), 42, 1991.)

than front one—then the roll moment is distributed to the front. The control law of the RWS considered here is that the rear wheel is steered proportionally to the front steer angle so that the steady-state sideslip angle equals zero. The results are shown in Figure 32.3 and summarized by the sideslip and yaw rate response state plane to single sine-wave steer input. It is found that the RWS alone does not necessarily give the vehicle motion with smaller sideslip or reduce spin tendencies in the vehicle motion with high lateral acceleration. It is obvious, however, that the combination control with the RDC can eliminate large sideslip angle and reduce the spinning tendency at the latter part of the single sine-wave steer input, though the stand-alone use of the 4 WS brings us the vehicle motion more liable to spin at high speed rather than even the conventional vehicle without the 4 WS.

Reference [19] presents more strategic and theoretically more sophisticated examples of the integrated controls of the steer controls and RDC. Three control input variables—front and rear steer angles and roll moment distribution ratio—are adopted and the nonlinear vehicle model is provided especially considering tire nonlinear characteristics. In order to apply a linear control theory, the vehicle model is exactly linearized by nonlinear transformation from three input variables to two pseudo-inputs, in which the linearized vehicle includes perturbations in the front and

rear cornering stiffness. The control law of two pseudo-inputs is designed using "two degree of freedom" control system and the feed-forward part is designed by model matching method; on the other hand, feedback part is designed by applying μ-synthesis. The roll moment distribution ratio is determined to minimize the square sum of the front and rear tire sideslip angles and the difference of the distribution ratio from 50/50, in which both sideslip angles are functions of predetermined two pseudo-input variables and the roll moment distribution ratio. The effects of the integrated control are prominent especially in tire nonlinear region under low-friction road surface.

Reference [20] is an additional example of combined use of RDC with an active drivetrain for variable torque distribution at a center differential, a kind of controlled 4 WD. The RDC controller is a yaw rate model reference PI controller and a variable torque distribution control is based on a sideslip angle feedback PI controller. In the combined control, the center differential just distributes the torque to front and rear with the same ratio as the roll moment distributed by RDC; however, the benefits of the combined control as well as the insight behind the integration strategy are not necessarily clear.

32.6 INTEGRATION OF STEER CONTROL(S) AND DYC

As is discussed in Section 32.2, not only steer controls (FWS and RWS) but also DYC is one of the promising components for the integrated controls, because it is a more effective vehicle control in nonlinear regions. Hence, there are many approaches to the integration of steer control(s) and DYC.

There are trials to apply a model matching control by LQ method for integrating steer control(s) and DYC [21–23]. They are simultaneous use of two or three control variables (multivariable control) for the model matching control. As is the same in the case of the introduction of the integration of steer controls—FWS and RWS in Section 32.4.2—the vehicle models used to introduce the controls are linear and no consideration to intentionally deal with the problems due to tire nonlinear characteristics is found in this strategy of the combined control. However, again the effect of the integrated controls that is extended eventually under nonlinear region is found.

In order to intentionally overcome the problem due to tire nonlinear characteristics, there are applications of the nonlinear predictive controller design for the reference model following control to introducing the integration of steer control(s) and a full DYC [24,25]. A nonlinear nominal vehicle model is assumed from the beginning in this controller design, and the theory for continuous time nonlinear predictive control is used for designing the integrated control. The effects of the integration are investigated by the simulations. An example of the simulation results is shown in Figures 32.4a and b in which it is clear that the vehicle response with the integrated control is closest to the reference model response in yaw rate as well as in sideslip angle compared with the responses with other controls.

As is described in Section 32.2, it is obvious that the RWS is effective rather in a linear range of vehicle motion; on the other hand, the DYC is more effective in a nonlinear range so that there is a simple and intuitive approach to the coordination strategy of FWS and DYC [26,27]. This approach in coordinating the two controllers is that FWS is used to improve the vehicle handling properties at low- to mid-lateral accelerations and the DYC is only used when the stability limit of the vehicle is approached. Both controllers are designed based on stand-alone controller design and a rule-based integration scheme is developed to coordinate the two stand-alone control systems. The rules are the product of investigations carried out empirically in simulation and are to distribute the control demands to the two individual controls. Though the integration strategy could be reasonable, the substantial effects are not necessarily clear so far.

Another integration approach to deal with the problems due to tire/vehicle nonlinear characteristics and compensate for drawbacks of the stand-alone using each active control is to

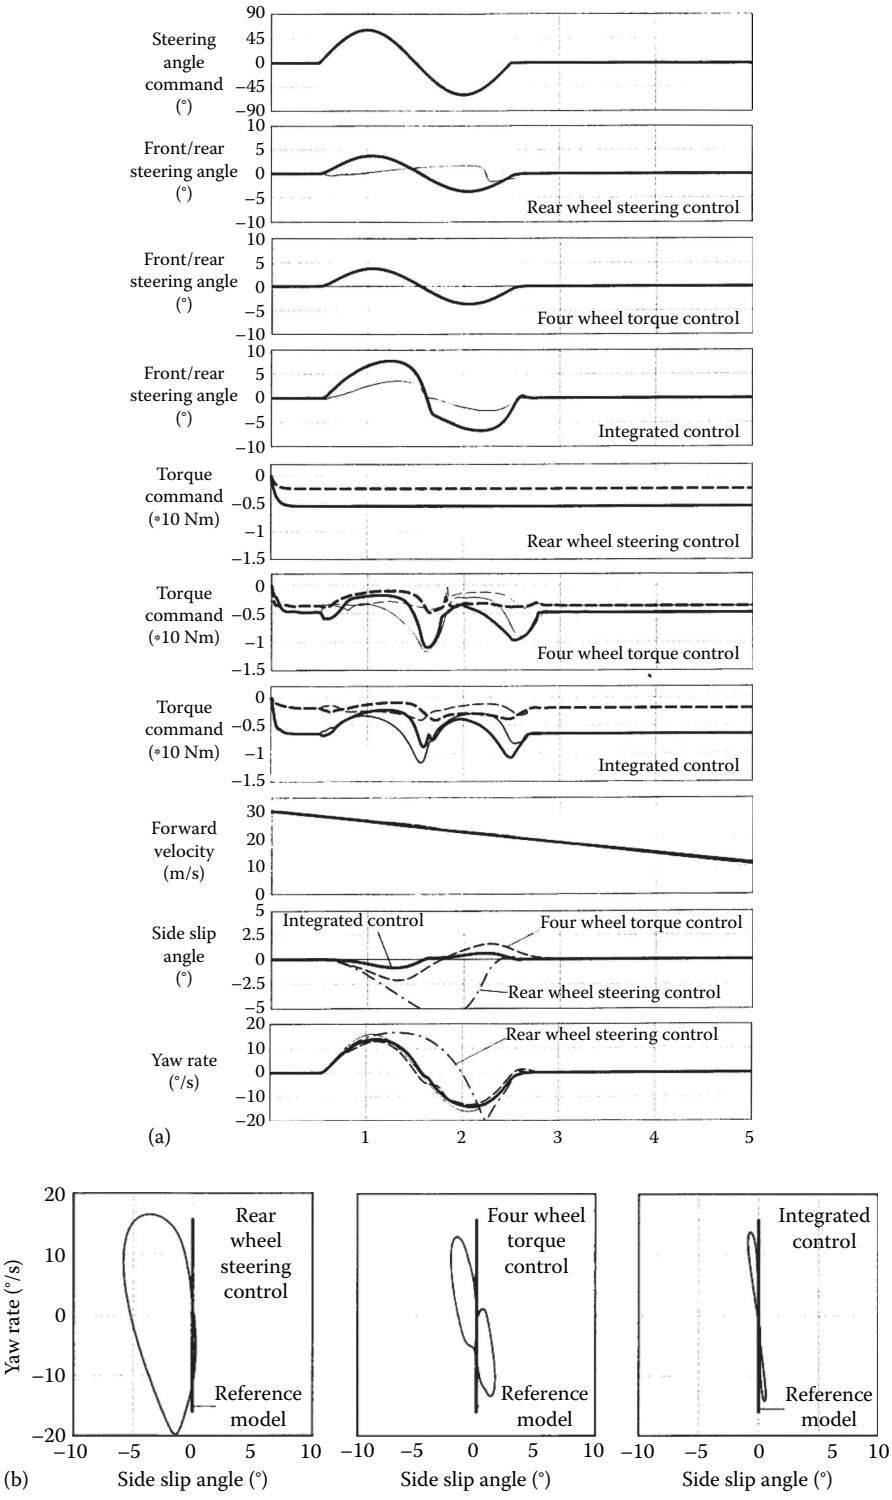

FIGURE 32.4 (a) Effects of the integrated controls on vehicle responses to sine-wave steer input with braking. (b) Effects of the integrated controls on vehicle response on state plane. (From Horiuchi, S. et al., *Vehicle Syst. Dynamics*, 33, 680, 1999.)

apply a sliding control type of nonlinear model following control to integrating steer control(s) and DYC [28–30]. A simple nonlinear tire model in which the saturation characteristics of lateral force to sideslip angle as well as the effects of longitudinal force on reducing lateral force with friction circle concept and the nonlinear dependence of lateral force on vertical load are considered appropriately is used in the controller design. As the intended integrated control has more than two control variables, the exact model following control of, for example, sideslip and yaw rate simultaneously is possible. In this approach, the sideslip and yaw rate responses of the two-degree-of-freedom vehicle model with linear tires are adopted as reference model responses.

Then it is expected that basically no active control is required so long as the vehicle motion remains in a linear range so that the primary objective of the integrated control eventually turns out to keep the vehicle response in a linear region as if it were monitoring how much the vehicle motion is nonlinear at each moment by using the simple nonlinear tire model. The model following error in sideslip angle is taken as a sliding surface and the first-order lag of the error equal to zero is taken as a sliding condition. From this condition it is possible to calculate a total lateral force required to follow the model sideslip response using the fact that the lateral force required is a product of vehicle mass and the required lateral acceleration.

The model following error in yaw rate is also taken as another sliding target and the first-order lag of the error equal to zero is again taken as a sliding condition. From this condition the total yaw moment required to follow the model yaw rate is led because the first-order derivative of the required yaw rate is the yaw moment required.

By using the simple tire model mentioned earlier, the active front and/or rear steer angle(s) to satisfy the calculated total lateral force and the yaw moment to be produced by longitudinal tire forces, DYC, is calculated so that the total yaw moment to be produced by tires is equal to the required one. In the case of the integrated control by FWS, RWS, and DYC, there are three control variables available and at least two control variables are enough to follow the model responses of sideslip and yaw rate. Therefore, the additional condition is added to share the total tire lateral force required between front and rear wheels proportionally to the vertical load of the tires in the controller design. At the same time, sideslip angle of the vehicle to be estimated by using the simple tire model is needed for the controller design because a direct measurement of it is difficult.

The effects of the integrated controls are proved by simulations with the full vehicle model. Responses to single sine steer input with braking are shown on the state plane in Figure 32.5 in which both integration controls of DYC + FWS + RWS and DYC + FWS show almost the same good results. On the other hand, if the model response of the sideslip angle is changed to the response that is the same response as the normal linear vehicle model at transient period converges to zero at steady state, then the results are changed as shown in Figure 32.6. The results show that the RWS is essential in the integrated control if the reduction of sideslip response, sometimes equal to zero, is required. You can refer back again to Table 32.1 on how the sideslip responses are to FWS, RWS, and DYC, respectively.

Reference [31] is another type of integration of RWS and DYC (or VDC) with roll control to be referred in which H-infinity integration as well as an intuitive integrated chassis design are dealt with.

32.7 INTEGRATED CONTROLS AIMING AT OPTIMUM TIRE FORCE DISTRIBUTION

The integrated controls will have multiplevariables for the control so that, as is described earlier, the target vehicle motion or performance is rather easier to be obtained by, for example, any type of possible model following control. Therefore, the problem is rather how much workload the tires have during working to keep the vehicle behave as given model response. Then the motivation arises to use each tire reasonably within a limit in the integrated control, which is expected to result

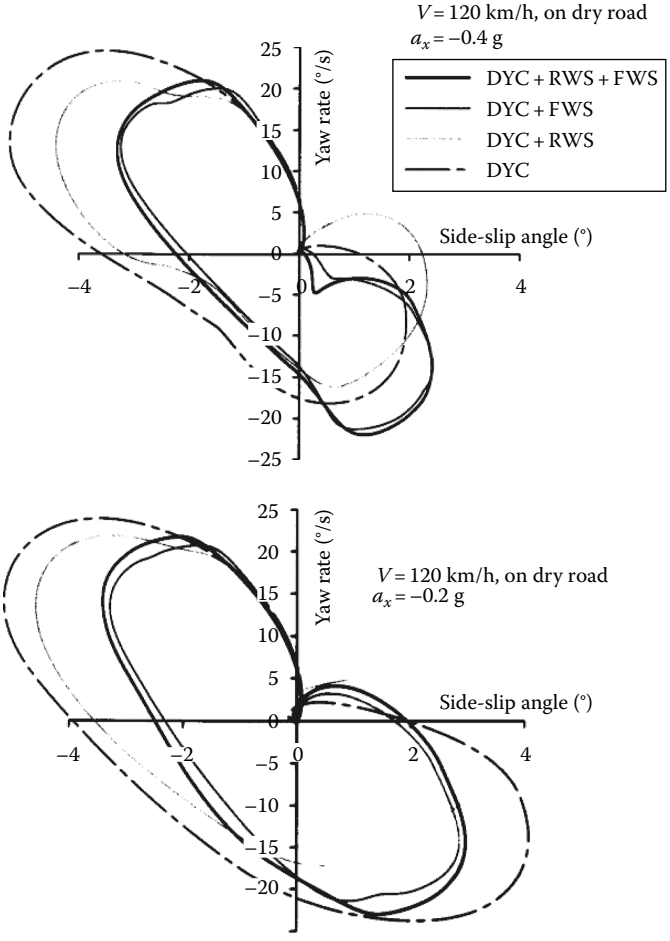

FIGURE 32.5 Effects of the integrated control on vehicle responses on state plane. (From Mokhiamar, O. and Abe, M., *Vehicle Syst. Dynamics*, 37, 246, 2002; Mokhiamar, O. and Abe, M., *Proc. IMechE Part D J. Automobile Eng.*, 216, 115, 2002.)

in solving the problems due to tire nonlinear characteristics and compensating the drawback of the stand-alone use of the chassis controls. It could be said that one of the generic strategies of the integrated controls is to distribute lateral and longitudinal forces to each tire to optimize the tire performance and obtain the required vehicle response. Of course the earlier idea rests on the premise of full drive-by-wire vehicle in which all the wheel steer angles and wheel torques are controlled independently to distribute lateral and longitudinal forces to each tire.

It is possible to mention the two important contributions [32,33] to the integrated controls in terms of the earlier text. An estimation of tire grip margin that is equivalent to friction coefficient between tire and road surface sensed the self-aligning torque of each tire is the basis of the control strategy in [33]. Based on the analysis of a physical tire model, it is assumed that a ratio of the measured self-aligning torque to a virtual self-aligning torque proportional to sideslip angle is equivalent to the margin of the tire lateral force. The following definition of the tire workload rate is adopted:

$$\gamma_i = \frac{\sqrt{X_i^2 + Y_i^2}}{\mu_i Z_i} \tag{32.1}$$

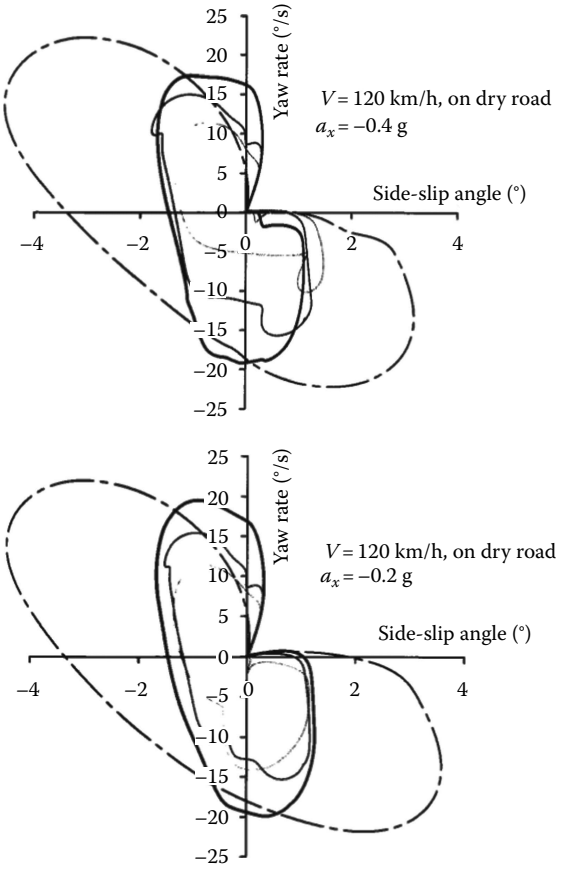

FIGURE 32.6 Effects of the integrated control of zero sideslip model response on vehicle motion. (From Mokhiamar, O. and Abe, M., *Vehicle Syst. Dynamics*, 37, 246, 2002; Mokhiamar, O. and Abe, M., *Proc. IMechE Part D J. Automobile Eng.*, 216, 115, 2002.)

where

X_i, Y_i, and Z_i (i = 1–4) are longitudinal and lateral forces and vertical load of each tire, respectively

μ_i is the friction coefficient between tire and road surface

A kind of nonlinear optimization technique, SQP (Sequential Quadratic Programming), provides the optimum distribution of the tire forces by keeping each γ_i to be equal and minimizing it under the constraints that the total lateral and longitudinal forces and the total yaw moment produced by tires satisfy the required target force and moment of the vehicle motion such as mentioned in Section 32.4.5. Once the lateral and longitudinal forces of each tire are determined, the steering and the traction or braking command are applied to each tire actuator to produce them. The effects of the integrated control are proved with the computer simulation. Additionally experimental investigations are carried out to validate the estimation of tire grip margin on icy road and also to prove the effects of the control applying only to the best balancing brake control of four wheels.

Other than the earlier, one of the possible approaches to the optimization of the tire performance is to minimize the square sum of tire workload expressed by

$$J = \sum_{i=1}^{4} C_i \frac{X_i^2 + Y_i^2}{Z_i^2} \tag{32.2}$$

where, C_i is a weighting coefficient and normally set equal to 1.0 [34,35]. This criterion of the tire performance optimization is basically the same as is adopted as Equation 32.1 in [33].

In order to guarantee the vehicle response to follow the model response described, for example, in Section 32.4.5 or whatever it is, a total lateral force of the tire must be equal to the target value to follow the sideslip model response and a total yaw moment produced by the tire forces must be equal to the target value to follow the yaw rate response. In addition to this, a total longitudinal force of the tire must be satisfied to reflect the driver's will of longitudinal speed control that is translated from brake or acceleration pedal pressure/stroke to longitudinal acceleration requirement. They are regarded as three constraints among the variables for the tire performance optimization and J is an objective function of the eight variables, X_i and Y_i (i = 1–4); thus, finally we can have the optimization problem with five variables without constraint. Applying the minimizing conditions, which are partial derivatives of J to the five variables equal to zero, to the objective function, it is easy to get a simple form of linear algebraic equation with five variables. Because the objective function is a second-order equation of the variables, the partial derivative of the function becomes always linear functions.

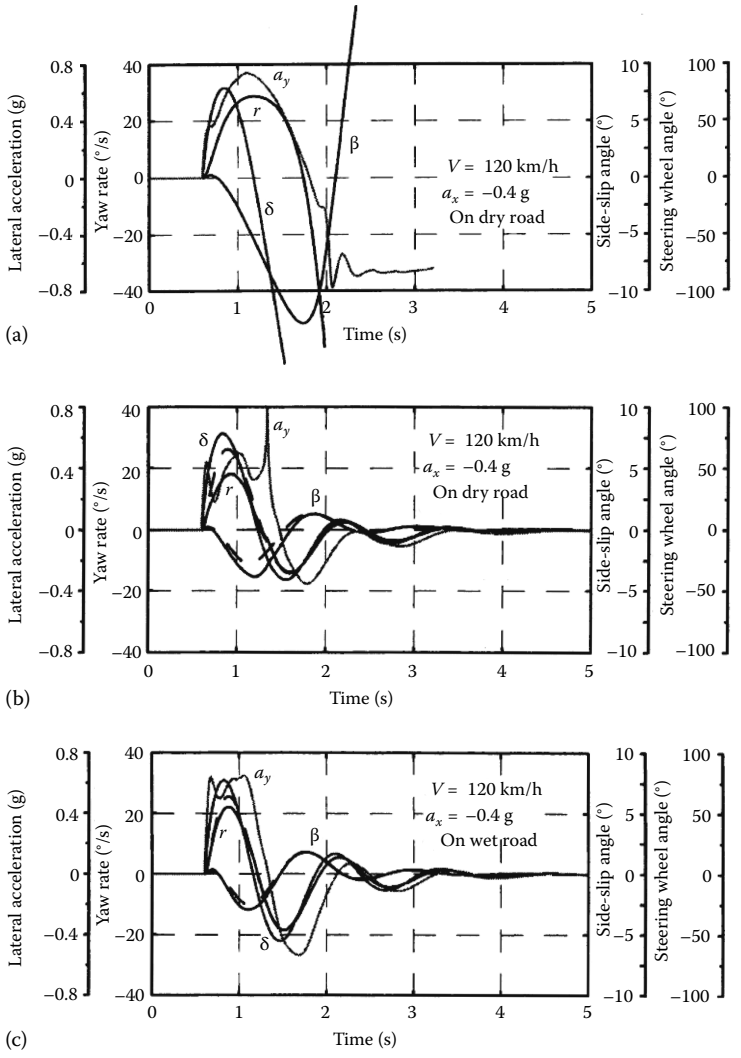

FIGURE 32.7 Effects of the integrated control on evasive lane change performance on dry road (a) Without control, (b) DYC + FWS + RWS, (c) Optimum tire force distribution. (From Mokhiamar, O. and Abe, M., *Trans. ASME, J. Dynamic Syst. Meas. Cont.*, 126, 753, 2004.)

Solving this algebraic equation at each time step brings us the optimum tire lateral and longitudinal forces to be distributed to each tire. This approach to the integrated control rests on the premise of full drive-by-wire system in which all the wheel steer angles and wheel torques are controlled independently. Thus once X_i and Y_i are determined, a torque of each wheel is given by $T_i = R_i X_i$ (R_i is a wheel radius) and a steering angle of each wheel δ_i is determined by using the simple nonlinear tire model mentioned in Section 32.4.5.

A computer simulation of the evasive lane change has validated the significant effects of the integrated control. The results are compared with the case of the integrated control of DYC + FWS + RWS mentioned in 32.4.5 and shown in Figures 32.7 and 32.8. The effect of the integrated control proposed is quite prominent especially in severe maneuvering conditions. However, the effects of the control on μ-split road surface are behind the effects brought by the integrated control introduced in [33] because the friction coefficient (tire grip margin) estimation is not taken into account [36]. Also it should be pointed out that it is possible to regard Z_i ($i = 1$–4) in the objective function J as variables to be controlled by the RDC with some constraints, though the problem becomes a strongly nonlinear optimization problem.

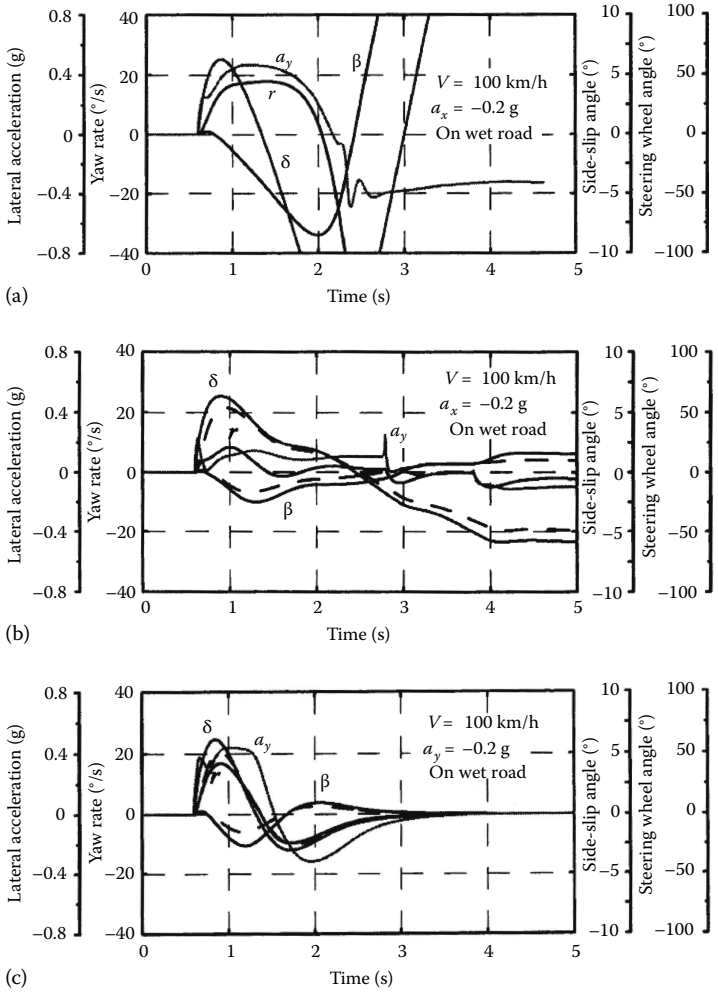

FIGURE 32.8 Effects of the integrated control on evasive lane change on wet road (a) Without control, (b) DYC + FWS + RWS, (c) Optimum tire force distribution. (From Mokhiamar, O. and Abe, M., *Trans. ASME, J. Dynamic Syst, Meas. Cont.*, 126, 753, 2004.)

32.8 CONCLUSIONS

A recent trend of the integrated controls is surveyed. An emphasis is laid on that the combination or coordination/cooperation of two or three chassis controls is expected to deal with the problems due to nonlinear tire and vehicle characteristics and to compensate the drawback of the stand-alone use of each control. Putting this viewpoint at the center, some details of typical integrated controls have been presented. It could be said that a future target of full drive-by-wire system is an ultimate integrated vehicle motion control system and the optimum use of the tires for getting required vehicle motion is the top priority for the integrated control. It is a control using tire forces in three directions arbitrarily for vehicle longitudinal, lateral, and vertical motion control depending on driver's three maneuvering commands *running, curving, and stopping.* A further research and development focusing on this direction especially from the practical point of view is recommended.

33.1 INTRODUCTION

The dynamics of heavy trucks, or heavy commercial vehicles as they are called in the ISO vocabulary, has obviously many similarities with the dynamics of passenger cars. There are however also some differences. This is due to the different areas and ways of use that call for different designs. While passenger cars are made to transport one or two or sometimes more people that often amount to less than 10% of the gross weight, trucks are made to transport as much goods as possible, with respect to weight or volume, within certain given weight and dimension limits [1].

One major difference is that heavy trucks, due to the laws of nature, are bound to roll over unless the driver is avoiding to exceed a certain lateral acceleration limit. Normally, passenger cars do not roll over, unless they are tripped, because the tires will saturate and start sliding long before

a sufficiently high lateral acceleration is reached. Exceptionally, however, it may occur in special maneuvers, like the so-called fishhook maneuver, with certain vehicle categories.

Another major difference is that heavy commercial vehicles and buses are quite often articulated with one or several articulation joints. This certainly makes the dynamics much more complex, as vehicle combinations have oscillatory modes that are excited in various maneuvers.

A third important difference is that, while passenger car chassis are fairly stiff with respect to torsion and bending, heavy commercial vehicles are normally not. This may have large effects on the dynamic behavior of the truck in various areas.

Although this chapter primarily deals with heavy trucks, much of the content also applies to heavy buses. Less research was carried out on heavy trucks and buses than on passenger cars, but there are still a large amount of papers dealing with various aspects of heavy vehicle dynamics [2] and also on more basic theories and surveys [3,4].

33.2 HISTORIC RETROSPECT

One could argue that much has not happened in the basic design of trucks since the middle of the last century. Trucks still have air-filled rubber tires, rigid axles, ladder frame with a cab on, some type of superstructure, and an internal combustion engine as on the Danish triple combination in Figure 33.1, with four articulation joints, from the late forties, transporting goods between Denmark and Germany.

This is true, but each of these systems has undergone a tremendous development, and the performance is so much better. There has been no revolution but rather an evolutionary process with continuous development. Figure 33.2 shows a Volvo Titan, which was still modern when the author

FIGURE 33.1 Old Danish triple combination.

FIGURE 33.2 Volvo Titan from 1954.

started his career at Volvo. It is a beautiful truck, belonging to Volvo's Veteran Truck Club, but it does not take a long ride to appreciate that the dynamic behavior is very far from a modern Volvo. It is definitely not as comfortable as it is beautiful.

The amount of transported goods has increased tremendously during the last half century. It has increased not only nationally but also, above all, internationally. This has resulted in that each vehicle is carrying more goods. The vehicles have become more specialized, and more weight optimized in order to be competitive. Also the engine performance has increased very much, giving higher average speeds. The demands on good ride for the driver as well as for the payload have been growing. So have the requirements on a high degree of availability of the truck. The traffic intensity is steadily increasing and this has put the active safety of the vehicles in focus. All these factors call for increasing vehicle dynamics considerations.

An interesting question is what factors are driving the development. The market is of course one. If there are no buyers of new developments, they will not take place. It is often said that the customer is always right, and that is true in one sense. It is however not entirely true, because the customer can only judge what already exists and is not always capable of assessing new features that may be very good. Another driver of the development is the company, the truck producer, and its core values. This is very important and assumes of course that the company is interested in driving the development in a certain direction and not only in making money. Finally, legislation and regulation may be an important driver, provided that the regulations are good regulations. If this is not the case, they may be counterproductive [5].

33.3 VIBRATION ENVIRONMENT

The vibration environment in a vehicle travelling on a given road at a given speed depends entirely on the dynamics of the vehicle. Good vibration environment means low dynamic forces and low acceleration levels. There are a number of aspects on the vibration environment, illustrated in Figure 33.3. The driver's vibration environment, the ride, is perhaps the most obvious, maybe because the driver can express what they perceive. It may also be the most important one, because human injuries, caused by vibrations, can rarely be repaired. Other aspects of vibration environment are related to the load, the vehicle structure, and the infrastructure [6–8]. The consequences of bad vibration environment for the driver may in the worst case be injuries from long-term exposure or fatigue decreased proficiency, detrimental to the traffic safety. The consequences for the cargo may be damages if the goods are sensitive. The infrastructure may suffer from increased wear and the vehicle structure from reduced fatigue life.

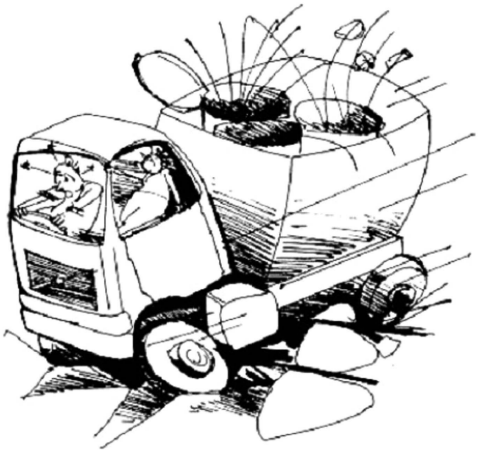

FIGURE 33.3 Consequences of bad vibration environment.

33.4 ACHIEVEMENTS

Large achievements have been made with respect to all four aspects of vibration environment mentioned earlier [9]. The most important is the improvement of the vibration environment for the driver, that is, in the cab. The reason for this is that if it is done in a clever way, the vibration environment for the rest of the vehicle, the load, and the infrastructure will also be improved as a spin-off effect. A clever way means that the dynamic forces shall be reduced as close as possible to their source, that is, in most cases the road. Another reason is of course the humanitarian aspect. There is absolutely no reason to accept that drivers should spend their working life in a miserable vibration environment. The current situation is not so bad, even if it varies throughout the world. The best trucks today offer a vibration environment close to that of a good passenger car.

A lot of research was carried out for many years concerning the effect of vibrations on the human body and how people perceive vibrations (see Chapter 36 of this book). It is a question of both amplitude and frequency. The human body is more sensitive in certain frequency ranges than in others. The reason for that is that the body may be seen as a biomechanical vibrating system. This is possible to model and the various body parts may then be seen as masses, springs, and dampers. The body has a number of resonances at which it has its highest sensitivity. For vertical whole-body vibrations, the maximum sensitivity is in the frequency range 4–12.5 Hz, and for horizontal vibrations, it is in the range 0.5–2 Hz. The way to measure, analyze, and assess whole-body vibrations is standardized, and the first edition of ISO 2631, appeared in 1974. It has since then been revised a couple of times. The evaluation is based on frequency-weighted root-mean-square (RMS) accelerations in three directions. The weighting filters have been discussed a lot and there have been many opinions concerning their shape. The present ISO filters are probably a good compromise, and since the sensitivity among individuals varies, there is no absolute truth [10]. Figure 33.4 shows asymptotic approximations of the weighting curves. *Wd* is the curve for horizontal accelerations and *Wk* the curve for vertical accelerations.

There is a growing attention from society on the potential risk with vibration exposure. Since 2002, there is a directive in the European Union concerning limits for whole-body and hand-arm vibrations, and it is now being implemented in national regulations [11]. For whole-body vibrations, there are two limits for 8 h exposure time. One is an action value of 0.5 m/s^2 and the other is an exposure limit of 1.15 m/s^2. These values are weighted RMS accelerations, in accordance with ISO 2631, measured over the whole 8 h working day. The important shortcoming with only using wideband RMS values is that these assume more or less stationary vibrations and do not take

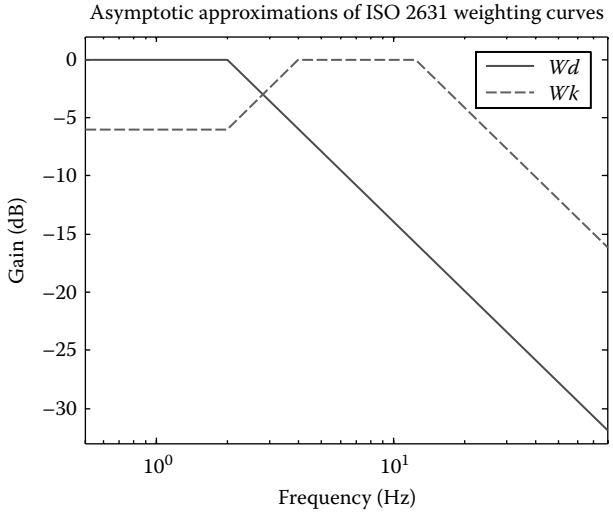

FIGURE 33.4 Weighting curves for horizontal (*Wd*) and vertical (*Wk*) accelerations.

shocks and transients into account. This new directive will anyhow put the vibration environment in focus and will probably drive the development.

The effect of heavy vehicles on wear and damage of the infrastructure has been studied in many large research projects lately. It is well known that the static axle load has a major influence and much of the research was focused on the effect of dynamic axle loads. This resulted in a definition of the so-called road-friendly suspensions, friendly in the sense that they provide low dynamic wheel forces. To fulfill the requirements for road friendliness, the dominant eigenfrequency, obtained when the axle is excited with a step input, must not exceed 2 Hz, and the relative damping must be at least 20%. In practice, this demand is difficult to reach without air suspension. In order to promote road-friendly suspensions, existing regulations use incentives like increased gross weight or axle load. Although the definitions may be discussed, it is basically a good way of using regulations [12–15].

33.5 SUSPENSION SYSTEMS

The key elements for a good vibration environment are well-functioning suspension systems. In heavy trucks, there are several important systems. Starting from the ground, there are the tires, the chassis suspension front and rear, the frame, the engine suspension, the cab suspension, and sometimes a seat suspension. They are all there to provide vibration isolation. It is important that they are matched together from the start. If not, the risk for suboptimization is obvious. Figure 33.5 illustrates the principal isolating effect of the various suspension systems.

The lower the rigid body eigenfrequencies are, the better the potential for good vibration isolation is. This is because the road input is basically broadband random excitation. There are three basic characteristics of suspensions: stiffness or compliance, damping, and space or spring travel. The lower the stiffness, the more compliant the suspension is, and the better the vibration isolation. In other words, the softer the suspension, the better it is. But in order to be able to make a soft suspension, there must be enough space. This is a law of nature and may not be violated without severe punishment. The punishment consists of transients, due to bottoming, when the road gets rougher. The third characteristic is damping. It is necessary to dissipate energy and limit the amplitudes at resonance frequencies. There is an optimum value of the damping that gives minimum vibration response. It is also important to minimize low-frequent movement both vertically and in particular in roll in order to get a feeling of good control. By using nonlinear damper characteristics in a clever way, it is possible to damp these slow, large movements without interfering too much with the vibration isolation, that is, to achieve good control without harshness and bumpiness. Principally it is better to have a low spring rate with high damping than a higher spring rate with less damping (see Chapter 8).

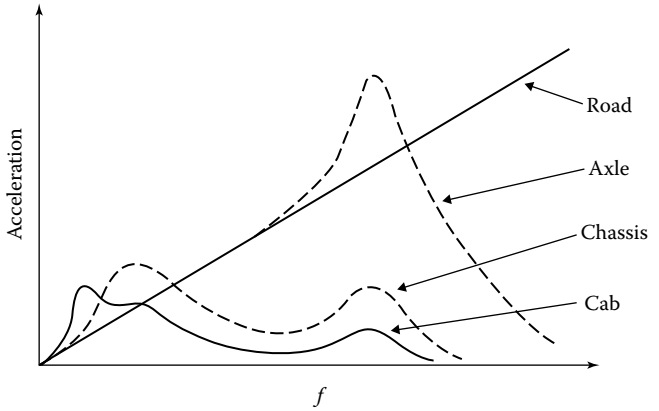

FIGURE 33.5 Vibration isolation effects of various suspension systems.

33.5.1 Chassis Suspension

Damping shall ideally be viscous, but some spring elements, for example, leaf springs, have more or less inherent friction, which also provides damping due to the hysteresis. The friction does however not only provide damping but also stiffness, especially at small amplitudes. Figure 33.6 shows the behavior of a leaf spring. It can be modeled with a model developed at University of Michigan Transport Research Institute (UMTRI) that has an upper and a lower stiffness envelope and an exponential approach to the envelopes. The rate of the approach is described by a special parameter [16].

The friction causes a phase shift between force and displacement, which introduces equivalent viscous damping. The equivalent viscous damping and stiffness of a leaf spring with coulomb friction may be estimated from experiments, where the spring is excited with realistically shaped noise. The results are obtained in the frequency domain. Figures 33.7 and 33.8 show damping and stiffness for three excitation levels as a function of the excitation frequency. It appears that both damping and stiffness are higher for low excitation levels. This implies that the leaf spring is acting as a much stiffer spring on good and medium roads. The nominal spring rate is obtained only on very rough

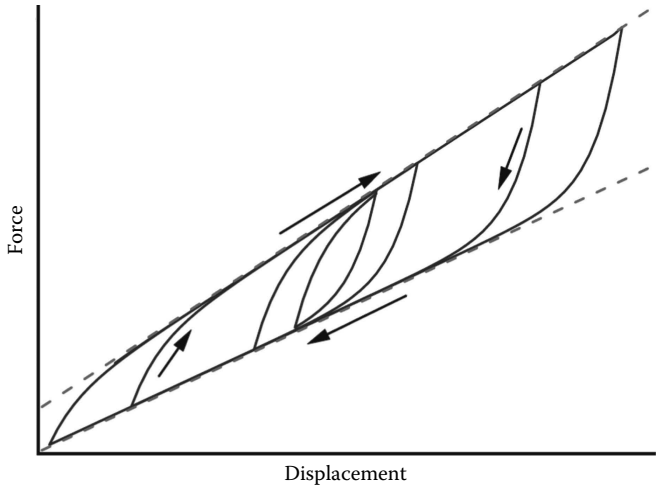

FIGURE 33.6 Characteristics of a leaf spring.

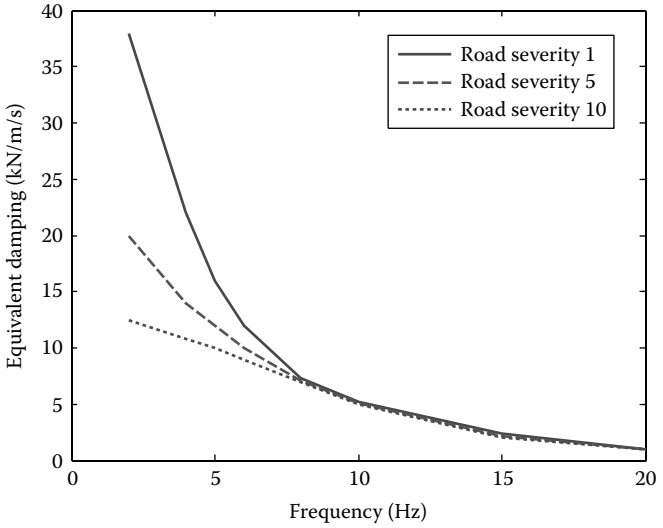

FIGURE 33.7 Equivalent damping of a leaf spring.

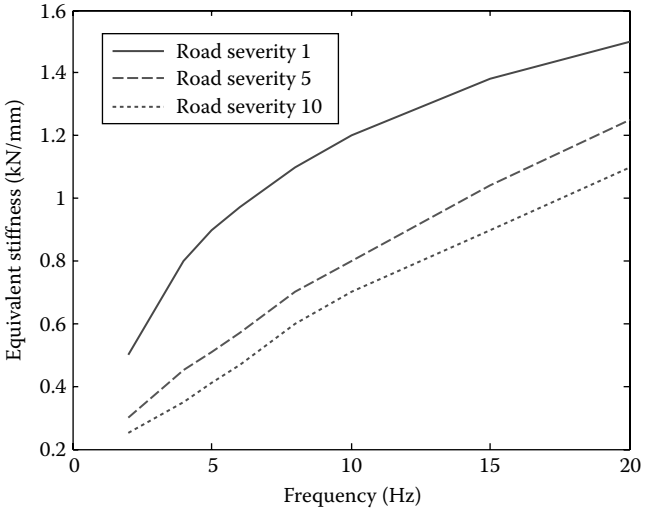

FIGURE 33.8 Equivalent stiffness of a leaf spring.

roads at low frequencies. While the damping is decreasing with frequency, the stiffness is increasing. The reason for this is that the leaf spring may be regarded as having stiffness not only in parallel with a viscous damper but also in series (see the Cab Suspension Section 33.5.2).

The friction impairs the ride significantly on good roads, but on rough roads, it affects less. One positive effect is however that the low-frequent movements are more efficiently damped, which improves both the vertical and the roll control. It is thus important to avoid and reduce friction in suspension systems. For leaf springs, this may be achieved by putting rubber spacers between the leaves. This is of course only possible on parabolic springs, as the one shown in Figure 33.9.

One characteristic of heavy trucks is the large load variation between laden and unladen condition, especially on the rear axles. This is a limiting factor for low spring rates of mechanical suspensions without level control. On front axles, however, the difference is rather small, and it is possible to use soft suspensions without leveling systems. This is one reason for still using leaf spring suspensions on the front axle of high-performance trucks. With high-quality steel, it is possible to make leaf springs with sufficiently low stiffness with few leaves. The spring rate range expressed as eigenfrequency of a quarter car model is thus different in front and rear for mechanical suspensions. Front suspensions are in the range 1.3–1.8 Hz, while rear suspensions have frequencies in the range 2–3 Hz.

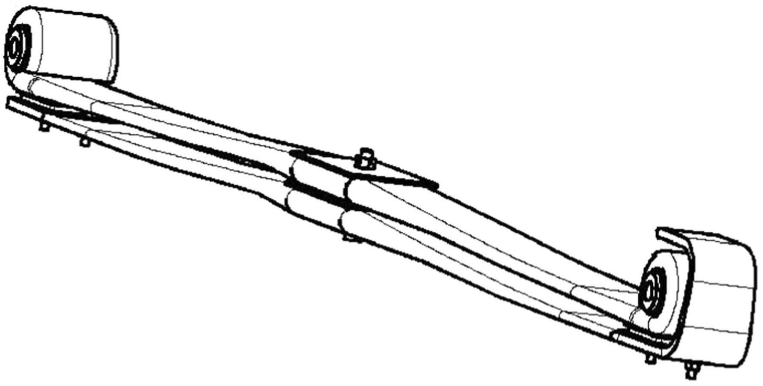

FIGURE 33.9 Parabolic leaf spring with rubber spacers.

An axle suspension shall provide both vertical compliance and roll stiffness. If these two features are not separated, but provided by the same spring element, it will usually end up in a poor compromise. The vertical stiffness will be too high and the roll stiffness too low.

Air suspensions were introduced in the 1980s and have since then gradually taken over most of the market on long haul trucks, at least on rear axles. There are a number of advantages with air suspensions. One is the built-in leveling, which keeps the vehicle at a constant ride height and facilitates load handling, for example, of swap bodies. Another big advantage is that air suspensions easily provide low spring rates, and due to the leveling system, it is possible to have low spring rates. A third one is that air springs with constant air volume provide spring rates proportional to the load, which gives a constant eigenfrequency and as a consequence good vibration isolation also in partly laden conditions. A fourth one is that the friction and the parasitic stiffness are normally very low in air suspensions. The negative aspect is that air suspensions are more expensive than leaf spring suspensions. The eigenfrequency range for air suspensions is 1–1.5 Hz.

Figure 33.10 shows a Volvo 6 × 4 rear air suspension, also available as 6 × 2 and 4 × 2. The axle is controlled by two longitudinal reaction rods and one V-stay. The axles can move vertically and in roll. The absence of pitch rotation prevents driveline vibrations. Vertical and roll stiffness are separated. Four air bellows provide the vertical stiffness, while the roll stiffness is obtained by a stabilizer.

Damping of the suspension is very important. Old trucks relied entirely on friction damping, but to achieve a good vibration environment, the damping should be viscous. Ideally the dampers should only damp the resonances, but as the damp forces depend on the relative velocity and not the frequency, this is not possible. Therefore, the dampers do not only damp the resonances but also increase the force transmission for frequencies between resonances. It is therefore necessary to optimize, tune, the damp characteristics with respect to various demands on vibration environment and handling. Modern passive dampers have good possibilities to adjust the forces. It is usually possible to shape the damp characteristic within three velocity ranges. Figure 33.11 shows an example of a damper characteristic. The compression forces are normally much lower than the expansion forces in order to reduce the force transmission into the vehicle. Too low compression forces on the other hand reduce the control or "stability" of the vehicle. The forces at very low velocities, below 0.05 m/s, are important for the control, both in roll and vertically, and a high damping rate is advantageous. Damping characteristics are usually very degressive in order to reduce bumpiness. The forces at high and medium velocities shall not be higher than is required to damp axle resonances.

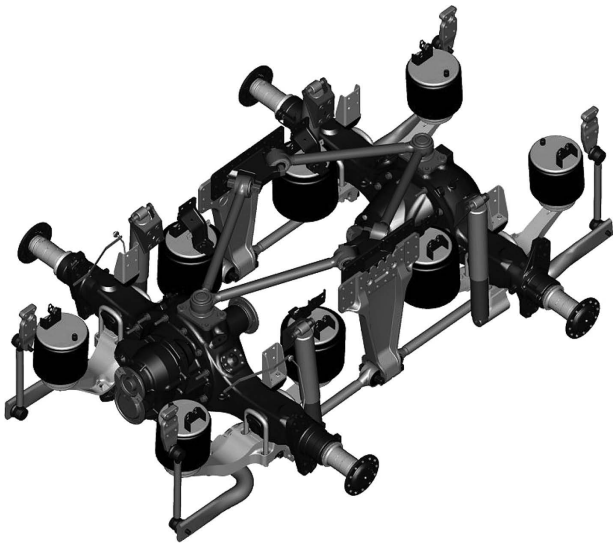

FIGURE 33.10 6 × 4 rear air suspension with reaction rods and V-stays.

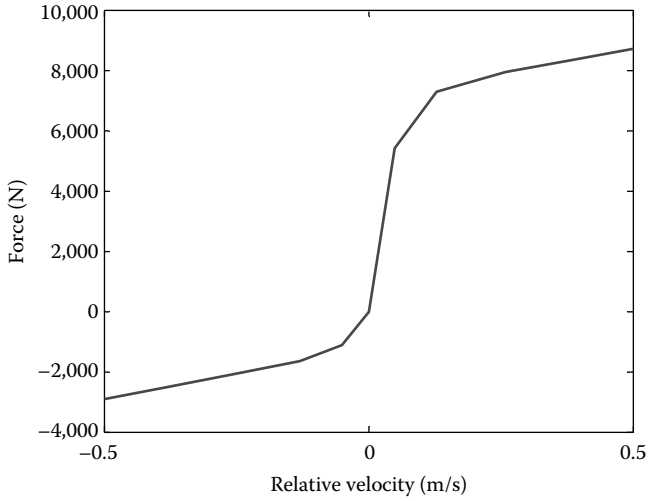

FIGURE 33.11 Example of damper characteristic.

The majority of heavy trucks are equipped with rigid axles. The majority of heavy buses are however equipped with independent front wheel suspension. Due to the large benefits for most applications, we will see a development with independent front wheel suspension also on heavy trucks. The main advantages are improved vibration environment and handling. Rear axle suspensions are however likely to keep the rigid axles for most applications.

33.5.2 Cab Suspension

The first fully suspended cabs appeared in the 1970s. Before that, the cabs were mounted either on stiff rubber mounts in four points or on two stiff mounts in the front and two softer springs in the rear. These arrangements gave very poor vibration isolation or even amplification. The very close relationship between vibration environment and fatigue life was illustrated very clearly in the development of Volvo F10/12, which was launched in 1977. Comparative accelerated endurance tests were then run between two vehicles, where one was equipped with a four-point soft cab suspension and the other with a traditional one with two stiff and two soft suspension points. Figure 33.12 shows the number of faults vs. cycles of the endurance test on the proving ground. The outcome of these tests was very convincing. The number of faults on the fully suspended cab was less than half of the number of faults on the other one.

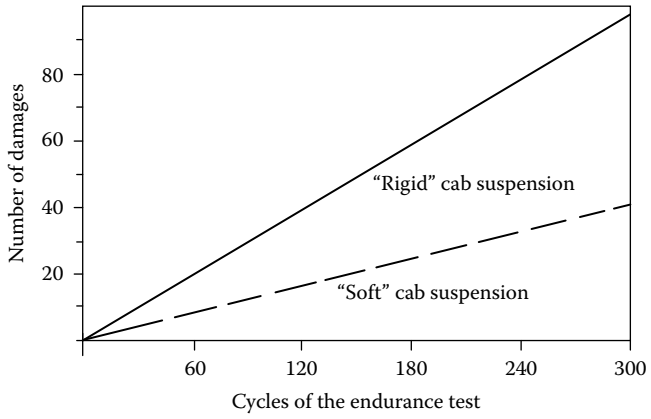

FIGURE 33.12 Comparison between soft and rigid cab suspension.

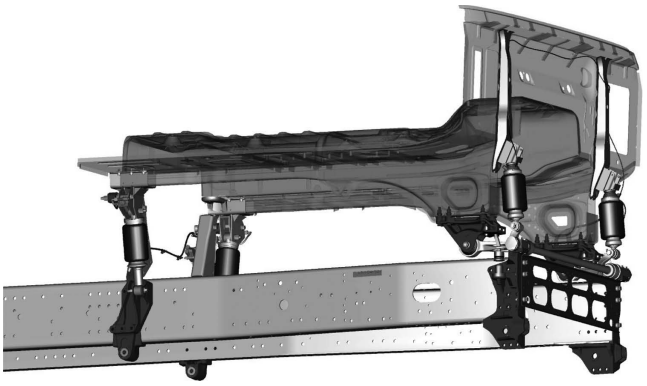

FIGURE 33.13 Example of a modern cab suspension.

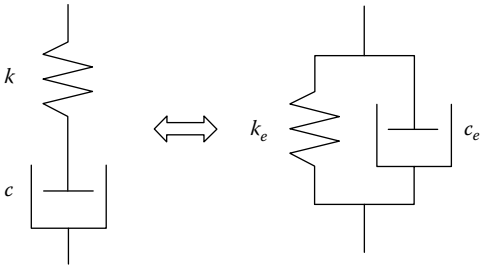

FIGURE 33.14 Stiffness in series converted to stiffness in parallel.

Since then, the use of air-suspended cabs has increased, and today air springs are predominantly used, for example, as the cab suspension shown in Figure 33.13. The basic principle is to make the bounce and pitch eigenfrequencies low and uncoupled in order to be able to isolate especially the pitch of tractors. The roll stiffness must be sufficiently high and is provided by an anti roll bar. It is obviously necessary to tune the cab suspension with the chassis suspension. The eigenfrequencies of the cab suspension should not coincide with other resonances. Lateral and longitudinal stiffness must be carefully considered together with the complex structural behavior of the front end of the chassis and with the engine suspension.

The design of the attachment points between the cab and the frame should also consider the transmission of structure-born sound. This is an area of conflict, and compromises have to be found. One example is the damper attachment. From a noise transmission point of view, this attachment should have a low stiffness, because noise is transmitted through the damper. From a vibration isolation point of view, it should be as stiff as possible. The reason for that is that a spring in series with a damper reduces the damping and adds stiffness in parallel with the damper as shown in Figure 33.14.

The following expressions for k_e and c_e, as a function of frequency f, can be derived:

$$k_e = \frac{k}{(1+(k/(2\cdot\pi\cdot f\cdot c))^2)}$$

$$c_e = \frac{c}{(1+((2\cdot\pi\cdot f\cdot c)/k)^2)}$$

The equivalent stiffness can be quite substantial in comparison with a soft cab spring. This is illustrated in Figure 33.15, which shows equivalent, frequency-dependent, stiffness, k_e, and damping, c_e, for a damper in series with a spring for the case when the damping rate c = 10,000 Ns/m and the spring rate k = 1,000 N/mm.

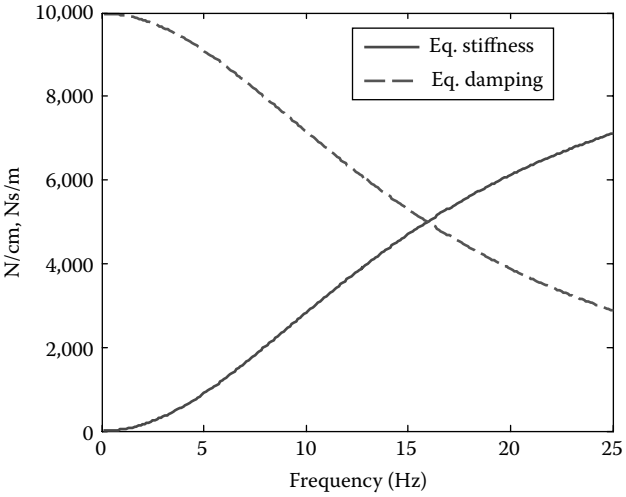

FIGURE 33.15 Damping and stiffness of a damper with elastic attachments.

It is also important, though difficult, to design the cab suspension in such a way that friction and parasitic stiffness are minimized. The cab suspension must on the other hand be well damped with viscous dampers. The relative damping is normally much higher than for the chassis suspension and often close to critical damping.

33.5.3 Frame

The frame is not really a suspension system, but it has a special impact on the vibration environment due to its flexibility. There are a number of internal excitation sources. One of these is tire runout, which is a periodic excitation. This may excite a phenomenon called "jumping ride" or "beaming" that occurs on rigid trucks and on tractors with exceptionally long wheelbase. It is a frame vibration and the frame vibrates with its first bending mode. The frame vibration causes a pitch movement of the cab, which is felt by the driver as a longitudinal vibration. It usually occurs in the frequency range 6–8 Hz and corresponds to the speed range 65–85 km/h. It is normally a narrow and undamped resonance peak. Although the amplitude is small, the vibration is very annoying for the driver. Weight optimization of the trucks easily worsens the situation, because that may imply reduced stiffness of the frame. The peak of this phenomenon was in the late 1960s and in the 1970s. An example, from this time, shows the vibration modes for the first two bending modes and the bounce and pitch modes in Figure 33.16. The roads had at the time become quite good. It sounds like a paradox, but even roads are a prerequisite; otherwise, this resonance is concealed in the noise. There were basically two ways to cure this problem. One was to make the tires round, and the other was to stiffen the frame with reinforcements. Neither solution is ideal. Another more sophisticated method was also successfully used. That was to use the engine as a dynamic damper by tuning the engine suspension. It requires a certain geometry of the engine suspension to be able to do that. The final solution to this phenomenon appeared when fully suspended cabs were introduced. The frame vibrations are still there, but they are effectively isolated from the cab.

33.5.4 Engine Suspension

The engine is an excitation source. The task of the engine suspension is to isolate the engine vibrations from the chassis. The engine has many excitation orders, but the most important for a six-cylinder engine is the third order. The highest eigenfrequency of the engine suspension must be well below this excitation frequency at idling, that is, ca. 25 Hz. The engine has a substantial mass and inertia that is

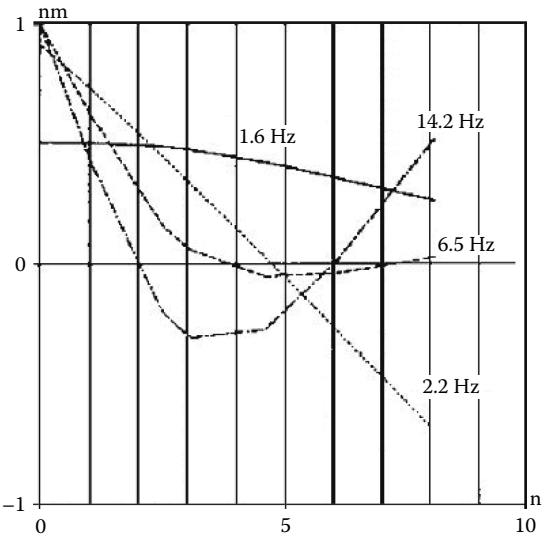

FIGURE 33.16 Mode shapes of a frame.

of at least the same magnitude as the other large masses in the front end, the cab, and the front axle installation. It is therefore important that the engine suspension is tuned in order to avoid uncontrolled dynamic couplings. The range of the eigenfrequencies of the engine suspension is 7–15 Hz.

33.5.5 Active Suspension

In fully active suspensions, spring and damper elements are replaced by a force generator, which is controlled by state variables of the vehicle (see Chapter 31). This implies that there is both energy input and energy dissipation in the suspension. The active suspension may be optimized with respect to a weighted sum of body acceleration (ride), tire force (road holding), and suspension travel (space). Another application is active stabilizers. Very good frequency response of the complete system is required in order to avoid high-frequent harshness. There are two important disadvantages, high cost and high power consumption. This makes fully active suspensions not suitable for trucks at the present stage. Semiactive suspensions are from these points of view more attractive. They have an actively controlled damper and can only dissipate energy. The principle of the control is the so-called skyhook damping, in which the damper is imagined to have one end fixed in the sky and thus being able to damp the absolute velocities of the body and the wheel instead of the relative velocity between the body and the wheel. Also here, the frequency response must be very good to avoid harshness. The ride improvement with well-functioning semiactive chassis suspensions is 10%–15%, measured as RMS acceleration. This is actually not enough to justify such a complex and expensive system. The fact is that passive suspensions have a very large potential. By using soft chassis springs and well-optimized, nonlinear dampers, very good results can be achieved. There is however a third possibility, and that is adaptive dampers. By adapting the damping to the load, to the road input, or to roll excitation, better performance may be achieved in certain situations. Another potential possibility would be to adapt the dampers to reduced space for the suspension in order to avoid bottoming. Adaptive damping is also a simpler system but still much more expensive than passive dampers.

33.6 OPERATING CONDITIONS

There are a number of internal periodic excitation sources in the engine, transmission, and wheels that are important for the ride comfort. The main excitation source is, however, the road unevenness. This is also the only source of large dynamic forces that are important not only for the ride comfort

but also of interest for fatigue and damage of the vehicle structure and wear of the infrastructure. As the nature of the road excitation is stochastic, the longitudinal road profile may be described by an autospectrum in the spatial frequency domain [17,8]. The road profile may also be assumed to be isotropic, that is, it has the same road spectrum in all directions. The nature of the road excitation was first described on runways of airfields, and since then, a large number of road profiles have been measured and analyzed. The results all show that a straight line in a log–log diagram, that is, with the following equation, may represent a road spectrum:

$$\Phi = \Phi_0 \cdot \Omega^{-w}$$

where

Φ is the power spectral density of the road profile
Ω is the spatial angular frequency
w is the waviness
Φ_0 is the road severity, the power spectral density at $\Omega = 1$

For a long time, a waviness of 2 was commonly assumed and used in simulations and elsewhere. The reason for that may be that it is simple, but it is not correct. For the most common road network, the waviness is rather 3, that is, the content of long wavelengths is larger. For networks of bad quality, the waviness may be 2.5, and only for extremely bad roads, the waviness is as low as 2. Figure 33.17 shows an average road spectrum for 25 km of a bad minor road and a linear curve fit.

Another common mistake that was made is the assumption that roads are stationary with a constant road severity. But the fact is that they are not. This may easily be overlooked because the RMS values for various responses would be the same for reasonably linear trucks for both stationary and nonstationary input. However, if there are nonlinearities when fatigue phenomena of the vehicle structure or of the human body are to be investigated, it will give completely different results whether nonstationary inputs are considered or not. In order to be able to optimize and differentiate the trucks for various applications and markets, it is necessary to describe the nonstationary excitation.

One way to describe the nonstationary road input is to use the Q-distribution. Q is a combined parameter of road severity, vehicle speed, and waviness and may be used to define the operating conditions [18]:

$$Q = \Phi_0 \cdot v^{w-1}$$

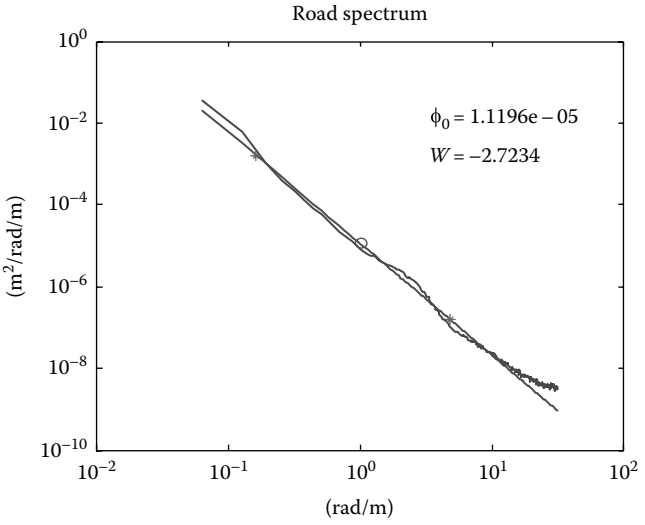

FIGURE 33.17 Measured road spectrum.

The Q-distribution is expressed by a Weibull distribution, which has the probability-density function:

$$f(Q) = \frac{\beta}{\theta}\left(\frac{Q}{\theta}\right)^{\beta-1} e^{-(Q/\theta)^{\beta}}$$

where different operating conditions are defined by different sets of Weibull parameters β and θ.

Another way is to define a discrete number of road severities based on the Q-distribution and then for each road severity describe a distribution of transient inputs.

The description of the nonstationary excitation is based on extensive measurements in real operations [19].

33.7 HANDLING

Good handling of a truck is driven by active safety requirements. Handling and stability are the most important features for active safety. Transport effectiveness is another important driver for handling and stability features. Vehicle combinations are configured in order to optimize the weight or the volume of the payload. It is vital that this is done without degrading the stability. Higher speeds also increase the requirements on the handling and stability of heavy trucks. The driving pleasure, finally, is also an important factor.

The handling feature may be divided into three areas. One is the directional response of the vehicle or the vehicle combination due to a steering input or to a road input. The second response of importance is the roll behavior due to steer input or road input. The third area of interest is the interface between the driver and the vehicle, that is, the driver's perception of the vehicle and its controls. The two first areas deal with objective handling characteristics and the last one with subjective characteristics.

33.8 DIRECTIONAL RESPONSE

The steady-state behavior of a truck is determined in a circular test procedure, where either the radius or the longitudinal velocity is constant [43]. The relationship between steering-wheel angle and lateral acceleration is the most basic one. The derivative of the steering-wheel angle, divided by the steer ratio, with respect to lateral acceleration gives the understeer gradient, which is an important characteristic value. The understeer gradient shall be positive. A negative understeer gradient gives instability at a certain critical velocity. The relationship between steer angle and lateral acceleration should preferably be linear, but if it is not, the understeer gradient should increase with lateral acceleration. For heavy vehicles with more than two axles, the relationship between steer angle and lateral acceleration is speed dependent, which is not the case for simple vehicles with two axles. By using the concept equivalent wheelbase, l_e, multiaxle vehicles may be treated as simple vehicles [20]. Figure 33.18 shows a handling diagram in a constant velocity test with the three-axle rigid truck in Figure 33.19 [21]. The different behaviour in left and right turns is due to assymetric stiffness of the steering system.

The understeer gradient is obtained from $(\partial\delta_H/\partial a_c)\times(1/i_s) - (\partial\delta_D/\partial a_C)$ where $\delta_D = l_e/R$.

The transient behavior of a truck may be determined in a number of different test procedures [22]. Most often the yaw velocity and the lateral acceleration responses in relation to the steering wheel input are studied. Since the lateral acceleration response is dependent on where it is measured, the yaw velocity response is preferably used. If the truck behaves linearly, which it often does, methods employing analyses in the frequency domain may be used. Analyses in the time domain usually yield results only for specific maneuvers. One important characteristic value is a quantification of the time delay between yaw velocity and steering-wheel angle, such as response time, time lag, phase time, or phase angle. Another characteristic value is the yaw velocity to steer angle gain. A third important characteristic value is the frequency bandwidth of the yaw response.

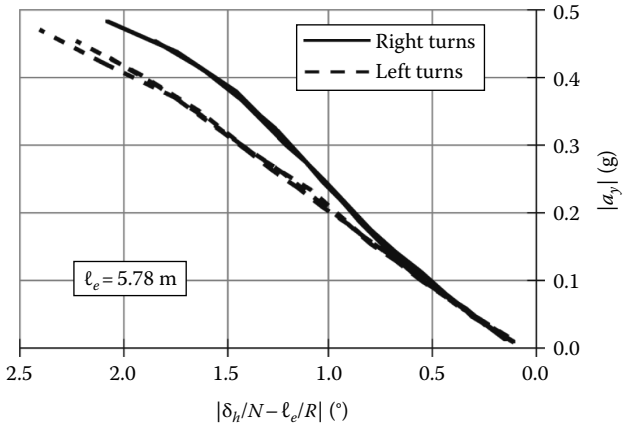

FIGURE 33.18 Handling diagram (Note: δ_h is the steering-wheel angle, $a_y \approx a_c$ is the lateral acceleration, $N = i_s$ is the steer ratio, R is the radius).

FIGURE 33.19 6 × 2 rigid truck.

33.8.1 Tire Performance

The magnitude of the forces between wheels and ground and how they are generated determine the behavior of the truck in all situations (Figure 33.20).

Tires are thus the single most important component of the truck for its handling characteristics and stability. The relationship between lateral, cornering, tire force, and tire slip angle is very non-linear, seen over a large span of the slip angle. Figure 33.21 shows an example of the relationship between lateral force and slip angle for various vertical forces. These curves are based on the "magic formula" of which the early development took place at Volvo in cooperation with Delft University of Technology and now is the widely accepted way of presenting tire data (see Chapter 17).

As trucks however very seldom are driven close to the limit of the tires, that is, at large slip angles, but rather at slip angles normally not exceeding 2°, the relationship may be considered as a linear one and can be expressed with the cornering stiffness, C_α:

$$c_\alpha = \left(\frac{\partial F_Y}{\partial \alpha} \right)_{\alpha=0}$$

FIGURE 33.20 Truck in equilibrium.

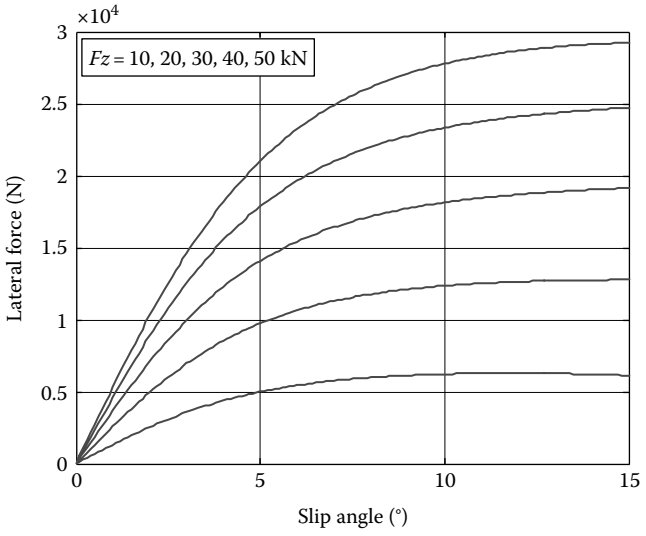

FIGURE 33.21 Example of tire characteristics.

There is still one nonlinearity of importance, and that is the relationship between cornering stiffness and the vertical tire force. Figure 33.22 shows this relationship for the same tire as previously mentioned.

This nonlinearity causes a reduction of the total axle cornering stiffness due to load transfer between left and right wheels. This reduction is more pronounced when the load transfer is large, that is, for high lateral accelerations.

It is advantageous to use cornering compliance instead of cornering stiffness. The cornering compliance is the inverse of the cornering coefficient, which is the cornering stiffness normalized with the vertical force. The difference between cornering compliance front and rear determines the understeer/oversteer behavior. It is therefore extremely important to have the correct tire combination front and rear. The understeer gradient may vary with the lateral acceleration, mainly due to tire nonlinearities. Obviously, also the load distribution and the center of gravity height affect the understeer gradient.

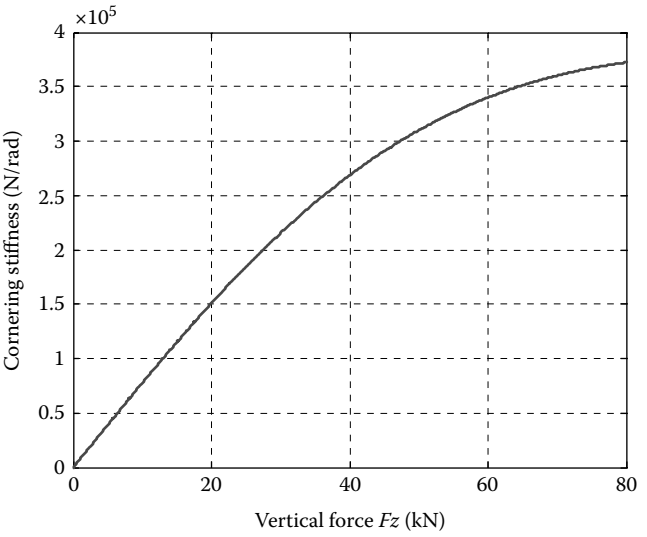

FIGURE 33.22 Nonlinear cornering stiffness.

There are large differences between passenger car tires and truck tires. Good truck tires have a cornering compliance around 8°/g, while good passenger car tires have not more than a fourth, that is, around 2°/g. This depends on that tire life and rolling resistance are very important for transport economy and are prioritized for truck tires. This is the main reason for the quicker response of passenger cars.

The state of wear has a large effect on the cornering characteristics of truck tires because a large part of the compliance is located to the thread. The cornering stiffness may increase between 25% and 50% when tires wear. Figures 33.23 and 33.24 show an example on the effect of worn tires on the frequency response of yaw velocity for a 4 × 2 tractor/semitrailer combination [23].

It appears that the bandwidth increases significantly and the phase delay is reduced with the worn tires.

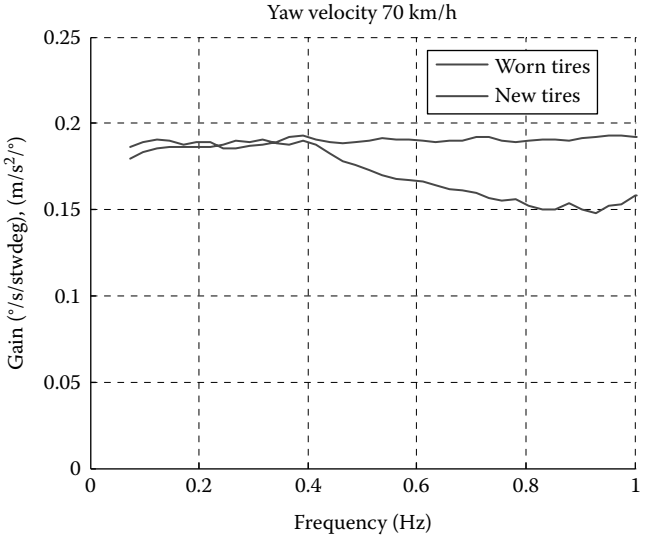

FIGURE 33.23 Effect of the state of wear on gain.

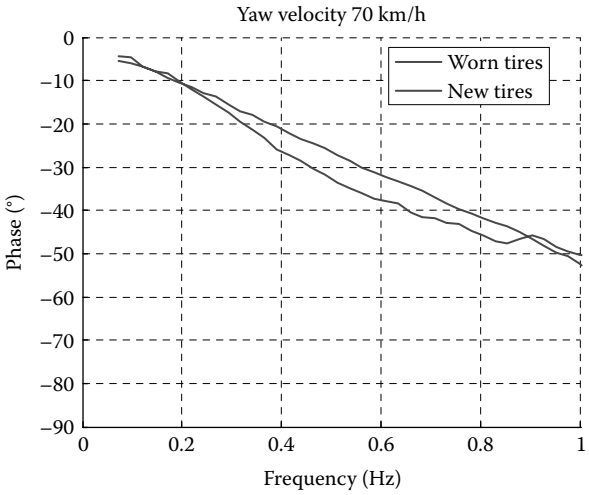

FIGURE 33.24 Effect of the state of wear on phase.

Tire characteristics, obtained from measurements, are dependent not only on the state of wear but also on the temperature and on the measuring equipment. Comparisons of measurements therefore have to be done with caution.

There has been a tremendous development of truck tires with respect to most characteristics such as cornering capability, life, and rolling resistance. One major step was the shift from cross-ply tires to radial tires. Low-profile tires were developed for passenger cars in order to reduce the cornering compliance. For trucks, low-profile tires are used primarily to reduce the outer diameter of the tires in order to be able to increase the load volume.

Another difference between passenger car tires and truck tires is the change of the cornering stiffness when the tire pressure is reduced. While the cornering stiffness is often reduced for passenger car tires, it increases for truck tires. There is obviously a limit for this increase. If a tire explosion occurs and the tire is completely deflated, the cornering stiffness will also be close to zero. This obviously changes the characteristics of the vehicle drastically and may cause instability. If dual tires on the rear axles are replaced by singles, special precautions must be taken to prevent the risk for instability. Tire explosions on front axles may however also cause accidents. The side pulling in such a situation is moderate and the truck is easy to steer and brake, but if the driver does not have full attention on the driving for some reason, they or she may be reacting too slowly and an accident may happen. The conclusion of this is that there is a need for run-flat tires on trucks, which can maintain most of their characteristics at a sudden pressure loss.

33.8.2 Suspension Effects

Induced steering effects by the suspension, such as roll steer and compliance steer, create a cornering compliance of the suspension in terms of steer angle/acceleration. This adds to the tire cornering compliance and contributes to the total cornering compliance for each axle. Thereby, both the understeer/oversteer behavior and the transient response are affected. It is advantageous to let the induced steering at the rear axles be induced understeer, which means that the cornering compliance of the rear is reduced. This has a similar effect as to increase the cornering stiffness of the rear tires. Compliance-steer effects are better than roll-steer effects because they are in phase with the lateral force buildup, while the roll-steer effects are delayed. Induced understeer at the front axle also increases the understeer gradient. This is not as advantageous as at the rear axles because it will not improve the transient characteristics as effectively.

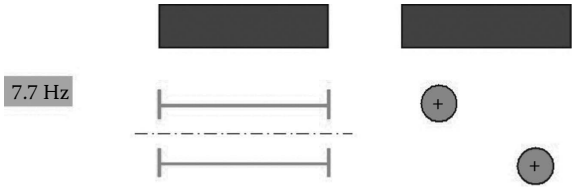

FIGURE 33.25 Front and side view of a bogie pitch mode.

Poorly damped suspensions may lead to loss of road grip when the wheels are bouncing at axle resonance. This leads to reduced lateral force capability of the tires due to relaxation effects. Loss of road grip at the rear axles leads to instability and at the front axle to an unsteerable vehicle.

Bogies of walking-beam type can easily loose the road grip, especially when unladen or partly laden, because they have an additional, very lightly damped mode, a bogie pitch (see Figure 33.25). On rough roads, this may lead to a bogie skip, which may cause a jackknife. It is therefore important that bogies are equipped with viscous dampers.

33.8.3 Steering System

The steering system is for many reasons important for the handling characteristics. Flexibility between the steering wheel and the road wheels adds to the total cornering compliance of the front axle and increases the understeer of the vehicle. Without this flexibility, many trucks would actually be oversteered. Front suspensions of heavy trucks most commonly use leaf springs as spring element, due to their cost-effectiveness. It is likely to stay this way as long as rigid axles are used. This makes the design of the steering geometry more difficult. In order to control steering errors, the kinematics of the leaf spring must be well known, for example, position of Ross center and inclination of Ross line. Sometimes steering errors are deliberately built in to give roll steer in order to increase the understeer. This is not recommendable, because steering errors may also cause both brake steer and ride steer at unacceptable levels. To achieve good steering with minimized errors in all respects, not only the kinematics of the steering but also all flexibilities have to be considered.

Another phenomenon is steering kicks, which are characterized by high transient forces in the steering linkage that are transmitted to the steering wheel. They may occur in potholes and on bad roads and are caused by steering errors and unfavorable kinematics of the front suspension. In such a situation, it is however easy to jump to conclusions, because the steering kicks occur at axle resonance. A substantial increase of the axle damping eases the problem, but it may then cause large ride problems. Another not-so-clever way of reducing steering kicks is to increase the power assistance in the steering gear. The downside of that is that the steer feel becomes impaired.

Friction in the steering system is unavoidable, and it is both a good thing and a bad thing. It is good because damping is necessary in the steering system in order to avoid shimmy and wobbling. A sufficient amount of friction makes it possible to avoid a viscous damper in the system. It is bad because it deteriorates the steer feel. A good compromise is necessary. However, friction between the steering wheel and the steering gear should be minimized.

33.8.4 Steered Rear Axles

In order to improve low-speed maneuverability and to avoid wheel scrub, heavy trucks use more and more frequently steered rear axles. This affects the directional response. There are two types of rear-wheel steer. The most simple one is self-steering, which implies that virtually no lateral tire forces are generated. Self-steering will result in shimmy unless there is a high amount of friction in the steering. This happens because the lateral tire forces will lag behind the steer angle due to tire relaxation. Consequently, self-steered axles require dampers in order to avoid shimmy. The other one is forced or positive steering, which means that the steer angle of the rear wheels is proportional

to the front steer angle. In this case, lateral tire forces are generated but at a lower level than in the case with fixed axles. In both cases, the steering results in increased cornering compliance at the rear, which gives less understeer and a slower transient response [24]. Because of this impairment of the handling, the steered axles should be locked above a certain, rather low speed. For the self-steer case, this must always be the case. The same thing applies to trailer applications. The forced-steer case gives obviously a potential to steer the rear wheel in such a way that the response of the truck becomes quicker at normal speeds, if the rear wheels are steered "by wire." This may be done by simply countersteering the rear wheels proportionally to the front wheels or to steer them actively, controlled by yaw velocity or other state variables [25].

33.9 STABILITY

Yaw instability of a single-unit truck rarely occurs. It requires an oversteered vehicle driven above its critical speed or special maneuvers. It is more likely to happen on low—than high—friction surfaces. Special circumstances, for example, an empty tractor that is braked during cornering, may however lead to aperiodic yaw instability. Roll instability, on the other hand, happens frequently. It occurs easily in a steady-state or quasi steady-state situation, when the rollover threshold is exceeded. There is a very strong correlation between the steady-state rollover threshold and the risk for rollover in real traffic [26]. The rollover limit is mainly determined by the track and the center of gravity height, but it is also influenced by other factors such as various sources of compliance and lash. The suspension compliance and lash are important but also the distribution of roll stiffness between the axles. The torsional compliance of the frame can have quite an impact as is illustrated in Figure 33.26. Turning the skilifts 180° shifts the weight closer to the axles and reduces the deflection of the frame substantially, which increases the rollover threshold.

Single-unit vehicles are mainly used as construction or distribution trucks. In long haul operations, they are very rare, and the reason is of course transport effectiveness. It is a matter of getting as large a volume as possible within given constraints.

As vehicle combinations are much more complex than single-unit vehicles, one may run into problems, if the dynamics of various types of vehicle combinations is unknown. The specific behavior of vehicle combinations in general is that the response to a steering input is an oscillatory, more or less damped, movement. These oscillations may in the worst case lead to a true instability where the damping is negative and the oscillations become self-excited. In other cases, they may just lead to an amplification of the movements of the first vehicle unit, the motor vehicle, to the last trailer

Rollover threshold = 0.24 g;	Bucket to bucket gives 0.31 g

FIGURE 33.26 Rollover test at UMTRI.

FIGURE 33.27 Vehicle combination with stability problems.

in the vehicle combination. A high rearward amplification of the lateral acceleration may lead to overturning of the last trailer. High rearward amplification of the yaw velocity may lead to that the last trailer is sliding off the road or hitting other vehicles. Commonly used characteristic values for dynamic stability are rearward amplification and damping. Figure 33.27 shows a car transporter consisting of a truck/central-axle trailer combination. This particular combination appeared to be weakly damped and very sensitive. Oscillations were easily excited by steer inputs, road ruts, and wind gusts.

Each type of vehicle combination has to be investigated separately, but there are a couple of guidelines, generally valid for maximum dynamic stability. Some of these are that the number of articulation joints shall be as small as possible, the overhang to coupling points shall be minimized, the wheelbase of trailers shall be long, the trailer tires shall have high cornering stiffness, and of course the height of the center of gravity of all vehicle units shall be as low as possible [27–29].

There is a strong trend toward high cube goods. This results in low chassis, since downward is the only way that the volume can be increased. The inevitable consequence of this is tires with smaller diameter and suspensions with shorter spring travel, and this is detrimental both to the vibration environment and to the dynamic stability. The stability suffers because these small tires normally have less cornering capability. The modular concept, now used in a growing number of countries within the European Union, offers a good solution to this problem [30,31]. The modular concept makes it possible to couple vehicle units based on modules defined in the EC directive 96/53 to longer combinations than normally allowed. This results in vehicle combinations with superior dynamic stability than current European vehicle combinations. When these new modular combinations shall be defined in regulations, it would be a good approach to use performance-based standards (PBS) as a basis [32]. The regulations have to be prescriptive in their nature but based on PBS. Figure 33.28 shows the result of the conversion of three current European vehicle combinations, two tractor–semitrailer combinations and one truck/center-axle combination, into two longer modular vehicle combinations.

Active vehicle stability control systems reduce the risk of instability significantly. This may be achieved by differential braking of the wheels, which is possible to do with electronic brake systems (EBS). Such systems assist the driver to avoid rollovers and yaw instability.

The rollover control intervenes when the lateral acceleration is approaching the static rollover threshold by cutting off the engine torque and using the wheel brakes to reduce the speed (see Figure 33.29). If a wheel lift is about to occur, full brake power is used.

FIGURE 33.28 Three vehicle combinations converted to two.

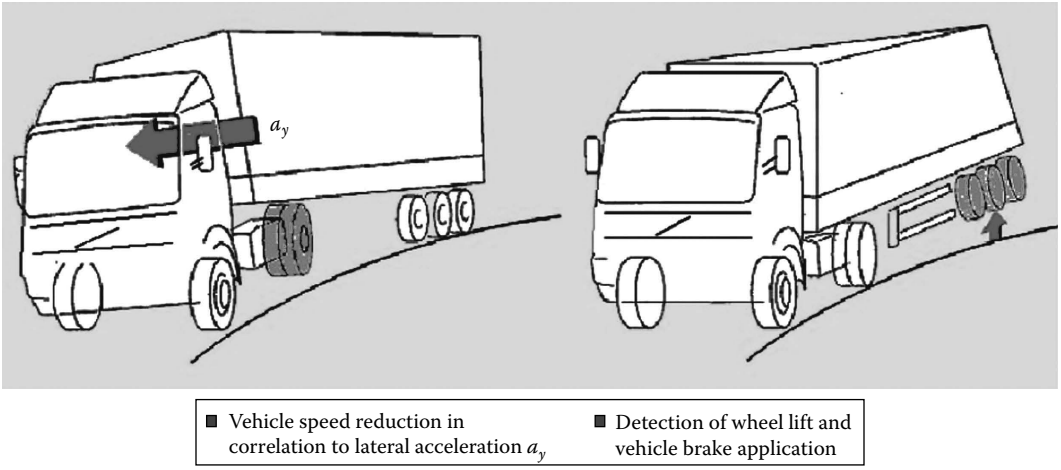

FIGURE 33.29 Rollover prevention.

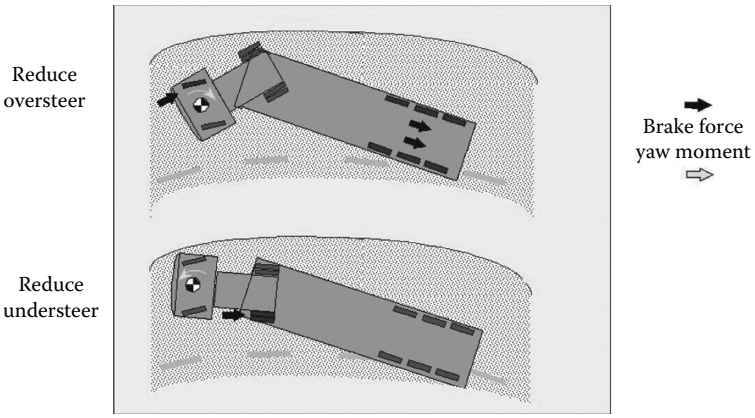

FIGURE 33.30 Yaw control.

The yaw control intervenes when the measured yaw behavior of the truck does not agree with the estimated yaw behavior that the truck should have for a certain combination of steering-wheel angle and speed. There may be two situations. One is that the yaw velocity of the tractor is too large, which leads to instability. The other is that the tractor is not turning enough, which may lead to that the vehicle cannot be kept on the road. In the first case, the outer front wheel of the tractor and the trailer wheels are braked in order to stop the yaw instability. In the second case, the rear inner wheel of the tractor is braked in order to increase the turning (see Figure 33.30).

33.10 PERCEPTION

The driver's perception of the truck is what matters at the end. Various control tasks such as path following, obstacle avoidance, or headway control have to be performed. The driver shall feel comfortable and relaxed also during long driving periods. It is important to understand that driver and vehicle together constitute a system. The driver acts as a controller getting feedback from a large number of sources and giving instructions via the controls to the vehicle. It is then important to understand on what stimuli the driver reacts. In order to make a mathematical model of the driver to include in a vehicle model, one must also understand how the driver reacts. There are a number of perception channels [33]. The most important one is vision. If the driver cannot see the road, for example, due to fog, they cannot drive. Another channel is motions of the vehicle, translational and rotational. They can be obtained from the inner ear or be body-distributed. The tactile input finally is from the controls, steering wheel, and pedals. The most important tactile channel is probably force and displacement of the steering wheel. It is important to know the correlation between the driver's perception of the vehicle behaviour and various vehicle dynamics characteristics. Driving simulators with large moving base are excellent tools for investigation of these relationships [34]. Figure 33.31 shows the high-performance driving simulators at VTI, Swedish National Road and Transport Research Institute.

Objective characteristic values obtained from directional response investigations correlate very well with the subjective perception of maneuver stability in lane changes and avoidance maneuvers. They are also a part of parameters that are relevant for the perception of on-center handling. Both the understeer gradient and the gain of yaw velocity with respect to steering-wheel angle have optimum values. The response time shall be as short as possible. The tactile sensory channels are very important for the perception of on-center handling. Among the more important relationships is the

FIGURE 33.31 VTI driving simulator.

relationship between steering-wheel torque and lateral acceleration. Both gradients and hysteresis correlate well with the subjective perception. Uncontrolled motions of the truck, primarily roll, are detrimental to the perception of on-center handling.

Steer by wire is currently used to steer rear axles. In the future, we may also see the front wheels steered by wire. This gives extended possibilities to tune the characteristics of the steering and optimize the tactile interface. It also gives the possibility to adapt the steering to the preferences of individual drivers. It is important to know how drivers are reacting on various stimuli, and it is also essential to have that knowledge in the context of active control systems and various driver-assist systems and how the driver's behavior is affected by these systems.

A driver is very adaptive to nonlinear dynamics, that is, they is a very robust controller. One example is that a driver, at least some drivers, can cope with an oversteered vehicle running above its critical speed, although it is unstable. Another example is the case with a blowout of a front tire. Although the dynamics of the truck changes significantly when one front tire loses almost all cornering stiffness, the drivers have no difficulty to adapt to the new characteristics and follow the prescribed path in all kinds of maneuvers, without and with braking. It is however also so that if the driver does not have full attention to the driving, there is a long reaction time before they takes action. Driving simulator tests have confirmed this. It was also shown that the reaction time is long only the first time a blowout happens. If it happens again during the same test run, the driver is prepared and acts accordingly [35].

33.11 VEHICLE MODELS

Mathematical modeling is fundamental for the understanding and the analysis of vehicle dynamics, both for vibration analysis and for the analysis of handling. It is important that the model covers what is relevant for the phenomenon that is to be analyzed. It is also an advantage if the model is simple and not more complex than necessary. It is, for example, sufficient if the model contains only the modes that are of interest. An unnecessary high degree of complexity makes it more difficult to make a correct model and to interpret the results. With current multi body system (MBS) software, it is easy to make large models with a lot of degrees of freedom (DOFs) without having to set up the equations, which is done by the software. An advantage is obviously that the equations have no errors, but the disadvantage is that the understanding of what happens may not be so good and the interpretation of the results is then more difficult [36,37].

Linear models have big advantages and are advantageous to use for qualitative studies because the analyses may be easily done in the frequency domain. Quite often, suspensions have highly nonlinear elements. Leaf springs, for example, have often a high amount of friction and dampers have nonlinear characteristics. Linear characteristics of these elements may however be obtained from a nonlinear analysis with nonstationary excitation. A linear model may then use these linearized characteristics for the linear analyses. In similar ways, the nonlinear characteristics of tires can be linearized and used for the analysis of the lateral dynamics [38].

Validation of models is always important, and in particular with large models, it is essential. There are various ways to do the validation. One is to use field measurements. This is the only alternative, and a good one, for handling models. For models with road input, the advantage is that the excitation is realistic, but the disadvantage is that it is difficult to obtain exact knowledge of the input. False conclusions may therefore be drawn from road measurements, for example, due to periodicities of the road excitation that give peaks in a spectrum, which may be misinterpreted as resonances. The so-called wheelbase filter is another phenomenon that filters the spectra and therefore causes new peaks or attenuation of resonance peaks [39]. Many mistakes have been done in the interpretation of measurement results due to lacking knowledge of the excitation mechanisms. The wheelbase-filter effect in a simple 2-DOF vertical-pitch model is exemplified in Figure 33.32. Correlated inputs mean that the inputs on front and rear axles have a constant time delay. This causes the wheelbase-filter effect if the speed is constant.

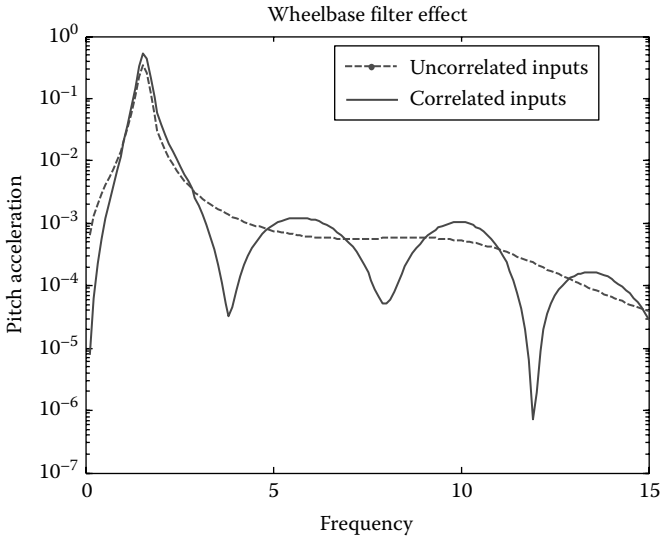

FIGURE 33.32 Wheelbase-filter effect.

FIGURE 33.33 Volvo road simulator.

An excellent way to validate a vehicle model with vertical input is to use a road simulator with vertical input on each wheel. Figure 33.33 shows the road simulator at Volvo in Gothenburg. It can also be used to visualize various phenomena. The road simulator measurements give very reproducible results and the excitation is well controlled and well known. In order to be able to correctly compare different vehicle configurations, independent of speed, the excitation on different axles shall be uncorrelated.

If the fatigue life of a front leaf spring is to be estimated, this can of course be done in a very elaborated vehicle model with a large number of DOFs. By studying what is influencing the spring force and the stress in the spring, it is possible to reduce the complexity. From linear models, it was seen that the influence from structural modes defined by frame flexibility, chassis packaging, and cab/engine installation was negligible. The wheelbase-filter effect can also be seen on the RMS

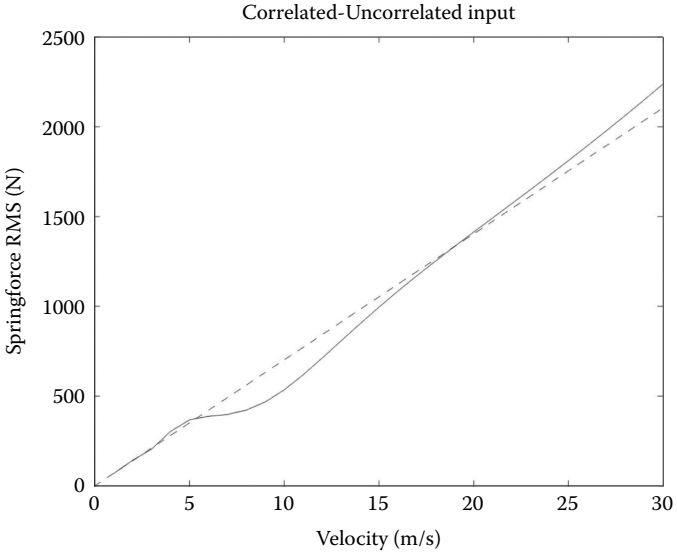

FIGURE 33.34 Wheelbase-filter effect on RMS values.

values of the spring force. Figure 33.34 shows that the RMS force is not proportional to the velocity (road severity), as it should be expected to be in this case, where the road has a waviness of 3.

The contributions from other axles than the front axle are however normally small. If the relationship between the squared radius of inertia and the product of the distances, front and rear, to the center of gravity, that is, the dynamic index, equals one, there is no contribution at all, because all the axle inputs are dynamically uncoupled. It is therefore sufficient to use a model with only front axle input. Figure 33.35 shows a comparison between the spring-force power spectral density (PSD) for a 2-DOF "quarter car" model (full line) and for a 7-DOF "half car" model (dashed line) with body and axle roll DOFs. The axle resonances differ (range 8–12 Hz), but as can be seen, the dynamic spring forces are mainly caused by low-frequency deflections, and the 2-DOF model may be used for a principal study. The nonlinear characteristics of the suspension are significant and are

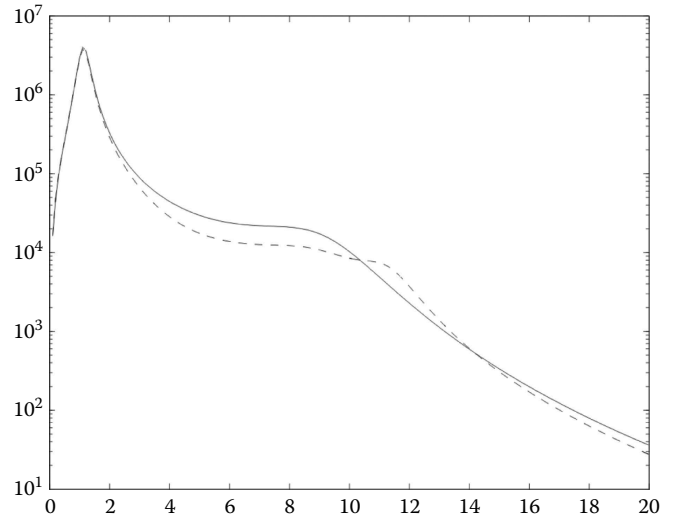

FIGURE 33.35 PSD from "quarter car" and "half car."

included, that is, a hysteresis of the leaf spring, a strongly nonlinear auxiliary spring as a bump stop, and a damper with nonlinear characteristic and elastic attachments.

The fatigue life of the front leaf spring is predicted by using a rainflow-counting algorithm on the simulated time responses. The reference spring is designed to have a maximum stress of twice the fatigue limit of the material. For comparison, a soft suspension in severe operations is used as reference.

The level-crossing distribution of the stress in Figure 33.36 shows the influence of the road description. Both the stationary and the nonstationary roads have the same RMS value and waviness. A nonstationary road consists of a mixture of good and bad roads, while a stationary road has constant road quality. It is not possible to obtain an adequate estimate of the fatigue life in the stationary case. The maximum stresses are less than the fatigue limit, which results in an infinite fatigue life [40].

Table 33.1 shows how the fatigue life is influenced by road description, type of model, operation severity, and spring stiffness.

The necessity of a nonlinear model is not as crucial as the nonstationary road description. The operation severity is obviously very important for the fatigue life. A very interesting fact is that a soft suspension not only improves the ride but also increases the fatigue life of the leaf spring.

For handling analysis, quite a few basic characteristics may be satisfactorily analyzed with a simple two-DOF model, linear or nonlinear. Also for qualitative analysis of vehicle combinations,

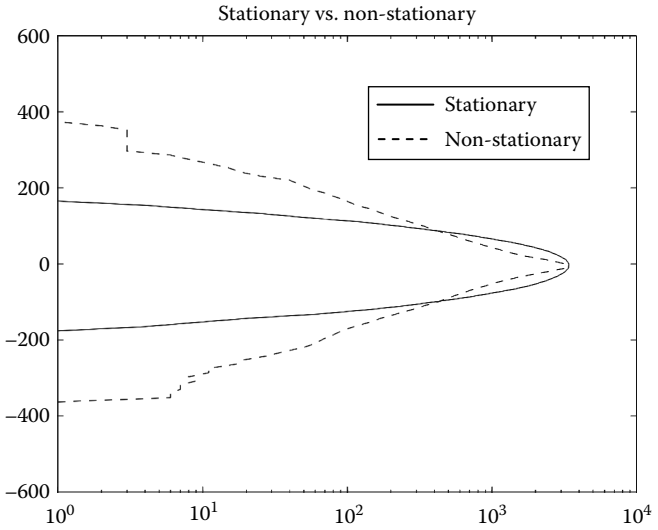

FIGURE 33.36 Level-crossing distributions of stress.

	x		x		x		x	0.25

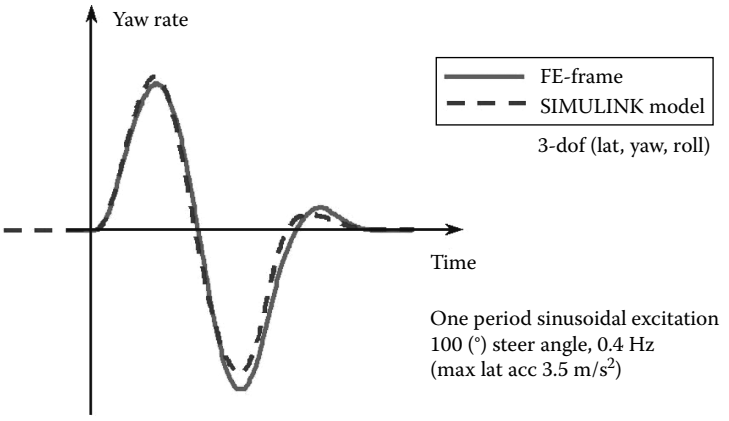

FIGURE 33.37 Responses from single sine-wave steer input.

it may be sufficient to use models, where each vehicle unit has just yaw and sideslip DOFs. The most important nonlinearity is the nonlinearity of the tires.

The example in Figure 33.37 shows the yaw velocity response from a single sine-wave steer input obtained from two different models of a rigid three-axle truck, one complex MBS model with flexible FE frame and one simple 3-DOF model. The comparison shows good agreement despite the large difference in complexity.

This illustrates that simple models may give sufficiently accurate results depending on what kind of phenomenon is to be analyzed. However, even when simple models are employed, they must reflect the real behavior of the truck.

One example is the flexible frame of the truck. It plays in many cases an important role in the dynamics of the truck, because it affects the load transfer left to right on the different axles. In a tractor, for example, the compliance of the frame must always be taken into account because no superstructure stiffens it. The frame should then not be modeled as a torsion model, with a torsion spring between two masses, as is often done, but as the warp model in Figure 33.38, which behaves in a similar way as the real frame [40].

It is difficult to understand how cab roll of a tractor is affected by stabilizers at different locations if a warp model is not used. Another example is a tipper with three-point attachment. This gives the effect that the resulting force that rolls the vehicle via the frame is moved rearward. The handling diagram in Figure 33.39 illustrates that the truck becomes oversteered at a rather low lateral acceleration, when this point moves away from the center of gravity. This behavior is due to the behavior of the frame and the effect of nonlinear tires.

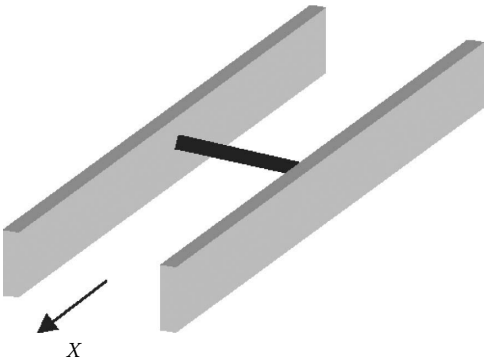

FIGURE 33.38 Warp model.

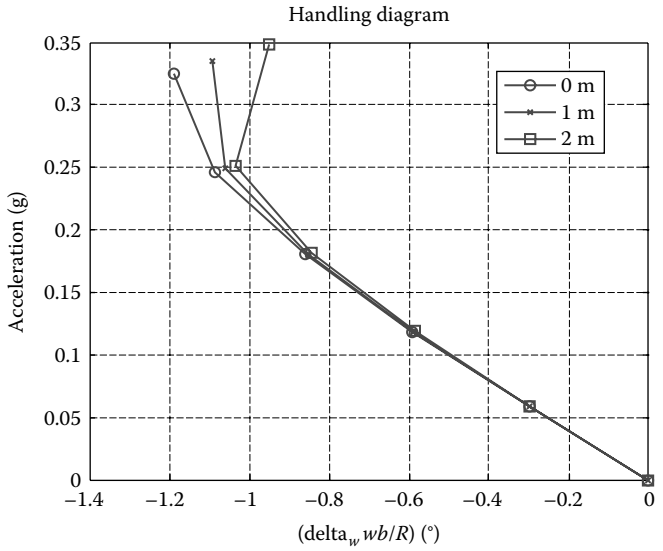

FIGURE 33.39 Steady-state responses with various superstructure attachments.

33.12 VERIFICATION AND VALIDATION

Verification of various vehicle dynamics feature characteristics is an important part in the product development process. A prerequisite for this is that there are feature requirements. The requirements consist of a set of quantified parameters for each feature area. It is obviously vital that these parameters are relevant for the perception of the feature they are measuring. This is a part of the validation. The verification is made with real prototypes but also with thoroughly verified vehicle models. One reason for using models in the verification process is to be able to verify a large number of different vehicle specifications used in different conditions.

For the verification of vehicle dynamics features, it is absolutely necessary to know in what environment and how the vehicle will be used. Figure 33.40 illustrates how the vehicle specification is affected by the operating environment, the vehicle utilization, and the transport mission. The optimal vehicle specification may be seen as an optimization of feature areas, weighted according to the preference of the customer.

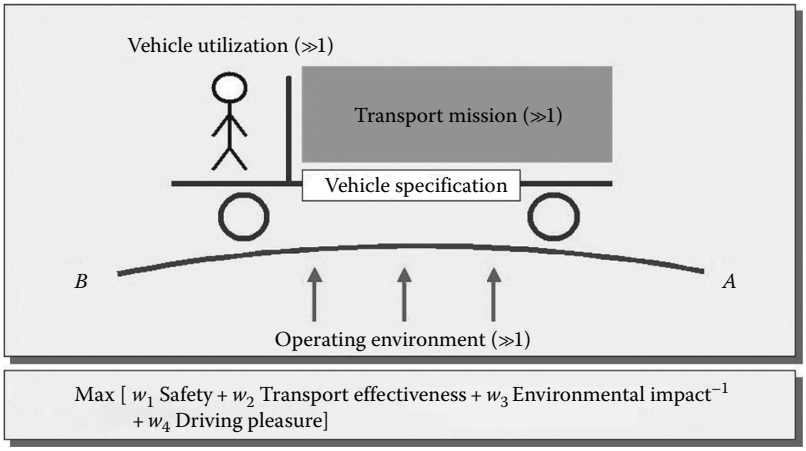

FIGURE 33.40 Factors affecting the vehicle specification.

TABLE 33.2
Examples of GTA-Parameters

Transport Cycle (Long-Distance Type, Distribution Type, Construction Type)			
Operative Environment		**Vehicle Utilization**	
Road condition	(Smooth, …., rough, …)	Speed changes	(Low, …, …, …)
Topography	(…, hilly, …)	Maneuvering	(Low, …, …, …)
Curve density	(Low, …, …)	Yearly usage	(…) kilometer/year or hours/year
Altitude	(…, 2000 m, …)	Transport mission	
Climate	(…, cold, …)	Body and equipment	(…, tank, tipper, …)
		GCW	(…, GCW20t, …, GCW200t)

A number of vehicle-independent parameters have been defined that specify differences in transport mission, operating environment, and vehicle utilization for haulage operations worldwide. These parameters define global truck application (GTA). Table 33.2 shows examples of GTA parameters.

The GTA parameters are high-level descriptions, which are a base that gives a uniform perspective on vehicle usage for all functions within the company such as product planning, product development, sales, and aftermarket. For the product development and for the feature verification in particular, the different parameter levels need to be quantified. The road condition is, for example, expressed in terms of Q-distribution and statistical distributions of the pothole content [41,42].

The quality of the verification results is an issue. There are a number of uncertainties related both to the description of the operation environment and to the quality of measurement and analyses (see Figure 33.41).

Also the features of a certain vehicle specification may vary from vehicle to vehicle depending on many factors, such as characteristic variations of vital components and the state of wear. All these result in a certain dispersion of the vehicle performance in various feature areas. This leads to that the targets of the vehicle performance have to be higher than the customer expectation in order to avoid problems. This may be called a probabilistic design (see Figure 33.42).

It is obviously necessary that the targets are objectively quantifiable parameters. Subjective assessments of vehicle dynamics features are however still rather frequent. There is a larger acceptance of objective ride measurements than of objective handling measurements. Much of the vehicle dynamics research has been focused on the driver's perception of various aspects of vehicle dynamics, and there is enough knowledge today to be able to rely entirely on objective measurements. Subjective assessments are often misleading and therefore detrimental to the development process.

The repeatability also among professional truck drivers is poor. Figure 33.43 shows results from a well-controlled driving simulator test in a histogram. The same vehicle was assessed twice and the

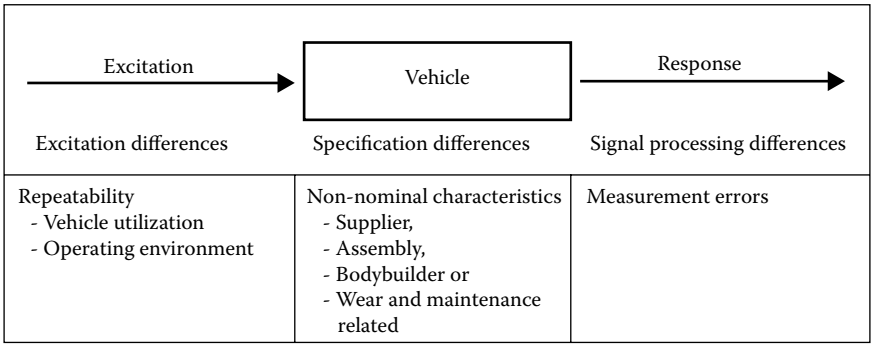

FIGURE 33.41 Quality of the verification process.

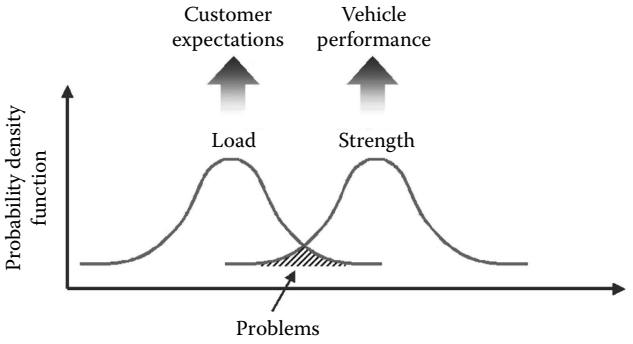

FIGURE 33.42 Matching expectations and performance.

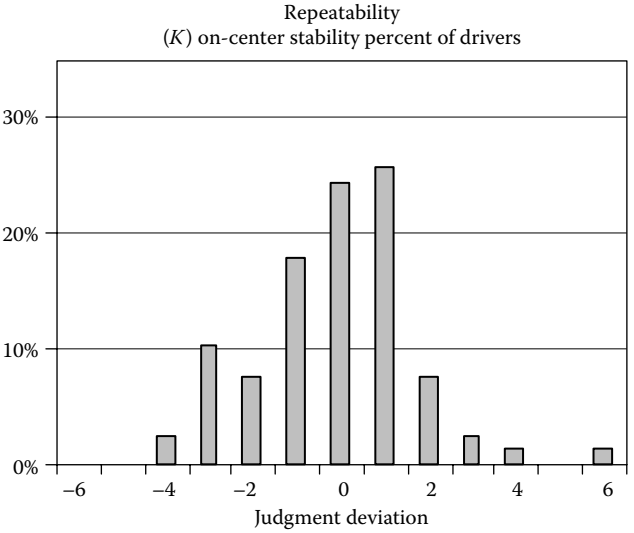

FIGURE 33.43 Result from repeatability test.

histogram shows how the assessment deviations are distributed. Only 25% of the drivers managed to give the same judgment each time. Sixty-eight percent stayed within 1 point's deviation and quite a few were completely unable to recognize the identical vehicle. The assessment scale had seven levels.

In another test, carried out on public roads, the drivers (A–K) were asked to judge the overall handling behavior at two occasions. Four of the drivers made three test drives. There were two test

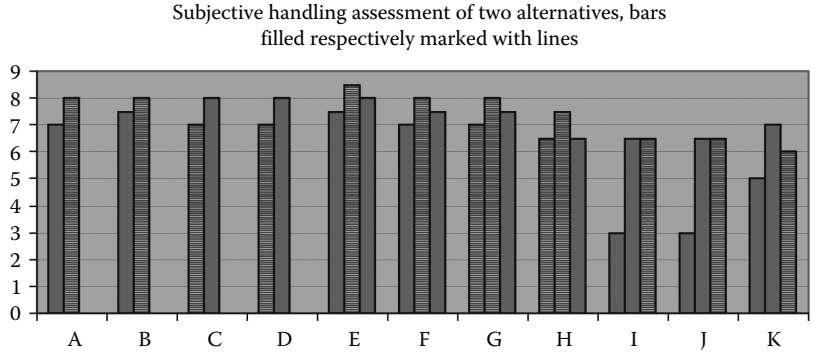

FIGURE 33.44 Results from handling assessment.

alternatives, and between the test runs, the vehicle was modified or said to be modified. The two test alternatives were driven in different order by the different drivers. The result from this test is shown in Figure 33.44. It appears that the order between test runs and assessment is the only correlation there is. The second test run always gives the highest rating regardless of which alternative it is. This illustrates the unreliability of subjective assessment.

33.13 CONCLUSION

There has been a tremendous development of heavy vehicles and of the dynamics of heavy vehicles during the latter half of the last century. The drivers for this development have been the increasing demands on transport effectiveness, the need of specialized and optimized vehicles, the requirements on better active safety, and better vibration environment.

The most important in the development process is to understand all aspects of the dynamics and to set up objective requirements.

Mathematical modeling is fundamental, but unnecessary complexity should be avoided.

Verification should be carried out both in real vehicles and with mathematical models and shall be based on objective criteria and not on subjective assessment.

Active control systems to assist the driver are developing quickly and increase the safety provided that they are added to a truck with good passive features.

34.1 INTRODUCTION

The dynamic behavior of an off-road vehicle may be described in terms of its performance (mobility), handling, and ride. Performance characteristics refer to the ability of the vehicle to overcome motion resistance, to develop drawbar pull, to negotiate slope, to accelerate, and to decelerate. Handling behavior is primarily concerned with the steering response of the vehicle to the driver's commands. Ride quality is related to the vibration of the vehicle excited by surface irregularities and its effects on the driver and passenger.

There are currently two basic forms of running gear for off-road vehicles: wheel and track. While both off-road wheeled vehicles and road vehicles use tires as their running gear, their functional requirements are significantly different. Off-road wheeled vehicles are designed for operation over unprepared terrain, which may have significant deformation under vehicular loads, whereas road vehicles are designed for operation over paved surfaces, which have relatively little deformation in comparison with unprepared terrain under similar loading conditions. For heavy off-road vehicles, tracks are usually employed as the running gear, primarily to obtain larger contact area in order to reduce the contact pressure on the terrain. It is interesting to note that the concept of the track was first conceived in the late eighteenth century as a "portable railway" to wheel carriages. This "portable railway" is laid down on the terrain in front of the road wheels and picked up at the rear as the vehicle advances. As the track system has certain unique features and tracked vehicles are widely used in off-road operations, in this chapter, greater emphasis will be placed on the discussion of the dynamics of tracked vehicles.

34.2 PERFORMANCE (MOBILITY) OF OFF-ROAD VEHICLES

Dependent upon the functional requirements, different criteria are employed to evaluate the performance characteristics of various types of off-road vehicles. For tractors, their main function is to provide draft to pull various types of implement or machinery. Consequently, their drawbar performance is of prime interest. It may be characterized by the ratio of drawbar pull to vehicle weight (drawbar pull coefficient), drawbar power (the product of drawbar pull and vehicle forward speed), and drawbar efficiency (the ratio of drawbar power to the corresponding power delivered by the driven wheels or sprockets). For cross-country transport vehicles, the transport productivity (the product of payload and vehicle forward speed) and transport efficiency (the ratio of transport productivity to the corresponding power delivered by the power plant of the vehicle) are often used as the basic criteria for evaluating their performance. For military vehicles, on the other hand, the maximum feasible operating speed between two specific points in a given region may be employed as a criterion for evaluating their mobility.

Although differing criteria are used to assess the performance of different types of off-road vehicles, there is a basic requirement common to all cross-country vehicles, that is, their mobility over unprepared terrain. Mobility in a broad sense refers to the capability of the vehicle in traversing soft terrain, in negotiating obstacles, in providing comfortable ride over rough terrain, and in water crossing. The ability in traversing soft terrain is a basic concern in vehicle mobility, and detailed analysis of the relationship among vehicle performance, vehicle design parameters, and terrain characteristics is, therefore, of prime importance.

In this chapter, emphasis will be placed on the discussion of the latest developments in computer simulation models for performance evaluation of off-road vehicles, including both wheeled and tracked vehicles.

As noted in Chapter 20, in the past owing to the lack of understanding of the response of natural terrain to vehicular loading and of the complex phenomenon of vehicle–terrain interaction, empirical and semiempirical methods have been widely used in the evaluation or prediction of off-road vehicle performance (mobility). In recent years, with the increasing globalization of the economy, improving competitiveness in the world market has become a major concern of industry. The empirical approach to product development adopted in the past has become extremely inefficient and prohibitively expensive. To gain a competitive edge, shortening the product development cycle is of vital importance. Virtual product development (virtual prototyping) is therefore being adopted by industry. To implement this process successfully, the development of realistic and comprehensive computer simulation models for performance and design evaluation of off-road vehicles is essential. In response to this requirement, a series of computer simulation models for tracked and wheeled vehicles has been developed [1,2]. In contrast with empirical or semiempirical methods developed earlier, these computer simulation models are based on the detailed analysis of the physical nature

of vehicle–terrain interaction and on the principles of applied mechanics. They take into account all major design features of the vehicle and its running gear. All pertinent characteristics of the terrain are also taken into consideration, including the pressure-sinkage and shearing characteristics, as well as the response to repetitive loading, as described in Section 20.6.1.

For evaluating the performance of vehicles with rubber-belt tracks or link tracks with relatively short track pitch, commonly found in military fighting, and logistics vehicles, a model known as NTVPM has been developed [3–9]. In this model, the track is idealized as a flexible and extensible belt. For tracked vehicles with rigid link tracks having relatively long track pitch, commonly used in farming and construction industry, a model known as RTVPM has been developed [10–12]. In this model, the track is considered as a system of rigid links connected through pins. For off-road wheeled vehicles, including wheeled armored vehicles and tractors, a model known as NWVPM has been developed. This model takes into account all major design features of the vehicle, as well as the tire. Multipass effects of the succeeding tires running in the ruts formed by the preceding tires are taken into consideration.

34.2.1 Computer Simulation Model NTVPM for Vehicles with Flexible Tracks

For high-speed tracked vehicles, such as military fighting and logistics vehicles and cross-country transport vehicles, rubber-belt tracks or link tracks with relatively short track pitch are commonly used. This kind of short-pitch track system typically has a ratio of road wheel diameter to track pitch in the range of 4–6, a ratio of road wheel spacing to track pitch ranging from 4 to 7, and a ratio of sprocket pitch diameter to track pitch of the order of 4. The rubber-belt track and short-pitch link track will be referred to as "flexible tracks," and they are idealized as a flexible and extensible belt in the analysis of track–terrain interaction.

The computer simulation model NTVPM has been developed for performance and design evaluation of tracked vehicles with flexible tracks. It takes into account all major design parameters of the vehicle, including vehicle weight, track system configuration, number of road wheels, road wheel spacing, track dimensions and geometry, initial track tension, track longitudinal elasticity, suspension characteristics, location of the center of gravity, arrangements for the sprockets, idlers, and supporting rollers, and vehicle hull (belly) shape (for the analysis of vehicle hull–terrain interaction, when the track sinkage is greater than the ground clearance and the vehicle hull is in contact with the terrain surface). All pertinent terrain characteristics, including the pressure–sinkage and shearing characteristics and the response to repetitive loading, are taken into consideration [1–9].

NTVPM can be used to predict the normal and shear stress distributions on the track–terrain interface and the external motion resistance, thrust, drawbar pull, and tractive efficiency of the vehicle as functions of track slip under steady-state operating conditions. It is particularly suited for the evaluation of competing designs, for the optimization of vehicle design parameters, and for the selection of vehicle candidates from tractive performance standpoint. The basic features of NTVPM have been validated by means of full-scale vehicle tests on a variety of terrains, including mineral terrain, organic terrain, and snow-covered terrain.

The basic approach to the development of NTVPM is outlined in the succeeding text [1–3].

34.2.1.1 Prediction of Normal Pressure Distribution under the Track

As noted previously, in the development of NTVPM, the track is treated as a flexible and extensible belt. A schematic of the track–road wheel system on a deformable terrain under steady-state operating conditions is shown in Figure 34.1.

When a tracked vehicle rests on a hard surface, the track lies flat on the ground. In contrast, when the vehicle travels over a deformable terrain, the normal load applied through the track system causes the terrain to deform. The track segments between road wheels take up load, and as a result, they deflect and have the form of a curve. The actual length of the track in contact with the terrain between the front and rear road wheels increases in comparison with that when

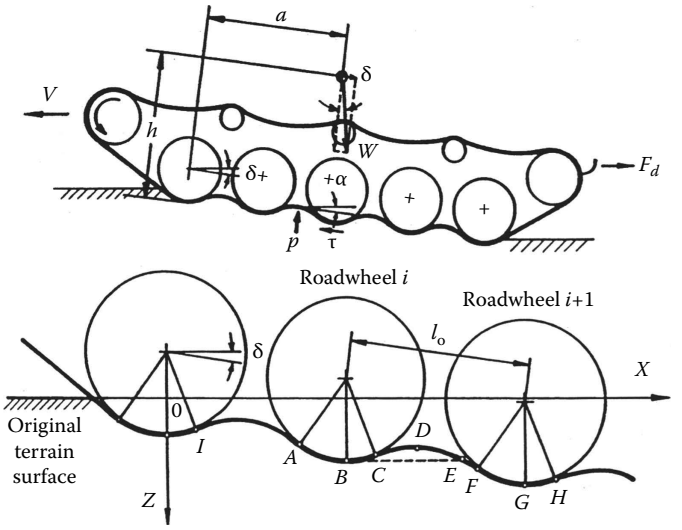

FIGURE 34.1 Interaction between a flexible track and a deformable terrain. (Reproduced from Wong, J.Y., *Theory of Ground Vehicles*, 4th edn., John Wiley, New York, 2008.)

the track rests on a firm ground. This causes a reduction in the sag of the top run of the track and a change in track tension. In the model, the elongation of the track under tension is taken into consideration.

The deflected track in contact with the terrain may be divided into two sections: one in contact with both the road wheel and the terrain, such as *AC* and *FH* shown in Figure 34.1, and the other in contact with the terrain only, such as segment *CF*. The shape of the track segment in contact with the road wheel, such as *AC*, is defined by the shape of the road wheel, whereas the shape of the track segment in contact with the terrain only, such as *CF*, is determined by track tension, road wheel spacing, pressure–sinkage relationship, and response to repetitive loading of the terrain.

Along segment *AB*, the pressure exerted on the terrain increases from *A* to *B*. From *B* to *D*, the pressure decreases corresponding to the unloading portion of the repetitive loading cycle shown in Figure 20.15. Along segment *DE*, the pressure increases again, corresponding to the reloading portion of the repetitive loading cycle. Beyond point *E*, which is at the same level as point *B*, the sinkage is higher than that at *B*. As a result, the pressure increases and the sinkage of the succeeding road wheel will be greater than that of the preceding road wheel. This causes the vehicle to assume a nose-up attitude. Beyond point *G*, the pressure exerted on the terrain decreases again and another unloading–reloading cycle begins.

Over highly compressible terrain, such as fresh, deep snow, track sinkage may be greater than the ground clearance of the vehicle. If this occurs, the hull (belly) of the vehicle will be in contact with the terrain surface and will support part of the vehicle weight. This will reduce the load carried by the tracks and will adversely affect the traction of the vehicle on frictional terrain. Furthermore, the contact of the hull with the terrain will give rise to an additional drag component, the belly drag. The characteristics of vehicle hull–terrain interaction and their effects on vehicle performance have been taken into consideration in NTVPM. In the model, the characteristics of the independent suspension of the road wheels are fully taken into account. Torsion bar suspensions, hydropneumatic suspensions with nonlinear characteristics, and others can be accommodated in the model.

Based on the understanding of the physical nature of track–terrain interaction described earlier, a set of equations for the equilibrium of forces and moments acting on the track–road wheel system and for the evaluation of the overall track length is derived. They establish the relationship among the shape of the deflected track in contact with the terrain, vehicle design parameters, and terrain characteristics.

The solution to this set of equations defines the sinkage of the road wheels, inclination of the vehicle body, track tension, and track shape in contact with the terrain. From these and taking into account the pressure–sinkage relationship and response to repetitive loading of the terrain, the normal pressure distribution under a tracked vehicle in steady-state motion is predicted.

34.2.1.2 Prediction of Shear Stress Distribution under the Track

The tractive performance of a tracked vehicle is closely related to the normal pressure and shear stress distributions on the track–terrain interface. As discussed in Section 20.6.1.2, shear stress is related to shear displacement. To predict the shear stress distribution, the development of shear displacement under the track should be determined first. The shear displacement under a flexible track may be evaluated by analyzing the slip velocity V_j on the track–terrain interface. The slip velocity of a point on the flexible track relative to the terrain surface is the tangential component of the absolute velocity V_a shown in Figure 34.2. The magnitude of the slip velocity V_j is given by

$$V_j = V_t - V\cos\alpha = r\omega - r\omega(1-i)\cos\alpha = r\omega[1-(1-i)\cos\alpha] \tag{34.1}$$

where

r and ω are the pitch radius and angular speed of the sprocket
i is the slip of the track
α is the angle between the tangent to the track at point P and the horizontal
V_t is the theoretical speed of the vehicle (i.e., $V_t = r\omega$)
V is the actual forward speed of the vehicle

Based on the analysis of slip velocity, the shear displacement j along the track–terrain interface is given by

$$j = \int_o^t r\omega[1-(1-i)\cos]dt = \int_o^l r\omega[1-(1-i)\cos\alpha]\frac{dl}{\omega} = l-(1-i)x \tag{34.2}$$

where

l is the distance along the track between point P and the front contact point of the track
x is the corresponding horizontal distance between point P and the front contact point of the track

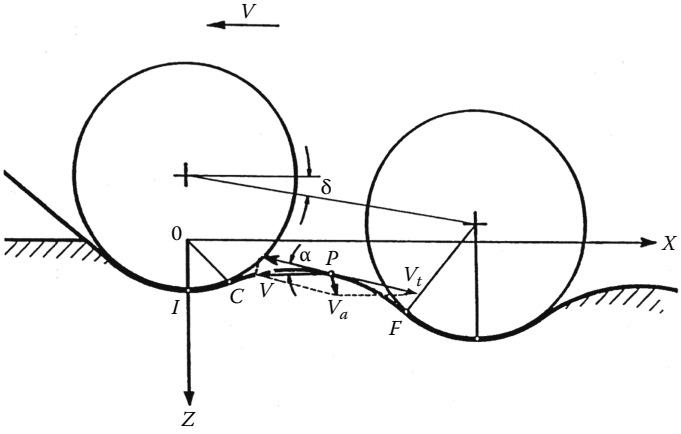

FIGURE 34.2 Slip velocity of a point on a flexible track in contact with a deformable terrain. (Reproduced from Wong, J.Y., *Theory of Ground Vehicles*, 4th edn., John Wiley, New York, 2008.)

If the shear stress–shear displacement relationship is described by the exponential equation (Equation 20.22), the shear stress along the flexible track $\tau(x)$ is given by

$$\tau(x) = [c + p(x)\tan\phi]\left[1 - \exp\left(-\frac{l-(1-i)x}{K}\right)\right] \tag{34.3}$$

where $p(x)$ is normal pressure on the track, which is a function of the horizontal distance x.

It should be noted that shear stress is related to normal pressure. At the beginning of the simulation process, an initial estimate of the normal pressure distribution is made by neglecting the presence of shear stress on the track–terrain interface, using the procedure described in the preceding section. After the initial normal pressure distribution is determined, the procedure outlined earlier is used to estimate the shear stress distribution. An iterative process is then initiated to recalculate the normal pressure distribution based on the estimated shear stress distribution. The shear stress distribution is subsequently revaluated, based on the recalculated normal pressure distribution. This iterative procedure will be repeated until the errors in the equilibrium equations for forces and moments acting on the vehicle are less than the prescribed values.

34.2.1.3 Prediction of Motion Resistance, Thrust, and Drawbar Pull

When the normal and shear stress distributions under a tracked vehicle at a given slip have been determined, the tractive performance of the vehicle can be predicted. The performance of an off-road vehicle is usually characterized by its motion resistance, thrust, and drawbar pull (the difference between thrust and motion resistance) as functions of slip.

The external motion resistance R_c of the track can be determined by integrating the horizontal component of the normal pressure acting on the track–terrain interface. For a vehicle with two tracks, R_c is given by

$$R_c = 2b\int_o^l p\sin\alpha\, dl \tag{34.4}$$

where

b is the contact width of the track
l is the contact length of the track
p is the normal pressure
α is the angle between a track element on the interface and the horizontal

The thrust of the vehicle can be calculated by integrating the horizontal component of the shear stress on the track–terrain interface. For a vehicle with two tracks, the thrust F is given by

$$F = 2b\int_o^l \tau\cos\alpha\, dl \tag{34.5}$$

where τ is the shear stress on the track–terrain interface.

It should be noted that the thrust calculated by Equation 34.5 is due to the shearing action of the track across the grouser tips. For a track with high grousers, additional thrust will be developed from the shearing action on the vertical surfaces on either side of the track, and this should be taken into consideration [1,2].

The drawbar pull F_d is the difference between the thrust and the external motion resistance and is expressed by

$$F_d = F - R_c \tag{34.6}$$

It should be noted that if the track sinkage is greater than the ground clearance and the vehicle hull is in contact with the terrain surface, the hull (belly) drag should be taken into account in the calculation of the drawbar pull [1,2].

34.2.1.4 Experimental Substantiation

The basic features of NTVPM have been validated with field test data of both single-unit and two-unit articulated tracked vehicles over a variety of unprepared terrains, including mineral terrain, organic terrain, and snow-covered terrain. As an example, Figures 34.3 and 34.4 show a comparison of the measured and predicted normal pressure distribution under the track pad and that of the measured and predicted drawbar performance of an armored personnel carrier over an organic terrain, respectively. More validation test results may be found in references [1–3].

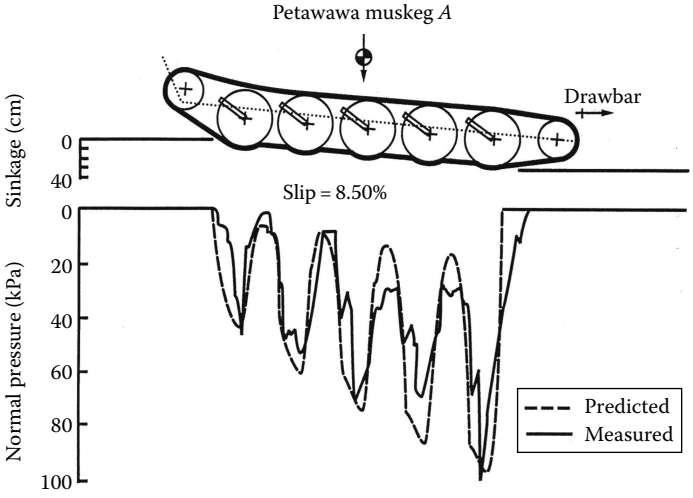

FIGURE 34.3 Comparison of the measured normal pressure distribution under the track pad of an armored personnel carrier and the predicted one using the computer simulation model NTVPM on an organic terrain. (Reproduced from Wong, J.Y., *Theory of Ground Vehicles*, 4th edn., John Wiley, New York, 2008.)

34.2.1.5 Applications

NTVPM can be employed to evaluate the effects of vehicle design and terrain conditions on vehicle performance. It can also be used in parametric analysis and design optimization. As an example, Figure 34.5 shows the effects of the number of road wheels and initial track tension on the drawbar pull to weight ratio of an armored personnel carrier over deep snow predicted by NTVPM [1,2,4]. It can be seen that both the number of road wheels and initial track tension have significant effects on vehicle mobility over soft terrain. For a given vehicle, its performance over soft terrain can be greatly improved by appropriate increase of the initial track tension in most cases, dependent upon suspension settings [1,2,4,5]. This research finding from the applications of NTVPM has led to the development of a driver controlled, central initial track tension regulating system. Over normal terrain, the driver sets the initial track tension at the regular level. However, when traversing soft terrain is anticipated, the driver can readily increase the initial track tension to an appropriate level to improve vehicle mobility. This system has been introduced into a number of high-mobility military fighting vehicles. The effects of the central track tension regulating system on tracked vehicle mobility are analogous to those of the central tire inflation system on wheeled vehicle mobility.

NTVPM has been successfully used to assist vehicle manufacturers in the development of new products and governmental agencies in the selection of vehicle candidates in North America, Europe, Asia, and Africa.

34.2.2 Computer Simulation Model RTVPM for Vehicles with Rigid Link Tracks

For low-speed tracked vehicles, such as those used in farming and construction industry, rigid link tracks with relatively long track pitch are commonly used. This type of track system has a ratio of road wheel diameter to track pitch as low as 1.2 and a ratio of road wheel spacing to track pitch typically 1.5. This type of track will be referred to as "rigid link track" and may be treated as a system of rigid links connected with pins.

The computer simulation model RTVPM has been developed for performance and design evaluation of tracked vehicles with rigid link tracks. It takes into account all major design parameters of the vehicle, including vehicle weight, track system configuration, number of road wheels, road wheel spacing, track dimensions and geometry, initial track tension, location of the center of gravity, arrangements for the sprockets, idlers, and supporting rollers, and drawbar hitch location. As the

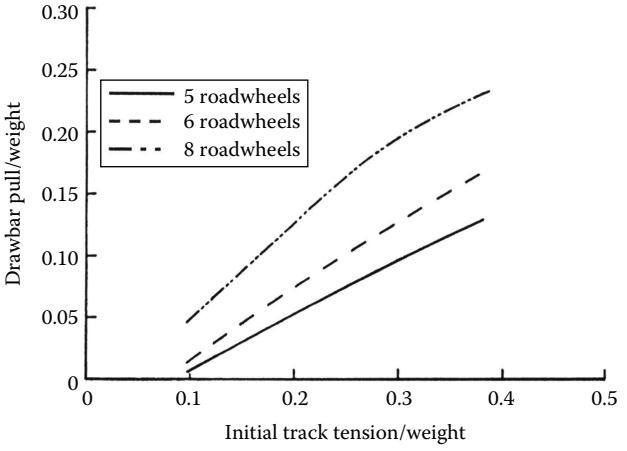

FIGURE 34.5 Effects of the number of road wheels and initial track tension to weight ratio on the drawbar pull to weight ratio of a tracked vehicle on snow predicted using the computer simulation model NTVPM. (Reproduced from Wong, J.Y., *Theory of Ground Vehicles*, 3rd edn., John Wiley, New York, 2001.)

track links are considered to be rigid, the track is regarded as inextensible [1,2,10–12]. Terrain parameters used in this model are the same as those in NTVPM.

34.2.2.1 Basic Approach to the Development of the Model

As noted previously, the model RTVPM treats the track as a system of rigid links connected with frictionless pins, as shown in Figure 34.6. The road wheels, sprockets, and supporting rollers are assumed to be rigidly attached to the vehicle frame. The center of the front idler is, however, considered to be mounted on a pre-compressed spring.

In the analysis, the track system is divided into four sections: the upper run of the track supported by rollers, the lower run of the track in contact with the road wheels and the terrain, the section in contact with the idler, and the section in contact with the sprocket. By considering the equilibrium of various sections of the track system, the interaction between the lower run of the track and the terrain, and the boundary conditions for various track sections, a set of equations can be formulated. The solution to this set of equations determines the track sinkage, inclination of the track system, normal and shear stress distributions on the track–terrain interface, and the track motion resistance, thrust, drawbar pull, and tractive efficiency of the vehicle as functions of track slip. Figure 34.7

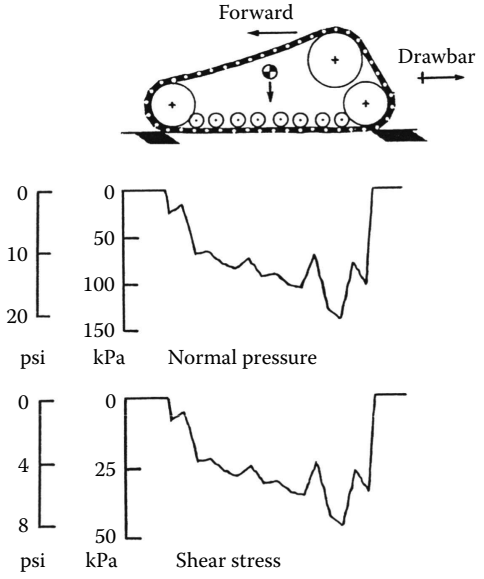

FIGURE 34.7 Normal and shear stress distributions under a tracked vehicle predicted using the computer simulation model RTVPM on clayey soil. (Reproduced from Wong, J.Y., *Theory of Ground Vehicles*, 4th edn., John Wiley, New York, 2008.)

shows the normal and shear stress distributions under a tracked vehicle with eight road wheels on clayey soil predicted using RTVPM [1,2].

34.2.2.2 Experimental Substantiation

The basic features of RTVPM have been validated with available field test data. Figure 34.8 shows a comparison of the measured and predicted drawbar pull coefficient (drawbar pull to weight ratio) for a heavy tracked vehicle used in construction industry. The terrain was a dry, disked, sandy loam. The measured data shown in the figure were provided by Caterpillar Inc., Peoria, Illinois, United States.

It can be seen that the drawbar pull coefficient of the vehicle predicted using RTVPM agrees reasonably well with the measured. This suggests that the model is capable of providing realistic prediction of the performance of vehicles with long-pitch link tracks in the field.

34.2.2.3 Applications

RTVPM can be used to evaluate the effects of vehicle design and terrain conditions on vehicle performance. It can also be employed in parametric analysis and design optimization of vehicles with rigid link tracks. The applications of RTVPM to design evaluation may be demonstrated through an example for determining the optimum ratio of road wheel spacing to track pitch.

To evaluate the effects of the ratio of road wheel spacing to track pitch, the tractive performances of three track systems were predicted using RTVPM. The three systems have the same track contact length but with five, seven, and eight road wheels and with tracks of various pitches. It has been found that for given overall dimensions of a track system, the ratio of road wheel spacing to track pitch is one of the most significant design parameters that affects the performance of a tracked vehicle with rigid link tracks. Figure 34.9 shows the variation of the drawbar pull coefficient at 20% slip with the ratio of road wheel spacing to track pitch on clayey soil. It is shown that as long as the ratio of road wheel spacing to track pitch is similar, the tractive performances of the three track systems with different numbers of road wheels ranging from five to eight will be similar. It can be seen that on the clayey soil, the optimum ratio of road wheel spacing to track pitch is approximately one. This implies that for a given track pitch, the vehicle designer should select an appropriate road wheel spacing in order to

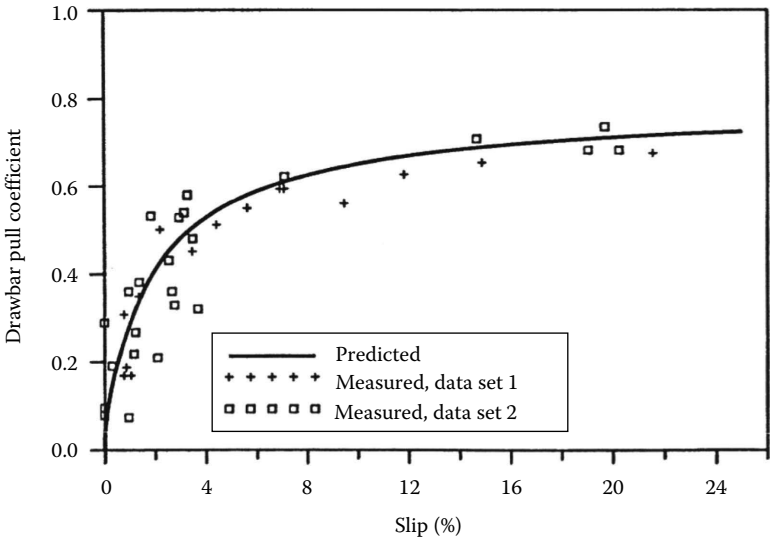

FIGURE 34.8 Comparison of the measured and predicted drawbar pull coefficient of a tracked vehicle on a dry, disked, sandy loam using the computer simulation model RTVPM. (Reproduced from Wong, J.Y., *Theory of Ground Vehicles*, 4th edn., John Wiley, New York, 2008.)

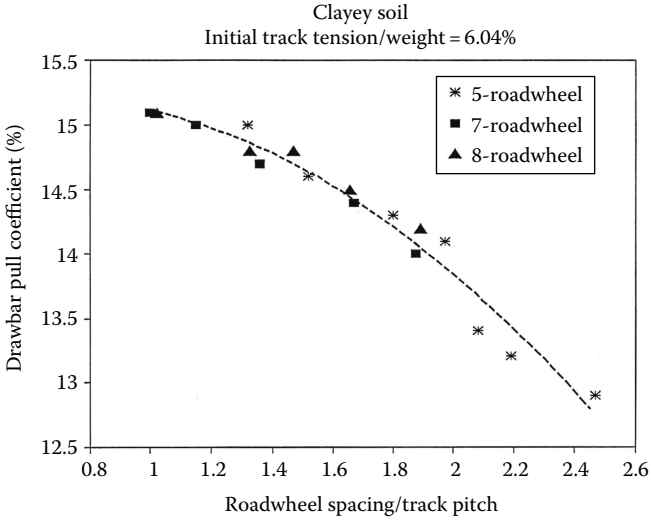

FIGURE 34.9 Effects of the ratio of road wheel spacing to track pitch on drawbar pull coefficient of track systems with different numbers of road wheels on clayey soil. (Reproduced from Wong, J.Y., *Theory of Ground Vehicles*, 4th edn., John Wiley, New York, 2008.)

achieve the optimum performance. It should be pointed out that track pitch also affects the fluctuation of vehicle forward speed, because of the polygon (or chordal) effect of the sprocket tooth–track link engagement. It can be shown that vehicle speed fluctuation due to the polygon effect is given by

$$\delta_s = 1 - \sqrt{1 - \left(\frac{P}{D}\right)^2} \tag{34.7}$$

where

δ_s is vehicle forward speed fluctuation
P is track pitch
D is the pitch diameter of the sprocket

For most agricultural and industrial tracked vehicles currently in use, the ratio of sprocket pitch diameter to track pitch varies from 3.7 to 4.3. Therefore, vehicle forward speed fluctuation will be in the range of 2.75%–3.72%. If the speed variation is to be kept to 2.75% and if the sprocket pitch diameter is 0.928 m, then the track pitch should be 0.216 m. As shown in Figure 34.9, to ensure good tractive performance on the clayey soil, the ratio of road wheel spacing to track pitch should be approximately one. Therefore, in this case, the optimum road wheel spacing should be approximately 0.216 m.

The example given earlier illustrates a practical application of RTVPM to the selection of optimum design parameters of vehicles with rigid link tracks. RTVPM has been successfully employed in assisting vehicle manufacturers in the development of new products.

34.2.3 Computer Simulation Model NWVPM for Off-Road Wheeled Vehicles

The computer simulation model NWVPM has been developed for performance and design evaluation of off-road wheeled vehicles, including military wheeled vehicles, tractors used in farming and construction industry, and cross-country transport wheeled vehicles. It can also be used in the selection of appropriate tires for a given mission and operating environment. The model takes into

account all major design features of the vehicle, including vehicle weight, axle load distribution, axle suspension stiffness, function of the axle (driven or nondriven), tread of the axle (distance between the left- and right-hand side tires), dynamic axle load transfer, multipass effects of tires (succeeding tires running in the rut formed by the preceding tires), wheelbase, location of the center of gravity, and location of the drawbar hitch. It also takes into consideration all major design features of the tire, including tire diameter, section width, section height, ratio of lug area to carcass area, lug height, inflation pressure and the associated average contact pressure on hard ground, and tire construction (radial or bias).

NWVPM can be used to predict the normal and shear stress distributions on the wheel–terrain interface, the internal (due to hysteresis of tire materials) and external motion resistance of the tire, thrust, drawbar pull, and tractive efficiency of the vehicle as functions of tire slip under steady-state operating conditions. Terrain parameters used in this model are the same as those in NTVPM or RTVPM.

34.2.3.1 Basic Approach to the Development of the Model

NWVPM first predicts the operating mode of the tires (rigid or elastic) on various axles, using the method outlined in Section 20.7.2. The normal pressure distribution on the tire–terrain interface is then evaluated, taking into account the pressure–sinkage characteristics and the response to repetitive loading of the terrain. Based on the normal pressure distribution, the shear stress distribution on the tire–terrain interface at a given tire slip is predicted, following the approach outlined in Section 20.7. The shear stress–shear displacement relationship and response to repetitive shear loading of the terrain are taken into account.

After the normal and shear stress distributions on the tire–terrain interface at a given tire slip have been determined, the motion resistance, thrust, drawbar pull, and tractive efficiency of the wheeled vehicle as functions of slip can be predicted, following the approach outlined in Section 20.7. The dynamic axle load transfer due to drawbar load has been taken into consideration.

34.2.3.2 Experimental Substantiation

The basic features of NWVPM have been substantiated by available field data. Figure 34.10 shows a comparison between the measured and predicted drawbar performance of a tractor on a stubble field [1,2]. The terrain data obtained in the stubble field vary within a certain range. The two solid lines in Figure 34.10 represent the predicted drawbar performance using the upper and lower bounds of the terrain data.

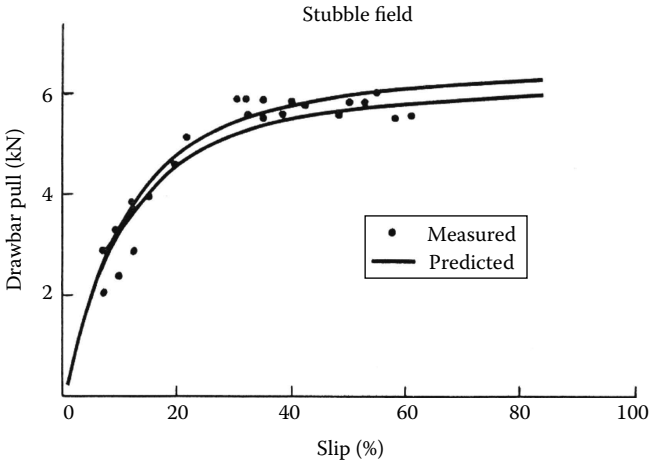

FIGURE 34.10 Comparison of the measured performance of a tractor on a stubble field with that predicted using the computer simulation model NWVPM. (Reproduced from Wong, J.Y., *Terramechanics and Off-Road Vehicle Engineering*, 2nd edn., Elsevier, Oxford, England, 2010.)

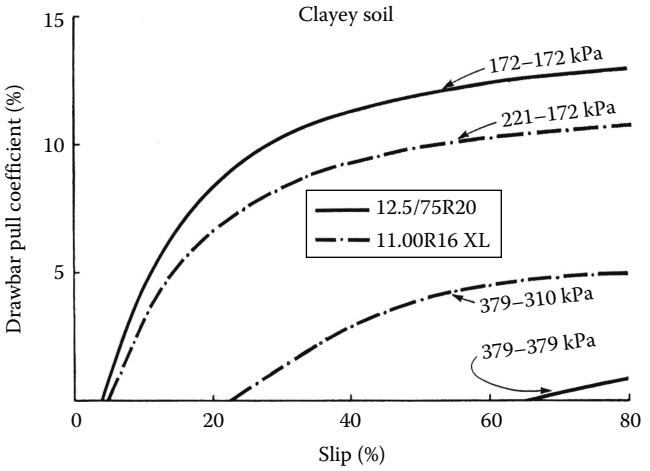

FIGURE 34.11 Drawbar performance of a two-axle, all-wheel-drive vehicle with different tires at various inflation pressure combinations on clayey soil predicted using the computer simulation model NWVPM. (Reproduced from Wong, J.Y., *Terramechanics and Off-Road Vehicle Engineering*, 2nd edn., Elsevier, Oxford, England, 2010.)

It can be seen that the drawbar performance of the tractor predicted using NWVPM agrees reasonably well with the measured data. This suggests that the model is capable of providing realistic prediction of drawbar performance of wheeled vehicles in the field.

34.2.3.3 Applications

NWVPM can be used to evaluate the effects of vehicle and tire design parameters and terrain characteristics on vehicle performance. It can also be employed to select appropriate tires for a given operating environment.

Figure 34.11 shows a comparison of the drawbar performances of a two-axle wheeled vehicle with two types of tire and at different inflation pressure combinations of the front and rear tires over clayey soil, predicted using NWVPM [2]. It is shown that both the tire type and inflation pressure have significant influence on the performance of the two-axle vehicle. For instance, the vehicle with the 12.5/75R20 tire at an inflation pressure of 379 kPa for both the front and rear tires is essentially immobile, whereas at an inflation pressure of 172 kPa for both tires, the performance of the vehicle improves significantly. It can also be seen that the vehicle with the 12.5/75R20 tire at an inflation pressure of 172 kPa for both the front and rear tires has better performance than that with the 11.00R16XL tire with an inflation pressure of 221 kPa at the front and of 172 kPa at the rear (this combination of inflation pressures for the front and rear tires is based on the manufacturer's recommendations). This demonstrates that the model NWVPM can play a useful role in performance and design evaluation of off-road wheeled vehicles and in the selection of appropriate tires for a given vehicle operating over a specific terrain.

In summary, the computer simulation models described earlier are based on understanding of the behavior of the terrain and the mechanics of vehicle–terrain interaction. Consequently, they offer considerable improvements over the empirical and semiempirical methods developed earlier in predicting and evaluating the performance of off-road vehicles. These models are gaining increasingly wide acceptance in industry and governmental agencies in many countries.

34.3 HANDLING CHARACTERISTICS OF OFF-ROAD VEHICLES

The handling characteristics of an off-road vehicle refer to its response to steering command on unprepared terrain. The handling of tracked vehicles is quite different from that of wheeled vehicles. Therefore, they will be discussed separately.

34.3.1 Steering of Tracked Vehicles

There are two basic methods for directional control of a tracked vehicle: one is commonly known as skid-steering and the other is articulated steering. In skid-steering, the thrust on one track (the outside track) is increased and that of the other (the inside track) is reduced or even braked, so as to create a turning moment to overcome the moment of turning resistance due to the skidding of tracks on the ground and the rotational inertia of the vehicle in yaw, as shown in Figure 34.12. Since the moment of turning resistance of the tracks is usually considerable, braking of the inside track is often required. This results in a reduction of the resultant forward thrust. On soft terrain, this often leads to immobilization. For tracked vehicles with two or more units (or chassis), steering may be accomplished by rotating one unit against the other using a steering joint to make the vehicle follow a prescribed curved path (i.e., articulated steering), as shown in Figure 34.13. In articulated steering,

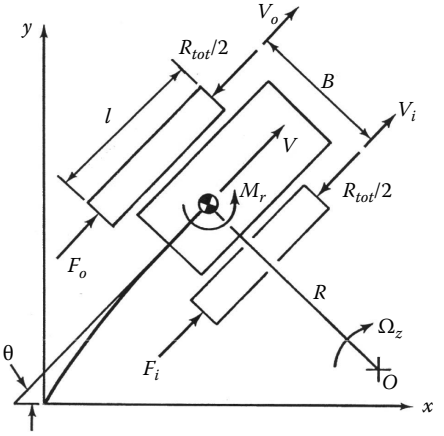

FIGURE 34.12 Skid-steering for tracked vehicles.

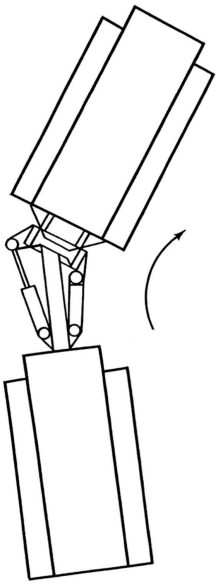

FIGURE 34.13 Articulated steering for tracked vehicles. (Reproduced from Wong, J.Y., *Theory of Ground Vehicles*, 4th edn., John Wiley, New York, 2008.)

turning is initiated by activating the steering joint between the two units, and no adjustment of thrusts of the outside and inside tracks is required. Thus, the resultant forward thrust of the vehicle can be maintained during a turn. On a soft terrain, articulated steering can provide tracked vehicles with better mobility during turning maneuvers than skid-steering.

34.3.2 Simplified Analysis of the Mechanics of Skid-Steering for Tracked Vehicles

The turning behavior of a tracked vehicle using skid-steering depends on the thrusts of the outside and inside tracks F_o and F_i, the resultant motion resistance R_{tot}, the moment of turning resistance M_r exerted on the track by the ground, and the vehicle dimensions, as shown in Figure 34.12. For low-speed turning maneuvers, the effects of centrifugal force may be neglected and the behavior of the vehicle can be described by the following two equations of motion:

$$m\frac{d^2s}{dt^2} = F_o + F_i - R_{tot} \tag{34.8}$$

$$I_z = \frac{d^2\theta}{dt^2} = \frac{B}{2}(F_o - F_i) - M_r \tag{34.9}$$

where

s is the displacement of the center of gravity of the vehicle
θ is the angular displacement of the vehicle
B is the tread of the vehicle (i.e., the distance between the centerlines of the two tracks)
I_z and m are the mass moment of inertia about the vertical axis passing through its center of gravity and the mass of the vehicle, respectively

With known initial conditions, the earlier two differential equations can be integrated with respect to time, and the path of the center of gravity and the orientation of the vehicle can be determined as functions of time.

Under steady-state conditions, both linear and angular accelerations are zero. Equations 34.8 and 34.9 become

$$F_o + F_i - R_{tot} = 0 \tag{34.10}$$

$$\frac{B}{2}(F_o - F_i) - M_r = 0 \tag{34.11}$$

The thrusts of the outside and inside tracks required to maintain a steady-state turn are therefore expressed by

$$F_o = \frac{R_{tot}}{2} + \frac{M_r}{B} = \frac{f_r W}{2} + \frac{M_r}{B} \tag{34.12}$$

$$F_i = \frac{R_{tot}}{2} - \frac{M_r}{B} = \frac{f_r W}{2} - \frac{M_r}{B} \tag{34.13}$$

where

f_r is the coefficient of motion resistance of the vehicle in the longitudinal direction
W is the vehicle weight

To determine the thrusts F_o and F_i, the moment of turning resistance M_r must be known. It can be determined experimentally or analytically. If the normal pressure is uniformly distributed along the track contact length, the lateral resistance per unit track length R_l be expressed by

$$R_l = \frac{\mu_t W}{2l} \tag{34.14}$$

where

μ_t is the coefficient of lateral resistance (friction)
l is the contact length of each of the two tracks

The value of μ_t depends not only on the terrain but also on the design of the track. Over soft terrain, the vehicle sinks into the ground, and the tracks together with the grousers will be sliding on the terrain, as well as displacing the soil laterally during turning maneuvers. The lateral forces acting on the tracks and the grousers due to displacing the soil laterally form part of the lateral resistance. Table 34.1 shows the average values of μ_t for steel and rubber tracks on various types of surface [1,13].

Assuming that the coefficient of lateral resistance μ_t is a constant, the resultant moment of the lateral resistance about the centers of the two tracks M_r (i.e., the moment of turning resistance of the vehicle) can be expressed by

$$M_r = 4\frac{\mu_t W}{2l}\int_o^{1/2} x dx = \frac{\mu_t W l}{4} \tag{34.15}$$

It should be emphasized that the value of M_r as calculated by Equations 34.15 is for a vehicle with uniform contact pressure and that the value of μ_t is a constant. Experimental evidence shows that in practice, the values of the moment of turning resistance M_r and the corresponding coefficient of lateral resistance μ_t appear to be functions of turning radius. This issue will be discussed further later.

Making use of Equation 34.15, Equations 34.12 and 34.13 can be rewritten in the following form:

$$F_o = \frac{f_r W}{2} + \frac{\mu_t W l}{4B} \tag{34.16}$$

$$F_i = \frac{f_r W}{2} - \frac{\mu_t W l}{4B} \tag{34.17}$$

TABLE 34.1
Values of Lateral Resistance Coefficient of Various Types of Track

	Coefficient of Lateral Resistance μ_t		
Track Material	**Concrete**	**Hard Ground (Unpaved)**	**Grass**
Steel	0.50–0.51	0.55–0.58	0.87–1.11
Rubber	0.90–0.91	0.65–0.66	0.67–1.14

Source: Hayashi, I., Practical analysis of tracked vehicle steering depending on longitudinal track slippage, *Proceedings of the 5th International Conference of the International Society for Terrain-Vehicle Systems*, Vol. II, Detroit, MI, 1975.

Equations 34.16 and 34.17 are useful in estimating the steerability of a tracked vehicle. As discussed in Chapter 20, the maximum thrust of a track is limited by the shear strength of the terrain, track contact area, and normal load on the track (see Equation 20.9 in that chapter). Accordingly, the maximum thrust that can be developed by the outside track is given by

$$F_{omax} \le cbl + \frac{W \tan \phi}{2} \tag{34.18}$$

where
b is the track width
l is the track contact length
c and ϕ are the cohesion and angle of internal shearing resistance of the terrain

Substituting Equation 34.16 into Equation 34.18, one obtains

$$\frac{f_r W}{2} + \frac{\mu_t W l}{4B} \le cbl + \frac{W \tan \phi}{2}$$

or

$$\frac{l}{B} \le \frac{1}{\mu_t}\left(\frac{4cA}{W} + 2\tan\phi - 2f_r\right) \tag{34.19}$$

where A is the contact area of one track.

This indicates that to steer a tracked vehicle without spinning the outside track, the ratio of track length to tread of the vehicle l/B must satisfy the following condition:

$$\frac{l}{B} \le \frac{2}{\mu_t}\left(\frac{c}{p} + \tan\phi - f_r\right) \tag{34.20}$$

where p is the average normal pressure on the track, which is equal to $W/2A$.

On a sandy terrain with $c = 0$, $\phi = 30°$, $\mu_t = 0.5$, and $f_r = 0.1$, the value of l/B should be less than 1.9. In other words, if the ratio of contact length to tread of a tracked vehicle is greater than 1.9, the vehicle will be unable to steer on the sandy terrain. On a clayey terrain, with $c = 3.45$ kPa, $\phi = 10°$, $p = 6.9$ kPa, $\mu_t = 0.4$, and $f_r = 0.1$, the value of l/B must be less than 2.88. These examples show the importance of the ratio of contact length to tread l/B to the steerability of a tracked vehicle.

34.3.3 General Theory for Skid-Steering

The analysis of the mechanics of skid-steering described in the preceding section is based on a number of simplifying assumptions. Consequently, the method can only provide preliminary prediction of the turning behavior of tracked vehicles. In an attempt to improve the prediction of the handling characteristics of tracked vehicles, Steeds developed a more detailed analysis of the mechanics of skid-steering [14]. In his analysis, the shear stress developed on the track–ground

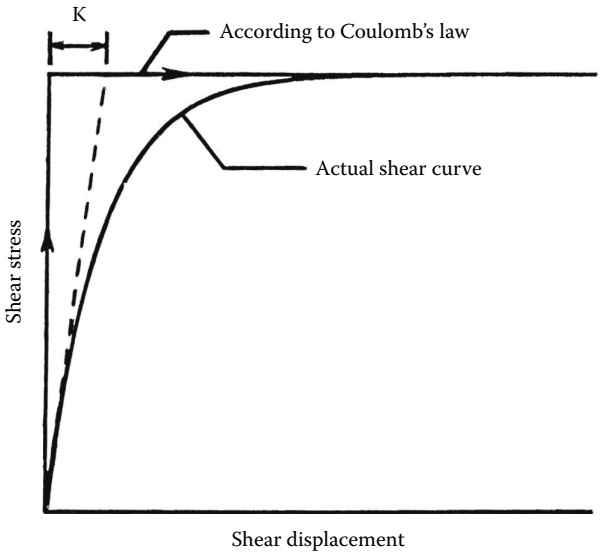

FIGURE 34.14 Comparison between the shear stress–shear displacement relationship measured in the field and that based on Coulomb's law of friction. (Reproduced from Wong, J.Y., *Theory of Ground Vehicles*, 4th edn., John Wiley, New York, 2008.)

interface is assumed to obey the Coulomb law of friction. The friction may be considered to be either isotropic or anisotropic. In the latter case, different values of coefficient of friction are assigned to the longitudinal and lateral directions of the track. It should be noted, however, that the Coulomb law of friction implies that as soon as a small relative movement between a track element and the ground is initiated, the maximum shear stress will develop instantly on that track element. Experimental evidence presented in Chapter 20 indicates that the shear stress will reach its maximum value only after a certain shear displacement has taken place, as shown in Figure 34.14. Field test data show that considerable discrepancy exists between the steering behavior of tracked vehicles predicted using Steeds' method and that measured. An improved, general theory for the mechanics of skid-steering on firm ground has, therefore, been developed recently by Wong and Chiang [1,15].

34.3.3.1 Basic Approach to the Development of the General Theory

The improved, general theory of skid-steering for tracked vehicles is based on the following premises [1,15]:

1. The ground is firm. Consequently, track sinkage and associated bulldozing effect of the track in the lateral direction during a turning maneuver are neglected.
2. The shear stress developed at a given point on the track–ground interface during a turn is dependent upon the shear displacement at that point, measured from its initial contact with the ground. For rubber-belt tracks or steel tracks with rubber pads, the shear stress is that developed between the rubber and the ground.
3. The direction of the shear stress at a point on the track–ground interface is opposite to that of the sliding velocity between the track and the ground at that point.
4. The component of the shear stress along the longitudinal direction of the track constitutes the tractive or braking effort, while the lateral component forms the lateral resistance of the track. The moment of the lateral resistance about the turn center of the track constitutes the moment of turning resistance.

The procedure for predicting the turning behavior of tracked vehicles using the general theory is briefly outlined in the following, and the details may be found in references [1,15]:

a. For a specific turning maneuver at a given vehicle forward speed and turning radius, the shear displacements of the contact points on the track–ground interface are first calculated, based on a kinematic analysis.
b. With known shear stress–shear displacement relationship, the distribution of shear stress on the track–ground interface is determined.
c. Based on the direction of the sliding velocity of the contact point relative to the ground, the direction of the shear stress at each contact point is evaluated.
d. The shear stress at each contact point is resolved into a longitudinal and a lateral component with respect to the track.
e. The integration of the longitudinal component of shear stress over the entire track contact area gives the resultant longitudinal force of the track, and the corresponding sprocket torque is equal to the product of the longitudinal force and sprocket pitch radius.
f. The integration of the lateral component of the shear stress over the entire track contact area gives the resultant lateral track force. The moment of the resultant lateral force about the turn center of the track determines the moment of turning resistance of the track.
g. From the analysis noted earlier, the dynamic equilibrium equations for a tracked vehicle in a steady-state turning maneuver are as follows (see Figure 34.15):

$$F_{xo} + F_{xi} = \frac{WV^2}{gR'}\cos\beta \tag{34.21}$$

$$F_{yo} + F_{yi} = \frac{WV^2}{gR'}\sin\beta + (R_o + R_i) \tag{34.22}$$

$$M_{Lo} - M_{Li} - \frac{B}{2}(R_o - R_i) + (s_o\cos\beta + c_x\sin\beta)\frac{WV^2}{gR'} = M_{ro} + M_{ri} \tag{34.23}$$

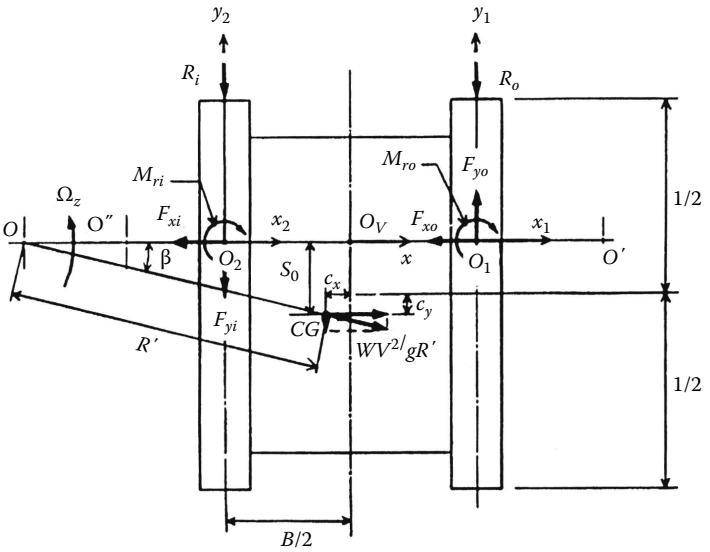

FIGURE 34.15 Forces and moments acting on a tracked vehicle during a steady-state turn. (Reproduced from Wong, J.Y., *Theory of Ground Vehicles*, 4th edn., John Wiley, New York, 2008.)

where

F_{xo} and F_{xi} are the resultant lateral forces acting on the outside and inside tracks, respectively
F_{yo} and F_{yi} are the resultant longitudinal forces acting on the outside and inside tracks, respectively
M_{Lo} and M_{Li} are the turning moments of the resultant longitudinal forces about the center O_v (shown in Figure 34.15) of the outside and inside tracks, respectively
M_{ro} and M_{ri} are the moments of turning resistance acting on the outside and inside tracks, respectively
R_o and R_i are the longitudinal motion resistances acting on the outside and inside tracks, respectively
g is the acceleration due to gravity
R' is the turning radius
s_o is the longitudinal offset of the turning center with respect to the center of gravity of the vehicle, caused by the centrifugal force
V is the vehicle forward speed
W is the vehicle weight

All other parameters are shown in Figure 34.15.

As noted previously, the shear stress on the vehicle–ground interface is related to the kinematics of the vehicle (i.e., vehicle forward speed V, turning radius R', and longitudinal offset s_o). Consequently, the forces and moments developed on the track–ground interface are functions of ω_o, ω_i, and s_o. For a specific turning maneuver with a given vehicle forward speed and turning radius, the values of ω_o, ω_i, and s_o can be determined by solving Equations 34.21 through 34.23 simultaneously. Thus, all forces and moments acting on the vehicle during a given steady-state turning maneuver are completely defined.

Various normal pressure distributions under the track can be accommodated in the general theory. They include normal loads on the tracks being concentrated beneath the road wheels, normal loads supported only by the track links immediately under the road wheels, and normal loads distributed continuously over the track contact length.

34.3.3.2 Experimental Substantiation

To validate the basic features of the general theory described earlier, the steering behavior of a military tracked vehicle was predicted, and the results were compared with available measured data reported in Reference [16]. Figure 34.16 shows the variations of the predicted sprocket torques for the outside and inside tracks with the theoretical turning radius (derived from the angular speeds of the outside and inside track sprockets ω_o, ω_i, neglecting the slip or skid of the tracks) at various vehicle forward speeds with different types of normal load distribution. In the figure, the measured data reported in reference [16] are also shown. For comparison, the predicted results obtained using Steeds' theory are presented as well.

It can be seen that predictions obtained using the general theory bear a strong resemblance to the measured data. Both show that the magnitudes of the sprocket torques generally decrease with the increase of theoretical turning radius. In contrast, predictions obtained using Steeds' theory differ greatly from the measured data. The sprocket torques predicted using Steeds' method remain essentially constant over a wide range of turning radii, particularly at low speeds. The reason for the poor predictions using Steeds' theory is primarily due to the assumption that the shear stress on the track–ground interface reaches its maximum value instantly, as soon as a small relative movement between the track and the ground takes place. Figure 34.17a and b show the lateral shear stress distributions along the longitudinal centerline of the outside and inside tracks, respectively, at various turning radii. It is noted that even at the front contact point where a track element just comes into contact with the ground, the lateral stress is at its maximum. In contrast, based on the general theory, the lateral stress at the front contact point of the outside and inside tracks is zero, as shown in Figure 34.18a and b, respectively. It should also be pointed out that the lateral shear

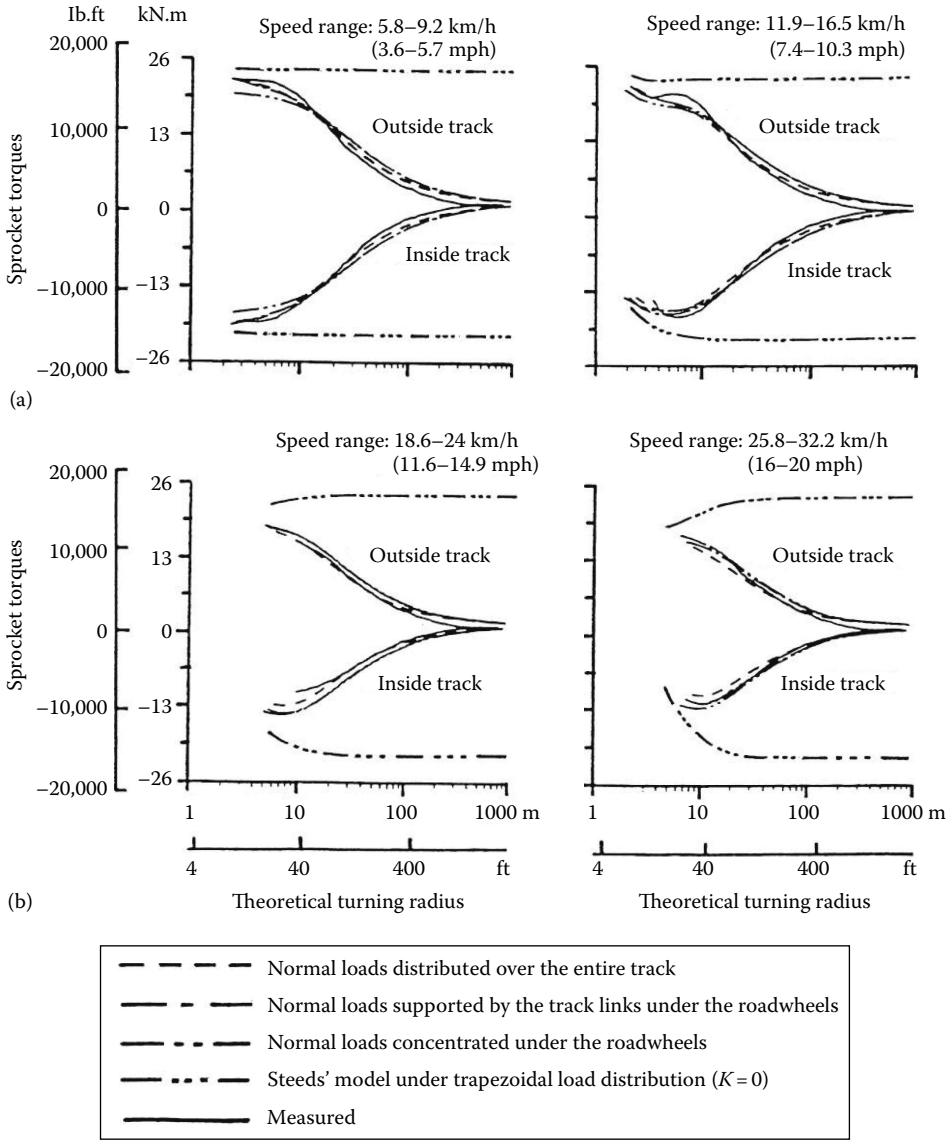

FIGURE 34.16 Comparison of the measured and predicted relationships between sprocket torques and theoretical turning radius for a tracked vehicle at various forward speeds using the general theory. (Reproduced from Wong, J.Y., *Theory of Ground Vehicles*, 4th edn., John Wiley, New York, 2008.)

stress distributions on the outside and inside tracks predicted using Steeds' theory remain essentially the same when the turning radius is larger than a certain value, such as 50 m shown in Figure 34.17. Since the moment of the lateral shear force about the turn center of the track constitutes the moment of turning resistance, this leads to essentially constant moments of turning resistance for the outside and inside tracks over a wide range of turning radii, based on Steeds' theory.

During a steady-state turn, the sprocket torques at the outside and inside tracks are to generate the required tractive or braking forces, which form a turning moment for the tracked vehicle to overcome primarily the resultant moment of turning resistance caused by the lateral skidding of the tracks on the ground. Consequently, as shown in Figure 34.16, based on Steeds' method, the sprocket torques for the outside and inside tracks remain essentially constant when the turning radius is larger than a certain value. In contrast, based on the general theory, the

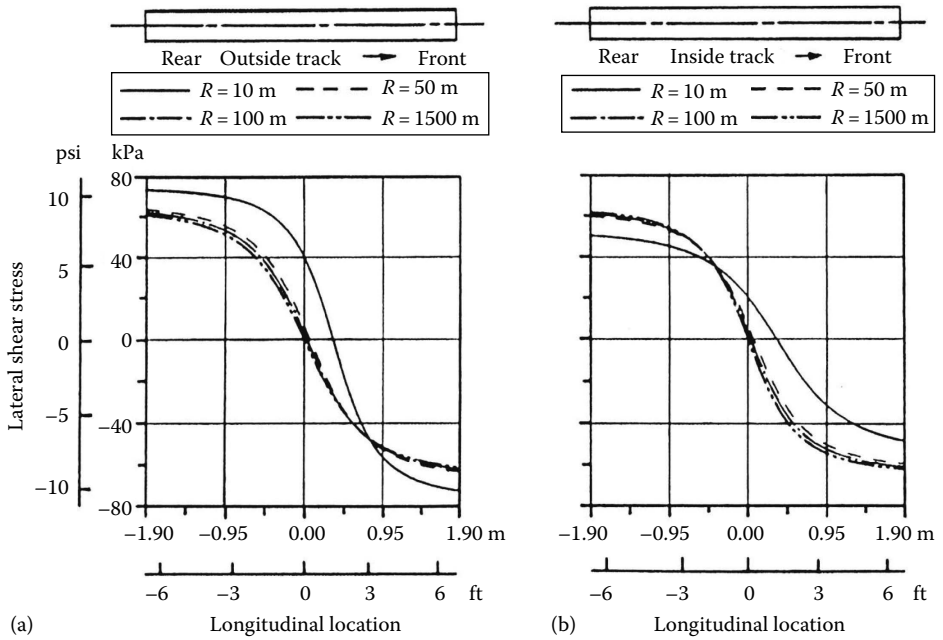

FIGURE 34.17 Lateral shear stress distributions along the centerline of (a) the outside track and (b) the inside track at different turning radii according to Steeds' theory. (Reproduced from Wong, J.Y., *Theory of Ground Vehicles*, 4th edn., John Wiley, New York, 2008.)

magnitude of the lateral shear stress decreases with the increase of turning radius, as shown in Figure 34.18. As a result, the magnitudes of the sprocket torques for the outside and inside tracks decrease with the increase of turning radius, as shown in Figure 34.16. This shows that the general theory provides much more realistic and accurate predictions of steering behavior of tracked vehicles than Steeds' theory. It is also interesting to note from Figure 34.16 that on firm ground the normal load distribution does not have a significant influence on the turning behavior of tracked vehicles.

34.3.3.3 Coefficient of Lateral Resistance

In the simplified analysis of the mechanics of skid-steering given in Section 34.3.2, a coefficient of lateral resistance μ_t (also known as the coefficient of lateral friction) is introduced in predicting the lateral force and moment of turning resistance acting on a track during a turning maneuver. If normal pressure is uniformly distributed along the track, the moment of turning resistance M_r due to track skidding is given by Equation 34.15.

Equation 34.15 indicates that the turning resistance moment M_r is independent of turning radius. Experimental evidence shows, however, that in practice the moment of turning resistance M_r varies with turning radius. As an expedient, it has been suggested that the coefficient of lateral resistance μ_t in Equation 34.15 be expressed as a function of turning radius. A number of empirical equations have been proposed to correlate μ_t with turning radius. These empirical equations contain a number of empirical constants and there is no evidence that these empirical relations can be generally applied.

As described previously, using the general theory, the moment of turning resistance M_r can be predicted analytically, using only the coefficient of friction μ that defines the shearing property of the track–ground interface. This means that using the general theory, it is not necessary to introduce a coefficient of lateral resistance μ_t in predicting the moment of turning resistance M_r. In fact the corresponding coefficient of lateral resistance μ_t used in Equation 34.15 can be derived quantitatively by equating the moment of turning resistance calculated from the general theory to that given by Equation 34.15. As the moment of turning resistance M_r calculated

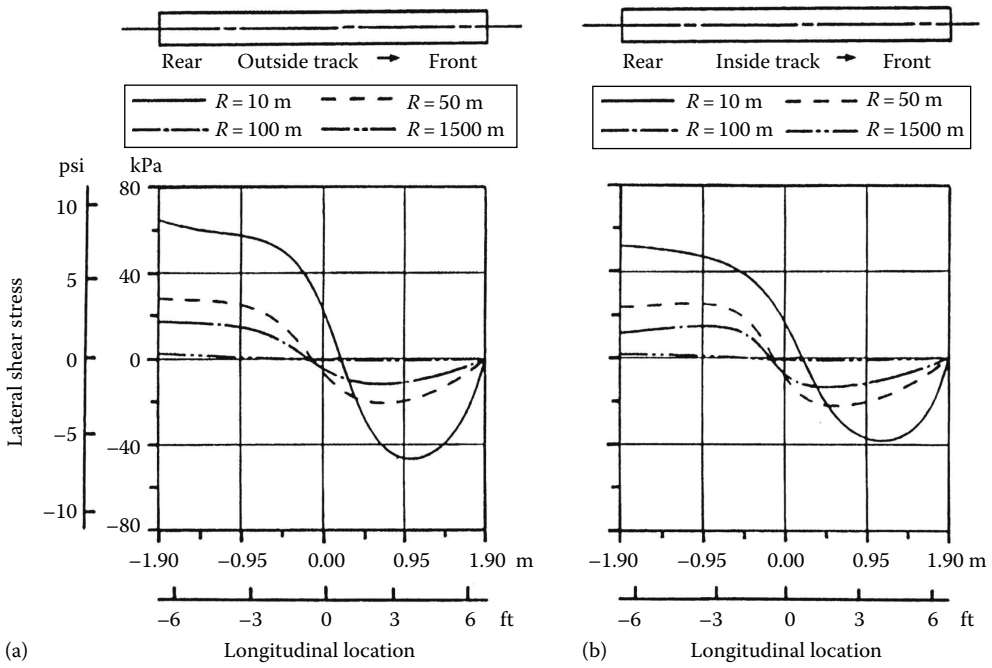

FIGURE 34.18 Lateral shear stress distributions along the centerline of (a) the outside track and (b) the inside track at different turning radii according to the general theory. (Reproduced from Wong, J.Y., *Theory of Ground Vehicles*, 4th edn., John Wiley, New York, 2008.)

by the general theory is related to turning radius, the relationship between the corresponding coefficient of lateral resistance μ_t used in Equation 34.15 and turning radius can be established.

As an example of the application of this method, Figure 34.19 shows the variations of the corresponding coefficient of lateral resistance μ_t with theoretical turning radius for the military tracked vehicle at a speed of 7.5 km/h, under different ground conditions, with the value of coefficient of

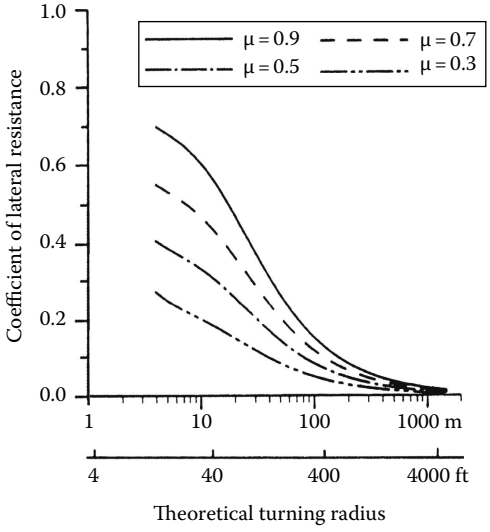

FIGURE 34.19 Variations of the coefficient of lateral resistance with turning radius predicted using the general theory for a tracked vehicle on surfaces with different values of coefficient of friction. (Reproduced from Wong, J.Y., *Theory of Ground Vehicles*, 4th edn., John Wiley, New York, 2008.)

friction μ varying from 0.3 to 0.9. This demonstrates that if Equation 34.15 is used to predict the moment of turning resistance, the relationship between μ_t and turning radius can be derived from the general theory for a given ground condition with known value of coefficient of friction μ. This means that by applying the general theory, the time-consuming field tests for defining the relation between μ_t and turning radii can be completely eliminated.

In summary, it appears that the general theory presented earlier provides an improved method for analyzing the mechanics of skid-steering and for predicting the turning behavior of tracked vehicles on firm ground.

34.3.4 Steering of Off-Road Wheeled Vehicles

Steering of most off-road wheeled vehicles is effected by changing the heading of front wheels through a steering system, similar to that of road vehicles. For multiaxle off-road wheeled vehicles, such as armored vehicles, in addition to the front wheels, intermediate wheels are in some cases made steerable. The prime consideration in the design of steering system for wheeled vehicles is minimum tire scrub during cornering. This requires that during the turn, all tires should be in pure rolling with minimum lateral sliding. To satisfy this requirement, the wheels should follow curved paths with different radii originating from a common turn center, as shown in Figure 34.20, for a 6 × 6 vehicle with steerable front and intermediate wheels. This establishes the proper relationship between the steer angle of the inside wheel and that of the outside wheel on the same axle. From Figure 34.20, it can be seen that for the 6 × 6 vehicle, the steer angles of outside and inside front wheels δ_{o1} and δ_{i1} and those of the outside and inside intermediate wheels δ_{o2} and δ_{i2} should satisfy the following relationships, respectively:

$$\cot\delta_{o1} - \cot\delta_{i1} = \frac{B}{L_1}$$
$$\cot\delta_{o2} - \cot\delta_{i2} = \frac{B}{L_2} \tag{34.24}$$

where

B is the tread (or track)

L_1 and L_2 are wheelbases, as shown in Figure 34.20

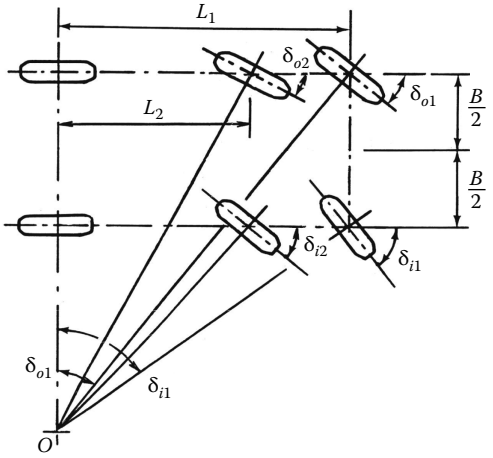

FIGURE 34.20 Desirable steering geometry for wheeled vehicles with steerable front and intermediate wheels.

The steering geometry that satisfies Equation 34.24 is usually referred to as the Ackermann steering geometry.

In many respects, the handling of off-road wheeled vehicles is similar to that of road vehicles. Since the handling characteristics of road vehicles are covered extensively in other chapters of this handbook, their discussion is not repeated here. However, there are differences between them. For instance, in many cases, the speed of off-road vehicles operating on unprepared terrain is much lower than that of road vehicles running on paved highways. Consequently, for these cases, the effects of centrifugal force may be neglected in the analysis of the handling of off-road wheeled vehicles. Furthermore, on unprepared terrain, the side (cornering) force–slip angle relationships of tires are usually quite different from those on paved road. Figure 34.21 shows the variations of the side (cornering) force coefficient (i.e., the ratio of side [cornering] force to normal load) with slip angle of a tractor front tire (7.5-18AS) on road and on a variety of unprepared terrains [17]. It can be seen that there are noticeable differences between the cornering behavior of a tire operating on unprepared terrain and that on paved road. It should be mentioned that the cornering behavior of tires on unprepared terrain has not been studied, both analytically and experimentally, as extensively as that of tires on paved road. This is an area that requires further research in order to be able to predict the handling behavior of off-road wheeled vehicles on unprepared terrain more accurately [18].

In addition to the Ackermann steering described earlier, articulated steering is also employed in off-road wheeled vehicles, particularly in heavy off-road wheeled vehicles used in earthmoving and construction industry. Detailed analysis of articulated steering of off-road wheeled vehicles may be found in Reference [19].

In summary, while the simplified analysis of skid-steering provides a basic understanding of the handling behavior of tracked vehicles, it cannot accurately predict the turning characteristics of tracked vehicles. The general theory for skid-steering developed by Wong and Chiang provides an improved method for predicting the turning behavior of tracked vehicles. Its basic features have been substantiated by field test data. For off-road wheeled vehicles, to improve the prediction of their handling behavior, further research into the cornering behavior of tires on unprepared terrain is required.

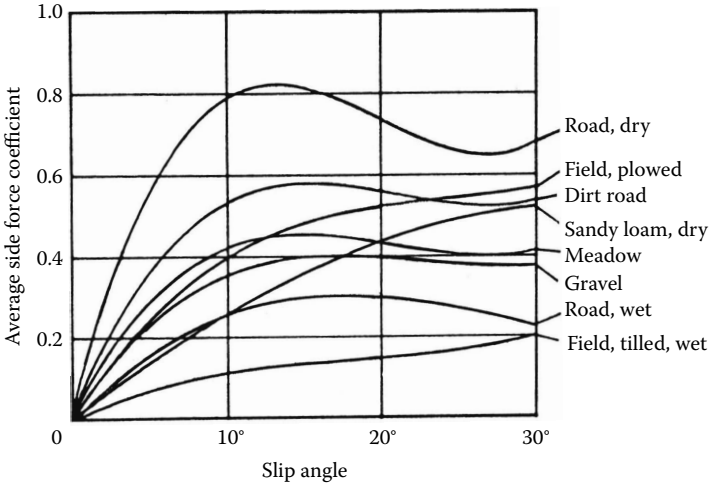

FIGURE 34.21 Comparison of the cornering characteristics of a tractor front tire on various types of terrain with those on paved road. (Reproduced from Schwanghart, H., Measurements of forces on steered, towed wheels (in German), *Proceedings of the 7th International Conference of the International Society for Terrain-Vehicle Systems*, Vol. I, Calgary, Alberta, Canada, 1981. 34.4 RIDE CHARACTERISTICS OF OFF-ROAD VEHICLES

Ride quality is concerned with the vibration of the vehicle excited by surface irregularities and with the effects of vehicle vibration on the comfort of the driver and passenger. To evaluate the ride quality of off-road vehicles, it is essential to have a basic understanding of the human response to vibration, of the characteristics of surface irregularities, and of the modeling of the vibration behavior of the vehicle (see also Chapters 29 and 36).

34.4.1 Ride Comfort Criteria

Over the years, a great deal of research has been conducted to define the limits of acceptable human exposure to whole-body vibration. Among the ride comfort criteria that have been proposed, the International Standard ISO 2631 is the most widely used [1,20]. It takes into account four physical factors that are of primary importance to the human response to vibration, namely, the intensity, the frequency, the direction, and the duration (exposure time) of the vibration. The International Standard 2631-1:1985(E) published in 1985 defines three distinct limits (boundaries) for whole-body vibration in the frequency range of 1–80 Hz:

A. Fatigue-Decreased Proficiency Boundary
This boundary specifies a limit beyond which exposure to vibration can be regarded as carrying a significant risk of impaired working efficiency in many kinds of task, such as vehicle driving.

B. Exposure Limit (Health or Safety)
The exposure limit as a function of frequency and exposure time is of the same general form as the fatigue-decreased proficiency boundary, but the corresponding levels are raised by a factor of 2 (6 dB higher). Exceeding the exposure limit is not recommended without special justification and precautions.

C. Reduced Comfort Boundary
Values of the reduced comfort boundary are obtained by lowering the corresponding values for the fatigue-decreased proficiency boundary by a factor of 3.15 (10 dB lower). In the transport situation, the reduced comfort boundary is related to difficulties in carrying out such activities as eating, reading, and writing.

The latest edition of the International Standard 2631-1:1997(E), published in 1997, recommends the use of frequency-weighted root-mean-square (rms) acceleration for evaluating whole-body vibration for health, comfort, and perception in the frequency range of 0.5–80 Hz and for motion sickness in the frequency range of 0.1–0.5 Hz. In the latest edition, potential effects of vibration on human performance (i.e., the fatigue-decreased proficient boundary in the previous edition) are no longer covered. For vibration with crest factor less than 9 (the crest factor is defined as the modulus of the ratio of the maximum instantaneous peak value of the frequency-weighted acceleration signal to its rms value), Table 34.2 describes the relations between the values of vibration magnitude and indications of comfort [20].

The "absorbed power," which represents the time rate of vibration energy transmitted to the human body, has also been proposed as a parameter of significance in evaluating human tolerance to vibration [1,21]. It is used in evaluating the ride quality of military vehicles negotiating rough terrain, especially in the United States. Currently, the tolerance limit is taken to be 6 W absorbed power at the driver's position. The ride-limiting speed is taken as the speed at which the driver's average absorbed power over the total elapsed time reaches a sustained level of 6 W. For a vibration environment characterized by a high crest factor, peak vertical acceleration is often used in conjunction with absorbed power to assess ride quality. The suggested limit for the peak vertical acceleration on the floor beneath the driver's seat is 2.5 *g*.

TABLE 34.2
Relations between Values of Vibration Magnitude and Indications of Comfort

Acceleration (rms) (m/s^2)	Indications
Less than 0.315	Not uncomfortable
0.315–0.63	A little uncomfortable
0.5–1.0	Fairly uncomfortable
0.8–1.6	Uncomfortable
1.25–2.5	Very uncomfortable
Greater than 2	Extremely uncomfortable

Source: ISO 2631-1:1997(E).

34.4.2 Characterization of Surface Irregularities

To predict vehicle vibration excited by surface irregularities, two methods are usually used to define the surface profile. If the time history of vehicle vibration is of interest, then surface profile is measured and directly used as input to vehicle vibration analysis. This type of analysis is usually referred to as the time domain analysis. The time history of vehicle vibration may be processed to obtain the vibration spectrum, from which the relationship between vibration intensity, such as the rms acceleration, and frequency of excitation may be established. The other method is to regard the surface profile as a random function and to characterize the surface profile in terms of power spectral density as a function of spatial frequency (expressed in terms of cycle/m) [1]. For a linear vehicle system, through its transfer function, vehicle vibration (as output) excited by surface irregularities (as input) can be predicted. This type of analysis is usually referred to as the frequency domain analysis. It has been found that in many cases, the relationship between the power spectral density of surface profile and spatial frequency may be approximated by

$$S_g(\Omega) = C_{sp}\Omega^{-N} \tag{34.25}$$

where

$S_g(\Omega)$ is the power spectral density function of surface profile in m^2/cycle/m
Ω is the spatial frequency in cycle/m
C_{sp} and N are constants for a given surface

Table 34.3 shows the values of C_{sp} and N for various types of surface [1].

In vehicle vibration analysis, it is more convenient to express the power spectral density of surface profile in terms of temporal frequency in Hz, rather than in terms of spatial frequency in cycle/m. The transformation of the spatial frequency Ω in cycle/m to the temporal frequency f in Hz is through the speed of the vehicle V:

$$f(\text{Hz}) = \Omega\ (\text{cycle/m})V(\text{m/s}) \tag{34.26}$$

The transformation of power spectral density of surface profile expressed in terms of spatial frequency $S_g(\Omega)$ to that in terms of temporal frequency $S_g(f)$ is also through the speed of the vehicle V:

$$S_g(f) = \frac{S_g(\Omega)}{V} \tag{34.27}$$

TABLE 34.3
Values of C_{sp} and N for Various Types of Surface

Surface Type	N	C_{sp}
Smooth highway	2.1	4.8×10^{-7}
Highway with gravel	2.1	4.4×10^{-6}
Pasture	1.6	3.0×10^{-4}
Plowed field	1.6	6.5×10^{-4}

Source: Wong, J.Y., *Theory of Ground Vehicles*, 4th edn., John Wiley, New York, 2008.

For a linear vehicle system with known transfer function $|H(f)|$, the power spectral density function $S_v(f)$ representing the vibration of the vehicle and the power spectral density function $S_g(f)$ representing the surface profile are related by

$$S_v(f) = |H(f)|^2 S_g(f) \tag{34.28}$$

After the power spectral density function $S_v(f)$ for the vehicle has been determined, the rms acceleration of the vehicle can be determined as a function of temporal frequency f. The results can then be compared with selected ride comfort criteria, such as the International Standard ISO 2631.

It should be pointed out that if the deformation of the terrain under vehicular load is significant, then the terrain profile will be modified as the vehicle traversing it. This will complicate the analysis of the vibration of off-road vehicles. The modification of terrain profile by vehicular load and its effects on vehicle vibration over deformable terrain are topics that so far have not been investigated extensively and warrant further research.

34.4.3 Modeling Ride Dynamics of Off-Road Vehicles

The approach to the modeling of the ride dynamics of off-road wheeled vehicles is similar to that of road vehicles. Since the ride dynamics of road vehicles is extensively covered in other chapters of this handbook, it will not be repeated here.

Modeling the ride dynamics of tracked vehicles, in certain respects, is similar to that of off-road wheeled vehicles, as they have similar suspension elements, such as springs and dampers. However, the presence of the track wrapping around the road wheels, sprockets, idlers, and supporting rollers introduces a great deal of complexity (see Figure 34.22).

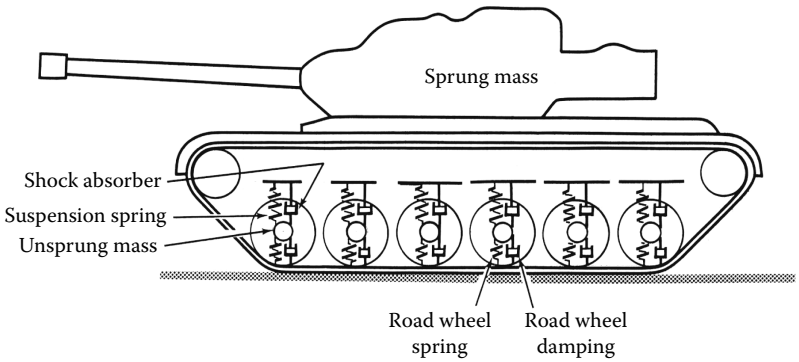

FIGURE 34.22 A ride model for a military tracked vehicle. (Reproduced from Wong, J.Y., *Theory of Ground Vehicles*, 4th edn., John Wiley, New York, 2008.)

The track acts as a mechanism to transfer mass between the vehicle's sprung and unsprung parts, as an elastic element with variable stiffness, as a terrain profile filtering mechanism, as a source of additional damping, and as an additional system capable of initiating its own vibrations. In existing ride dynamics models for tracked vehicles, a variety of assumptions are used in modeling the track. In some models, the track is idealized as a continuous flexible belt, inextensible or extensible with known longitudinal stiffness, whereas in others, the track is assumed as a system of rigid links connected with pins or rubber bushings.

Various assumptions on track tension distribution, ranging from constant track tension, through equal step increase (or decrease) in track tension between road wheels, to continuously variable track tension, have been made in existing ride dynamics models for tracked vehicles [22,23]. However, it appears that no existing model has taken into account the shearing action between the track and terrain and the resulting variation of track tension along the track.

In an earlier version of the vehicle dynamics module, VEHDYN, of the NATO Reference Mobility Model (NRMM), the track is modeled in the following way [22,24]:

a. If the terrain profile interferes with the tangent between the sprocket (or idler) and adjacent road wheel, the track will deflect to conform to the profile. This deflection will give rise to an increase in track tension, which will be transmitted through the sprocket (or idler) and road wheel to the vehicle. The increase in track tension is estimated by assuming that a virtual linear spring acts perpendicularly to the tangent between the sprocket (or idler) and adjacent road wheel. The force generated by this spring is determined by its stiffness and the maximum deflection of the track perpendicular to the tangent between the sprocket (or idler) and road wheel. The spring force is opposed by the track tension. Once the track tension is computed, the forces and moments transmitted to the sprocket (or idler) and road wheel can readily be determined.
b. The displacement of the road wheels with respect to each other will also cause track deflection. The resulting increase in track tension generates a restoring force on the displaced road wheel. This behavior is modeled by a vertically constrained, virtual linear bidirectional spring. If a road wheel is displaced relative to the adjacent one, the virtual spring will generate a vertical restoring force proportional to the relative displacement of adjacent road wheels.

An enhanced vehicle dynamics module of NRMM, VEHDYN 4.0, was released in 2008 [25].

It should be pointed out that existing ride dynamics analyses for tracked vehicles are all based on the assumption that the ground is rigid (nondeformable). Tests to validate these models have been conducted only on rigid surfaces with discrete obstacles or specific profiles. Figure 34.23 shows a comparison of the measured and predicted driver seat vertical acceleration of an armored personnel carrier with different track models traversing a 6′ obstacle on firm ground [22]. In Figure 34.23, track model #1 assumes the overall track tension being the initial track tension plus the tension due to the stretching of the track. In track model #2, the sag of the track segment between the sprocket and idler, represented by a quadratic polynomial, is incorporated in the evaluation of dynamic track load. Track model #3 is similar to track model #2, with the exception of the modeling of track sag, which is based on the classical catenary approach. Track model #4 is based on the model employed in the earlier version of VEHDYN mentioned previously.

It should be noted that while the ride quality of a tracked vehicle over rough, rigid surfaces may serve as a basis for comparing suspension designs, it does not represent the actual ride behavior of a tracked vehicle operating in the field. In an investigation carried out at Caterpillar into the vibration behavior of a D8L tracked tractor in the field, it has been found that the effects of dynamic stiffness and damping coefficient of the soil should be taken into consideration [26].

It should be mentioned that in recent years, a number of computer software packages for multibody dynamics, such as ADAMS and DADS, have become available. They have been used to

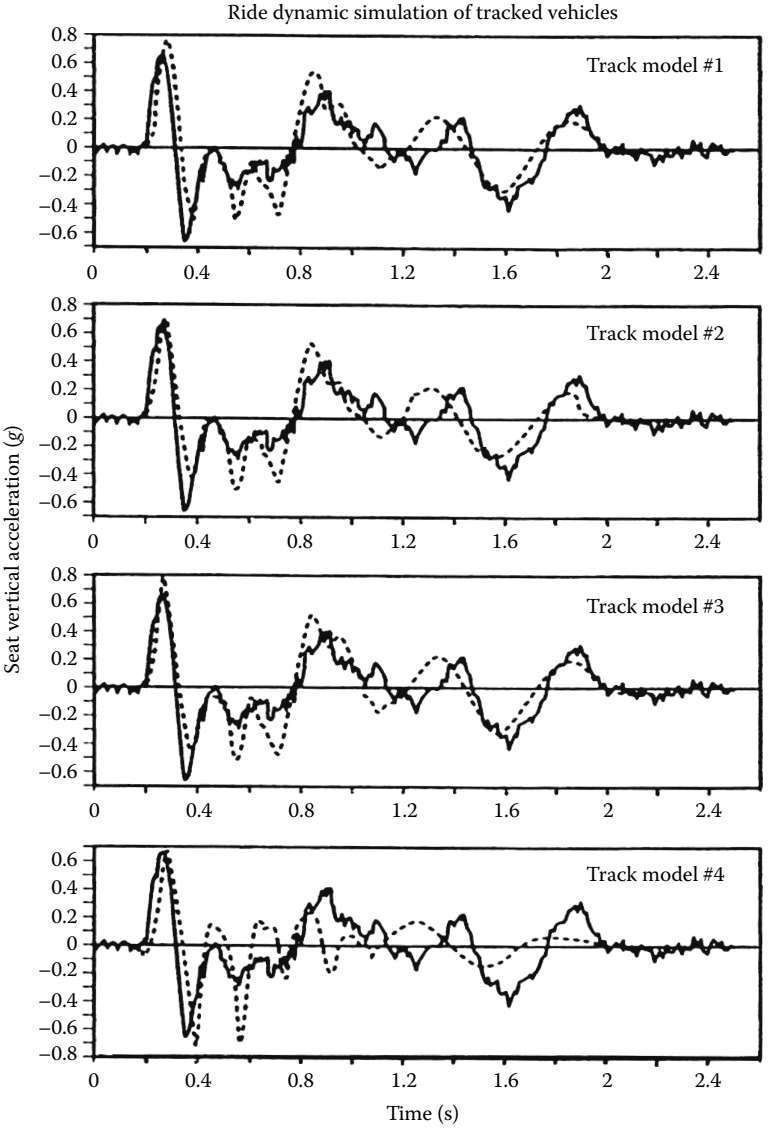

FIGURE 34.23 Comparison of the measured ride characteristics of an armored personnel carrier and those simulated using various types of track model over a 6 in. obstacle on a rigid surface (solid line for measured data and dotted line for simulated results). (Reproduced from Dhir, A. and Sankar, S., Analytical track models for ride dynamic simulation of tracked vehicles, *J. Terramech.*, 31(2), 107–138, 1994. With permission from the International Society for Terrain-Vehicle Systems.)

simulate the dynamic behavior of both wheeled and tracked vehicles over obstacles or on rough, rigid surfaces with encouraging results.

In summary, based on the brief discussion given earlier, it can be said that a great deal of effort has been expended on research into the ride dynamics of off-road vehicles over rough, rigid surfaces and considerable progress has been made. However, little research has so far been carried out on ride dynamics of off-road vehicles over deformable terrain, where the surface profile may be modified by vehicular load and the dynamic stiffness and damping of the terrain may have a significant influence on vehicle vibration.

34.5 CLOSING REMARKS

a. In recent years, comprehensive and realistic computer simulation models for predicting and evaluating the performance (mobility) of off-road wheeled and tracked vehicles over unprepared terrain have emerged. They take into account all major vehicle design parameters and pertinent terrain characteristics. The basic features of these models have been substantiated by field test data. It has been shown that these computer simulation models can provide more realistic and accurate predictions of vehicle performance (mobility) over unprepared terrain than empirical or semiempirical methods developed earlier.
b. A general theory for skid-steering of tracked vehicles on firm ground has recently been developed. It is shown that the turning behavior of tracked vehicles predicted using this new theory bears a strong resemblance to that measured in the field and that it provides significant improvements over existing methods. It is recommended that further research be conducted to extend this theory to the prediction and evaluation of turning behavior of tracked vehicles over deformable terrain where vehicle sinkage may be significant.
c. Significant progress has been made in recent years in the development of ride dynamics models for off-road vehicles, including both wheeled and tracked vehicles, over rough, rigid surfaces. Further studies should be carried out to extend these models to the prediction of ride dynamics of off-road vehicles over deformable terrain, where terrain profile may be significantly modified by vehicular load and the dynamic stiffness and damping of the terrain may have considerable effects on vehicle vibration.

Notations

B	tread (or track) of vehicle
b	width
c	cohesion
D	diameter
F	thrust
F_d	drawbar pull
F_i	thrust of inside track
F_o	thrust of outside track
f_r	coefficient of motion resistance
j	shear displacement
K	shear deformation modulus
l	contact length
M_r	moment of turning resistance
P	track pitch

35.1 INTRODUCTION

Motorcycle handling involves both machine and rider. It is a man–machine problem. The rider behavior probably can be influenced by education and training but only a little, so the main engineering focus is on the machine. However, the machine properties need to be aligned closely with the needs and preferences of the rider. Consequently, the relevant rider characteristics are reviewed first. Then, the behavioral features of motorcycles are discussed.

The view is taken that a high level of agreement between measured and computer-simulated responses of motorcycles and riders to steering control and other inputs has already been established [1–22], and it is therefore possible to use advanced computer model predictions to explain and to understand the real thing. This is not to imply that predicting the responses of a particular machine–rider combination to path demands or other control inputs over a wide spectrum of operating conditions with accuracy is a trivial matter. Such a task needs a very large expenditure on model building and parameter measurement, much of the latter demanding special equipment, as a minimum. However, in general terms, advanced model predictions can be regarded as sufficiently accurate to properly reveal much of how motorcycles respond to control inputs.

Ideal responses cannot be specified, although minimizing the lag between yaw rate response and steer torque input in single- or double-lane-change maneuvers, as revealed by the peak of the cross-correlation coefficient, has been shown to correlate with subjective good handling [14]. Other desirable properties have been suggested [19,21], while, for racing, minimum-time capability is clearly ideal. Indeed, for general use, it must be the case that sports machines, cruisers, and commuter bikes represent different ideals. However, all reasonably conventional motorcycles have some stability and response properties in common, which have to be understood and controlled. At very low speeds, an uncontrolled motorcycle will diverge in roll in particular and will fall over or capsize. At medium or high speeds, depending on the design, the steering system is likely to wobble, while at high speeds, a rolling/yawing/steering oscillation, weave, is likely to show.

In Section 35.2, rider properties are discussed and some deductions about motorcycles are made. In Section 35.3, a general theoretical background is provided. The background is used to make a connection between steady-turning behavior and static stability, and a comparison with the better-known car situation is made. In Section 35.4, there is a discussion of the fundamental needs of a mathematical model that is capable of representing real behavior in some detail. That background is used to explain the building of such a model. Some procedures for checking the health of the model are described. Section 35.5 contains behavioral results from the model. Steady-turning equilibrium "trim" states are shown, and eigenvalues and eigenvectors generated for small perturbations from trim are calculated. Frequency responses for straight running are given and stability in cornering is considered. Responses to regular road undulation forcing are computed and related to loss-of-control accidents. The possibility of replacing the standard steering damper with a more general mechanical or electromechanical steering compensator is mentioned, and the influences on stability of acceleration and deceleration are studied. The chapter concludes with some power accounting.

Section 35.6 is concerned with sensitivities to design parameter changes. Firstly, practical results from the literature are discussed. Then the motorcycle model is employed to predict behavioral changes resulting from small variations in a number of parameters. Section 35.7 is about rider

control, concentrating on optimal linear quadratic preview control, which is a recent development. This is believed to provide insight into how riders use knowledge of the machine dynamics and of the path to be followed to exercise effective steering control, especially near to straight-running conditions. Conclusions are stated in Section 35.8.

35.2 RIDER PROPERTIES

The rider is a significant part of the structure of a motorcycle, in addition to being the controller. Lateral control can be exercised by steering, body leaning relative to the motorcycle frame, and lateral body movement. Rider relative displacements may be consequences of motorcycle motions or of rider muscular control activity. Such control activity is often passive, insofar as it occurs pre-maneuver, and is apparently designed to obtain some advantage in the later maneuver. The rider's role as a part of the structure is most important when the machine is lightest and the rider is heaviest.

The responses of several riders as passive structural components to motions of a mock motorcycle frame without longitudinal movement were measured in the laboratory by Nishimi et al. [13]. A two-degree-of-freedom linear model of the rider was found to fit the results well. The freedoms involved lateral translation at the hips and rolling of the upper body relative to the frame, to which sinusoidal rolling motions were applied. Typical natural frequencies and damping factors of a rider model fitting the results were 4.2 Hz and 0.40 for the hip translation mode and 1.1 Hz and 0.47 for the body lean mode. Fortunately, since riders vary over a wide range, these values do not critically influence the behavior of motorcycle/rider combinations. They appear to provide a good basis for modeling a generic rider as a structure. Riders also have some capability to use muscle tensing to change their structural properties [13,24,25]. Experimental results to date suggest that such muscle tensing allows the rider to increase stiffnesses by at least an order of magnitude but to increase effective damping coefficients only a little [24]. The mobility of the rider's upper body provides some useful damping of the oscillatory modes of the system*, suggesting that the lightest riders represent worst-case configurations from this point of view.

From a controller viewpoint, the rider can use both body and arm muscles to cause body or steering inputs within the control bandwidth, with steer torque inputs being reacted on the rider's upper body. This is genuine active control. The bandwidth will increase with skill level, but it is likely that, even under racing conditions, very little control power is used above 0.5 Hz [26]. The rider can also use near-zero frequency control to effectively alter the higher frequency dynamics of the motorcycle/rider system. When the rider substantially alters his or her body position relative to the motorcycle for drag reduction or vigorous cornering, this is regarded as parameter adaptation, not as active control. The equilibrium or trim states of the system are affected and the dynamics involving small perturbations from trim are correspondingly influenced. When the rider finds favorable influences, reinforcement learning [27] will contribute to making the changes into a habit.

The rider may operate in "fixed control," effectively using steer angle and/or upper body lean angle as controlled variables, or alternatively, he or she may use "free control" in which steer torque and lean torque are the controlled variables. In principle, the same options exist in relation to longitudinal control by brake and throttle actions, but conventional arrangements more or less compel throttle position control and brake force control to be utilized by riders [28].

It is evident that riders are learning and optimizing controllers. They learn by repeated trials and observations, and they optimize some combination of system performance like path following accuracy and speed maintenance and control effort. In a learning phase, fixed- and free-control strategies are no doubt evaluated, to see which is easier and more effective. In application, the control mode and the concentration level chosen will vary with the circumstances from high effort and high accuracy at the one extreme to the converse. In the trials, the relative effort and

* To be elaborated in Section 35.5.2.

reward associated with body torque and steer torque controls will be assessed, it being apparent, at the outset, that using body muscles for active control is likely to be feasible only at very low frequencies. For most people, a realistic estimate of the bandwidth for body control is perhaps 0.1 Hz, rather than the 0.5 Hz associated with steer torque control. It is surmised, at this stage, that riders use feedback control for stabilization and disturbance rejection and preview control for path following and speed maintenance. Provided that the available steering torque and/or rider body lean torque actuations are effective, as will normally be the case, stabilization of divergent motions is possible if the time constant is sufficiently long and stabilization of oscillatory modes by active control is possible if the frequency of the oscillations is low enough in relation to the control bandwidth.

Sometimes, it is argued that good stability margins lead to poor maneuverability [29] and therefore that stability can be excessive. However, maneuverability depends fundamentally on the relationship between the external forces that can be called upon by the rider and the responsiveness of the motorcycle to those forces. This is substantially independent of the stability properties. The rider has more or less direct control of the lateral force at the front tire contact with the ground. From a straight and level condition, maximum response is obtainable by steering the front wheel quickly to the condition at which it will give maximum side force. Most riders are not brave enough or skillful enough to do this. Typically, they will extract much less than the full performance capability of their machine through conservative riding [30]. Then, the extent to which the machine will respond to the external forces imposed will depend on its mass and inertia properties, its wheelbase, and many design details, combining in a complex way that can be understood only by examining the full nonlinear system dynamics at limiting performance. It seems likely that good stability margins will actually make a positive contribution to maneuverability, by encouraging riders to fully use the performance envelope, without fear of losing control. Stability is an important theme in the discussion to follow.

35.3 THEORETICAL BACKGROUND

The equations of motion of a mechanical system are representable in the form [31]

$$\left[S(\underline{q},t)\right]\dot{\underline{q}} = \underline{v}(\underline{q},\underline{u},t) \tag{35.1}$$

for the kinematics and

$$\left[M(\underline{q},t)\right]\dot{\underline{u}} = \underline{f}(\underline{q},\underline{u},t) \tag{35.2}$$

for the dynamics. The equations of vehicle dynamics can normally be reduced to the form

$$\dot{\underline{x}} = \underline{f}(\underline{x}) + \underline{g}(\underline{u}) \tag{35.3}$$

in which $\underline{x}$ is the state vector, $\underline{u}$ is the input vector, and $\underline{f}$ and $\underline{g}$ are vector functions. For a motorcycle, the input vector $\underline{u}$ can be thought to include steering torque (or steer angle), rider lean torque, and throttle position or brake force. Front and rear brakes can normally be operated independently, but we will consider that to be too detailed a level for the present discussion. Also, later, consideration will be given to the rider's choice of fixed or free control and the relative importance of steer torque and lean torque. The functions involved in the equations will normally be continuous and differentiable. The system is likely to be smooth. Without losing any of the system dynamics, the states can be chosen in such a way that they all have zero values in a steady-state trim condition. Thus, we omit from consideration the longitudinal and lateral positions, the attitude angle, and the wheel spin and drive sprocket rotation angles.

A straightforward use of the equations of motion is to numerically integrate them for given initial conditions and defined control inputs, but such usage is not so cost-effective in terms of understanding the dynamics and the machine design. Linearization is highly desirable. Linear system theory is extremely effective in allowing behavior to be efficiently characterized and design and behavior to be related to each other.

The common linearization involves series expansion about a trim or equilibrium state, although other forms exist [32]. Trim states are solutions of

$$\underline{f}(\underline{x}) = -\underline{g}(\underline{u}) \tag{35.4}$$

solutions that imply constant speed running. Supposing the system order to be n and there to be m inputs, the constant-coefficient small-perturbation equations are of the form

$$\dot{\underline{x}} = \left[A\right]\underline{x} + \left[B\right]\underline{u} \tag{35.5}$$

in which the elements of $\left[A\right]$, the (n^*n) Jacobian matrix of derivatives $\underline{\partial f}/\underline{\partial x}$ and $\left[B\right]$, and the (n^*m) matrix $\underline{\partial g}/\underline{\partial u}$ depend on the trim state. Trim-state solutions may be plotted in a handling diagram form, conventionally consisting of lateral acceleration response to steer torque or steer angle input for a fixed speed and zero body lean torque [33]. The small-perturbation-from-trim equations are linear with constant coefficients. The lateral equations contain the forward speed and the rotor-spin velocities for the trim state as parameters. If and when the gradient of a handling curve such as that described becomes infinite, it is implied that the system at the trim state involved has a zero eigenvalue [28]. If the handling curve employs steer torque as a reference, it is the free-control motorcycle that has the zero root, while if steer angle is the reference, it is the fixed-control machine that has the zero root. These implications can be demonstrated by the following argument.

Suppose that $\underline{x}_0$ is a trim state including lateral acceleration α_0 and steer angle δ_0, corresponding to steer torque input τ_0 and speed v_0, and that a neighboring trim state is characterized by $\underline{x}_1$, α_1, δ_1, τ_1 and the same v_0. Due to the closeness of the second trim state to the first one, the second can be obtained from the first by way of the linearization of the system about the first trim state.

Suppose that $\left[A\right] = \left[A_0\right]$ and $\left[B\right] = \left[B_0\right]$ for the first trim state. Then the change in steady-state response due to a change in steer torque input is given by

$$(x_1 - x_0) = -\left[A_0\right]^{-1}\left[B_0\right](\tau_1 - \tau_0) \tag{35.6}$$

If the running conditions for the trim state are such that $\left[A_0\right]$ is singular, that is, if $\det\left[A_0\right] = 0$, the increment $(x_1 - x_0)$ is infinite. In particular, the gradient of the lateral acceleration versus steer torque handling diagram becomes infinite for such circumstances. Correspondingly, if the control input were steer angle instead of steer torque, the matrices $\left[A_0\right]$ and $\left[B_0\right]$ would belong to the fixed-control motorcycle.

The stability of the first trim state is indicated by the eigenvalues of $\left[A_0\right]$ and the roots λ of the characteristic equation, a polynomial in λ:

$$\det\left(\left[A_0\right] - \lambda\left[I\right]\right) = 0 \tag{35.7}$$

The zero-order term in the expansion of the determinant is $\det\left[A_0\right]$, and if this term has value zero, $\lambda = 0$ is a solution. Thus, a zero eigenvalue arising from the singularity of the characteristic matrix at a particular operating condition must be accompanied by an infinite slope on the handling diagram for the matching problem at the operating point.

If there exists some problem-specific knowledge, it may be possible to associate the infinite slope on the handling diagram with a transition from statically stable to statically unstable running of the system as it passes through the operating point. This is the case with the well-known yaw/sideslip car model [33], in which the low order of the system and the inherent stability of the car at low speeds make it certain that the infinite slope on the handling diagram does indeed indicate a transition to static instability. However, in the absence of such problem-specific knowledge and especially when the system of interest is of high order, the relationship between the steady-state responses and the static stability is less certain.

For any running condition making $\left[A_0\right]$ singular, $\det\left[A_0\right]$ will be zero and the system will have a zero eigenvalue. The characteristic equation of the system can then be written

$$\lambda.G(\lambda) = 0 \tag{35.8}$$

The roots of $G(\lambda) = 0$ may include positive reals, indicating monotonic divergence, or complex conjugate pairs with positive real parts, indicating oscillatory instability. Thus, there may be little significance in the zero eigenvalue in a relatively complex case. Great care needs to be exercised in translating ideas from one vehicle sector, like understeer and oversteer, for example, and applying them directly to another one. The steady-turning responses of a motorcycle are much less indicative of the stability than for a car.

In general, the longitudinal and lateral equations are coupled but, if the trim state involves straight running and the machine has right/left symmetry, the equations decouple into an in-plane set and an out-of-plane set [22,33,34]. The eigenvalues and eigenvectors of $\left[A_0\right]$ indicate the stability, natural frequency, and mode-shape properties of the small-perturbation system, and the frequency responses to inputs $\underline{u}$ show the response properties in the neighborhood of the relevant trim state [35].

If responses $\underline{y} = \left[C\right]\underline{x}$ are considered, the corresponding frequency response functions are given by

$$\underline{H}_0 = \left[C\right]\left(\lambda\left[I\right] - \left[A_0\right]\right)^{-1}\left[B_0\right] \tag{35.9}$$

and in the case of road profile excitation, when the rear input can be considered a time-delayed version of that at the front, responses can be combined using

$$h(j\omega) = h_f(j\omega) + e^{-j\omega\tau}h_r(j\omega) \tag{35.10}$$

in which τ is the wheelbase travel time.

For variable speed operation, linearization about a trajectory is possible [32]. Such linearization will yield a time-varying system, the stability and response properties of which are much more difficult to determine. However, if the rate of speed variation is sufficiently small, frozen-time theory yields a close approximation to exact behavior [32,36] and the difficulties associated with time-varying systems can be avoided. Constant-coefficient linear system analysis continues to be useful. The influences of acceleration or deceleration can be calculated with reasonable accuracy through frozen-time theory.

The linearizations described take into account only the system dynamics in the neighborhood of trim states. Away from these neighborhoods, there is no guarantee of accuracy. However, it is reasonable to take the view that, with a well-behaved man–machine system, the control by the man will be of sufficient quality, in the great majority of operating circumstances, that the motions will remain close to trim and that therefore the dynamics that matter will be computed properly by the methods described. If a rider wants to explore running conditions far from equilibrium, to develop skill in dealing with them, for example, large-amplitude transient control inputs should be applied with well-chosen phasing of the input stages to yield reinforcement of the successive responses. Similarly, in the theoretical world, large-amplitude transient control inputs are required to excite extreme responses, far away from trim states.

35.4 MODELING THE MOTORCYCLE

35.4.1 Minimum Requirements

Although quite simple models may be capable of representing low-speed and low-frequency behavior well, generally effective mathematical models of motorcycles are necessarily not simple. Essential freedoms to be included at the outset are lateral translation, yaw, roll, steer*, and frame twisting [22,37,38]. Some machines may have significant torsional compliance in the rear wheel attachment, which is known to destabilize the weave mode [39], but modern machines are usually stiff enough in this regard (stiffness >12 kN m/rad) to be treated as rigid. The rider also should be treated as compliant, although this issue is not so critical, with the characterization of [13] being the most compelling available. Tire lateral forces, aligning moments, and overturning moments in response to tire load change, longitudinal slip, sideslip, and wheel camber should be included. Also, tire forces and moments must be considered dynamic, rather than static [22,40]. Time lags in the tire force and moment system occur primarily because the tire sidewall structure is compliant. If these time lags are omitted from consideration, oscillatory modes are predicted wrongly [22,40]. It is essential to use an automated model builder for a system of this complexity [41].

35.4.2 Computer-Aided Model Building

AutoSim [42] is just one of a number of multibody modeling systems currently in common use. AutoSim is a set of LISP macros, enabling the description of mechanical multibody systems, with the addition of nonmechanical subsystems, if necessary. The syntactic rules of AutoSim are straightforward. The output from AutoSim takes one of several forms: (a) a Rich Text Format file containing the symbolic equations of motion of the system described, (b) a "C" or "FORTRAN" language simulation program with appropriate data files containing parameter values and simulation run control parameters (or Simulink S-function), or (c) linear state-space equations in a MATLAB® "M-file" format. AutoSim's linearization of the nonlinear equations of motion is symbolic and completely general. The linearization involves series expansions of smooth functions about trim states. From the general equations of motion, it is possible to determine trim states and all the parameters required to describe fully a small-perturbation dynamics problem. The multibody basis of AutoSim is Kane's equations [42], an expression of the virtual power or Jourdain principle [43], which deals equally easily with holonomic and non holonomic constraints. The simulation programs written by AutoSim contain many software engineering features that help to reduce execution times.

At the core of the language are commands like add body, add point, add speed constraint, add line force, add strut, add moment, and no movement, which, to some extent, are self-explanatory. Such commands contain argument lists that are required to make their meanings precise. A program begins by defining an inertial reference frame `n,` with fixed origin, `n0,` and fixed directions `[nx], [ny],` and `[nz]`. As new bodies are added, having freedoms relative to n, local origins and axes are employed. All the reference axis systems introduced are right-handed Cartesian sets, and inertias are normally referenced to axes parallel to these through the material body's mass center. The code can transform from local coordinates to global ones and vice versa. Points specified globally are conveniently used to define points in bodies. The body-fixed points coincide with the corresponding global points, fixed in `n,` when the system is in its nominal configuration. Most points are fixed in bodies, but a point may be defined as "moving" with its location in a body determined from its specified coordinates. This is especially useful for describing tire/ground contact.

Position constraints, velocity constraints, or both together can be added. The analyst has the option to specify which freedom should be eliminated from the problem as a result of each constraint added. Constraints may require points on two bodies to have no relative movement, for

* To analyze the fixed-control properties of the motorcycle, the steer degree of freedom is omitted [22,40].

example, or they may consist of symbolic expressions that must have zero value. To deal with a closed kinematic loop, this is first opened by an imagined cut in such a way that the longest chain of bodies contributing to the loop is as short as possible. The loop closure constraints are then added.

There are several commands for defining and manipulating vectors. For example, `pos(p1,p2)` defines a vector that points from `p2` to `p1`, `dot(vel(p1),[nz])` is the component of the absolute velocity of `p1` in the direction `[nz]`, `dir(pos(p1,p2))` is a unit vector in the direction `p2` to `p1`, `dplane([rwy],[nz])` is the projection of `[rwy]` onto the plane normal to `[nz]`, and `cross(a,b)` is the vector product of a and b. In each case, the square brackets indicate a unit vector along a (Cartesian) body axis. The "setsym" command is used to define a new symbol, such a symbol being identified subsequently by the "@" character.

New state variables can be added to a model and they can be made integral functions of existing variables. Differentials with respect to time and partial differentials of variables can be defined. Max, min, sign, and ifthen functions can be used, allowing discontinuous actions, like tires leaving the ground and limit stops being contacted, to be modeled easily. If necessary, the analyst can define how discontinuous functions are to be differentiated. Small-angle theory can be employed to reduce simulation times where it is considered appropriate.

At the head of an AutoSim program are some commands that are used to reset the system, define the gravitational field, select the unit system to be employed, specify the simulation language in which the code written by AutoSim is to be generated, and select the type of numerical integrator to be installed in the code and to control the symbolic manipulations in various other ways. When the analyst does not exercise choice overtly in these matters, default settings come from a configuration file that the analyst is free to access.

35.4.3 Bodies and Freedoms for the Motorcycle

Figure 35.1 shows a modern high-performance motorcycle diagrammatically. Separate masses are associated with the rear wheel, the gearbox sprocket, the swing arm, the rider's lower body, the rider's upper body, the main frame, the front frame, and the front wheel. The main frame has the freedom to translate in any direction and to yaw, pitch, and roll, while the front frame has relative twist and steer freedoms. The rider has lower body lateral translation and upper body relative roll freedoms. The rear suspension is by swing arm and monoshock spring/damper system, and the rear wheel is driven by chain and sprocket. The gearbox sprocket is given a spin inertia that accounts for its connection to the rotating masses in the gearbox and engine. The bodies and their relationships to each other are shown in Figure 35.2. Initially, the bodies, joints, and freedoms implied by Figures 35.1 and 35.2 and all the key points in the system's nominal state are defined.

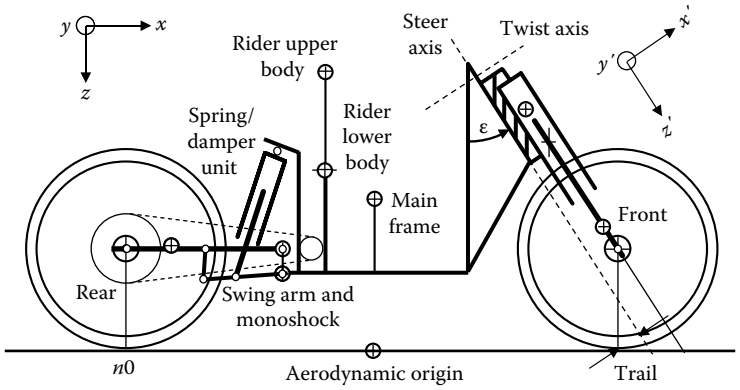

FIGURE 35.1 Diagrammatic motorcycle showing some geometric features.

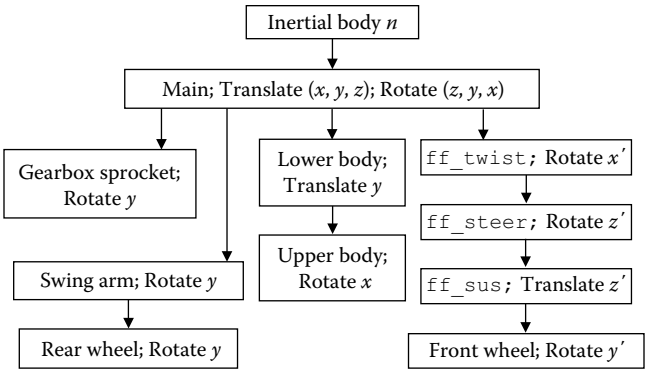

FIGURE 35.2 Body parent/child structure and relative degrees of freedom for motorcycle model. Axis directions are indicated in Figure 35.1.

35.4.4 Suspension and Steering Systems

Spring/damper units for suspensions, frame compliance, rider lower and upper bodies, and a steering damper are added. The monoshock rear arrangement requires special consideration and it is explained further in Section 35.4.8. Limit stops are associated with each suspension and the steering system. Forces or moments arising from limit stops become nonzero only when deflections exceed defined values and they are usually made a high power of the deformation of the stop, so that the force or moment rises from zero steeply once the stop is contacted.

35.4.5 Tire/Road Contact Description

The geometry of the contact between the front tire and the ground is a relatively complex part of the motorcycle modeling. It is also important to the behavior of the machine. To define each tire/ground contact point (Figures 35.3 and 35.4), the vertical and the wheel spindle directions are used in a vector (cross) product to describe the longitudinal direction, with respect to the wheel. Similarly, the wheel radial direction, OC in Figure 35.3, comes from combining the longitudinal and wheel spindle directions. The vector OC is of fixed length and so is completely specified. *G* is vertically

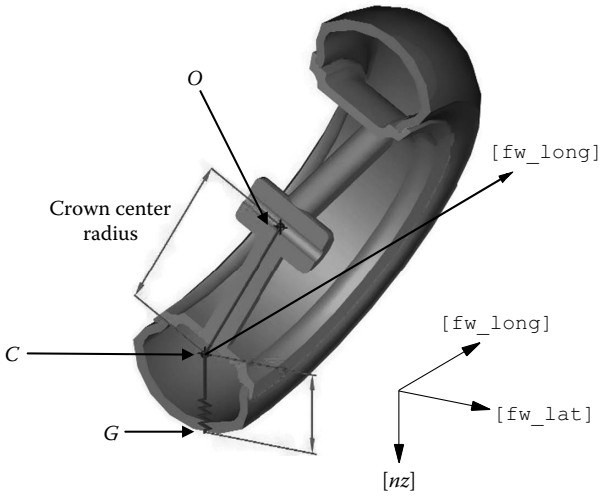

FIGURE 35.3 Diagrammatic 3D front wheel contact geometry showing the possible movement of the contact center circumferentially and laterally. The contact point is vertically below the point *C*.

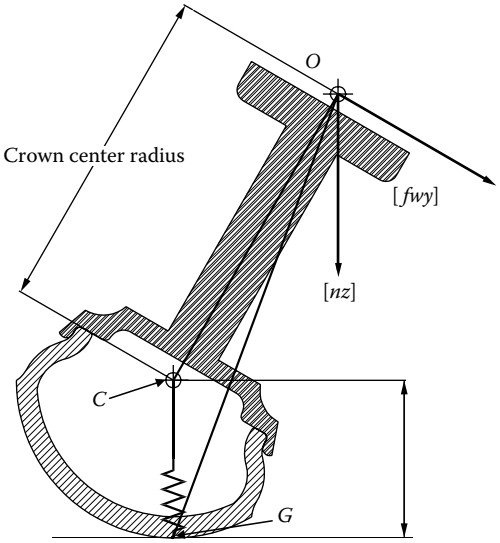

FIGURE 35.4 2D tire-to-ground contact geometry, showing the lateral movement of the contact center and the vertical flexibility of the tire structure. The change from nominal in the compression of the tire spring and the radial stiffness, together with the nominal load, allows the wheel load to be tracked.

below C, and the difference between the tire crown radius and the distance $\underline{CG}$ defines the change in the tire carcass compression from the nominal state and hence the change of the wheel load from the nominal, via the tire radial stiffness. If the road is profiled, the road height is accounted for in working out the wheel load. The vector $\underline{OG} = \underline{OC} + \underline{CG}$ defines the contact point, which belongs to the wheel but moves within it. G remains at road surface height, but the tire load cannot become negative. If the tire leaves the ground, the shear forces are zero, whatever the other conditions are. Tire forces are applied to the point G, in each case.

35.4.6 Tire Forces and Moments

The basis for the tire force and moment descriptions here is the "Magic Formula" [44–46]. The original development was for car tires [33], in which context, it has become dominant. The extension to cover motorcycle tires involves substantial changes to accommodate the completely different roles of sideslip and camber forces in the two cases. The "Magic Formula" is a largely empirical set of equations relating load, slip ratio (longitudinal slip), lateral slip, and camber angle to longitudinal force, side force, and aligning moment (and possibly overturning moment), with constraints on the parameters to prevent the behavior from becoming unreasonable in any operating conditions. Only very limited parameter values can be found in the literature, but a certain amount of relevant experimental data are available. Such data have been used for full Magic Formula parameter identifications for contemporary high-performance tires [47]. The parameter values for a given tire and the relevant equations [33,47] allow the calculation of the steady-state force and moment system for any realistic operating condition. Examples of experimental and fitted results are shown in Figures 35.5 through 35.7. Many more details are given in [47].

The tire force and moment model needs to be supplied with wheel load, longitudinal slip, lateral slip, and wheel camber angle. The wheel load comes from the nominal load, the tire radial stiffness, and the tire compression relative to the nominal state. The longitudinal slip is the rearward component of the material contact point velocity divided by the absolute value of the rolling velocity, the latter being the forward velocity of the contact point (or the crown center point, since these are the same). The contact point is defined by its coordinates in the parent body of the wheel, and it is de spun relative to the material contact point. Thus, the longitudinal slip is given by an expression of the form.

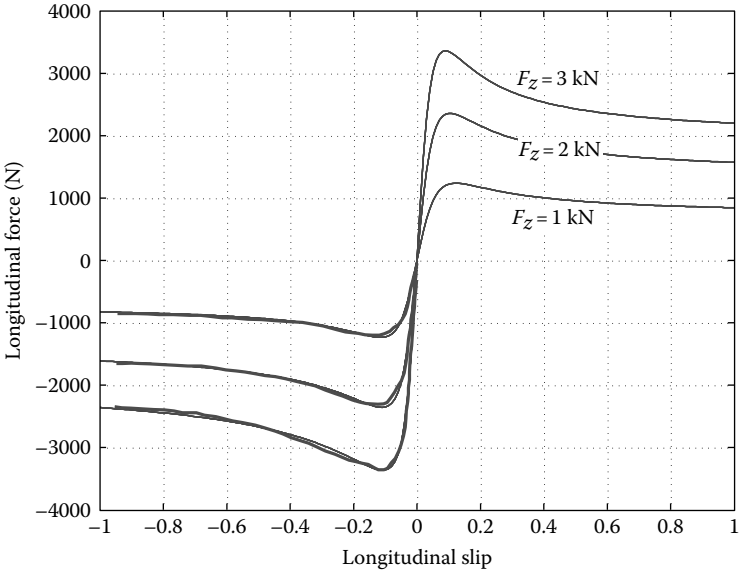

FIGURE 35.5 Tire longitudinal force results for a 160/70 tire (From Pacejka, H.B., *Tyre and Vehicle Dynamics*, Butterworth Heinemann, Oxford, U.K., 2002) (thick lines) with best-fit reconstructions by Magic Formulae (thin lines), for loads of 1, 2, and 3 kN.

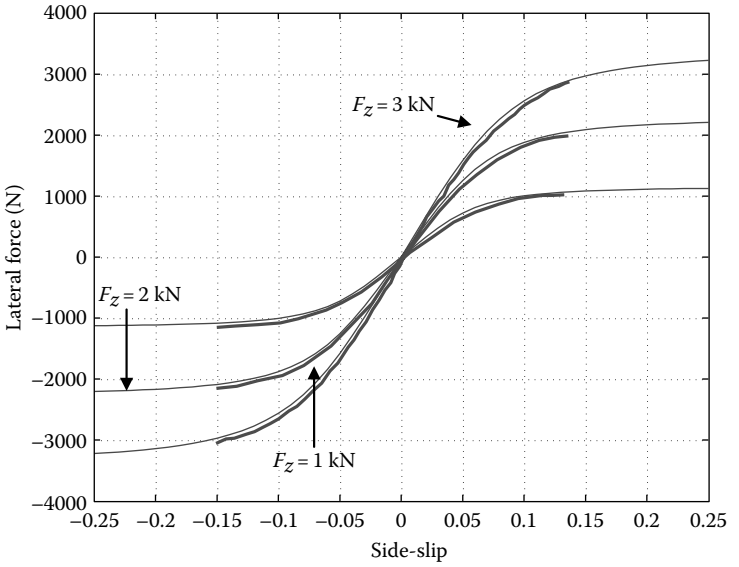

FIGURE 35.6 Tire lateral force results for a 160/70 tire at 1, 2, and 3 kN loads (From Sharp, R.S. etal., *Multibody Syst. Dyn.*, 12(3), 251, 2004 (thick lines) with best-fit reconstructions by Magic Formulae (thin lines).

$$\kappa = \frac{-(\text{rolling velocity} + \text{spin component of longitudinal velocity})}{\text{abs(rolling velocity)}}$$

The lateral slip is the ratio of the (negative) lateral velocity of the tire contact center point to the absolute value of the rolling velocity, and the wheel camber angle is the arcsine of the vertical component of the wheel spindle unit vector. A complete set of parameter values for a given, presumed symmetric tire [47] allows the calculation of the steady-state force and moment system for any realistic operating condition.

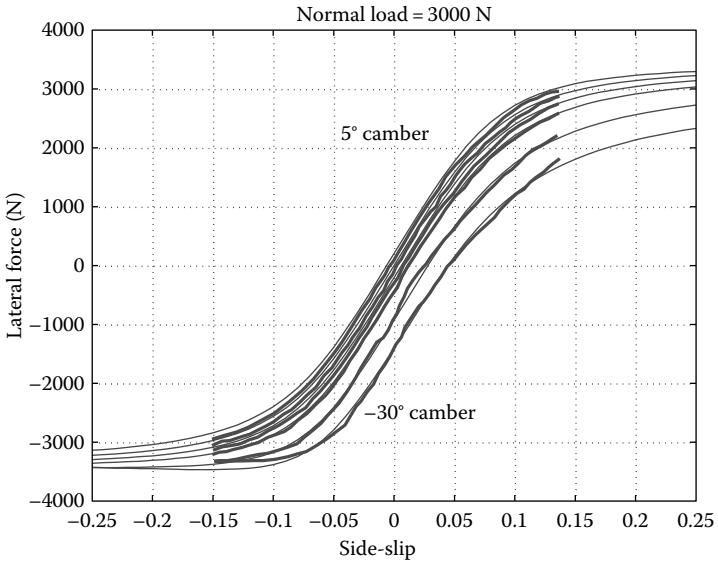

FIGURE 35.7 Tire lateral force results for a 160/70 tire at 3 kN load and camber angles of 5°, 0°,–5°,–10°,–20°, and–30° (From Sharp, R.S. etal., *Multibody Syst. Dyn*., 12(3), 251, 2004) (thick lines) with best-fit reconstructions by Magic Formulae (thin lines).

35.4.7 Aerodynamic Forces and Moments

Aerodynamic drag, lift, and pitching moment data come from a Triumph motorcycle of similar style and dimensions to the GSX-R1000 [47]. This is steady-state drag force, lift force, and pitching moment data from full-scale wind tunnel testing, with results for a prone rider being adopted. If the rider were upright, the frontal area would be larger by 20% and the drag coefficient would be larger by 15%. A fuller account of aerodynamic force and moment coefficients can be found in [14].

35.4.8 Monoshock Suspension

The motorcycle rear suspension arrangement is shown diagrammatically in Figure 35.8. It uses a single spring/damper unit with a mechanical linkage connection to the swinging arm. Many modern rear suspensions are of this type, although several variants of it exist [48]. It involves a closed kinematic loop. Such a suspension can be modeled literally, link by link and joint by joint, or via a separate geometric pre-analysis. Such a pre-analysis yields an analytic relationship between the swing-arm angle change and the moment of the spring force about the swing-arm pivot, which is used directly in the multibody model building. Alternatively, if the pre-analysis were too complex to give an analytic result, a numerical relationship between the angle and the moment could be found. This could be replaced by an approximate functional

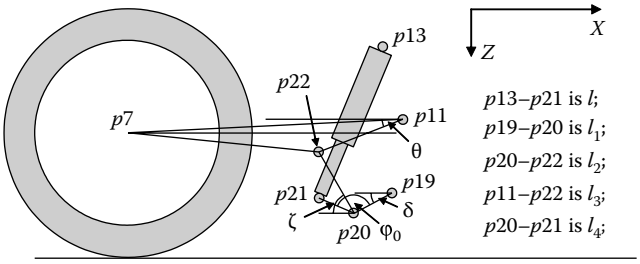

FIGURE 35.8 Geometry of monoshock suspension arrangement on GSX-R1000 motorcycle. Distances between various points are also defined in the diagram.

relationship covering the practical range of the swing-arm movement. A low-order polynomial will usually suffice [48]. Literal modeling is the simplest, but it may provide equations of motion that integrate relatively slowly, since the simulation has to solve the kinematic loop equations at each integration step [48].

An analysis from [48] follows.

Points $p11$, $p13$, and $p19$ are fixed to the main frame. l_1, l_4, and φ_0 are dimensions of the swinging link and l_2 the length of the pull rod. The length l_3 in the swing arm is fixed. The spring/damper unit is of variable length l. θ is the angle of the swing arm to the horizontal x-axis, while δ is the corresponding angle for the swinging link. Traversing the loop $p11$-$p22$-$p20$-$p19$-$p11$, both x and z displacements are nil, since we end where we begin. Therefore,

$$x_{11} - x_{19} - l_3 \cos\theta + l_2 \cos\zeta + l_1 \cos\delta = 0 \tag{35.11}$$

$$z_{11} - z_{19} + l_3 \sin\theta + l_2 \sin\zeta - l_1 \sin\delta = 0 \tag{35.12}$$

Forming l_2^2 as $(l_2^2 \sin^2\zeta + l_2^2 \cos^2\zeta)$ and substituting

$$c_1 = -x_{11} + x_{19} + l_3 \cos\theta \tag{35.13}$$

$$c_2 = -z_{11} + z_{19} - l_3 \sin\theta \tag{35.14}$$

we obtain

$$l_2^2 = (c_1 - l_1 \cos\delta)^2 + (c_2 + l_1 \sin\delta)^2 \tag{35.15}$$

from which it can be shown that

$$\delta = \arcsin\left(\frac{l_2^2 - l_1^2 - c_1^2 - c_2^2}{2l_1\sqrt{c_1^2 + c_2^2}}\right) + \arctan\left(\frac{c_1}{c_2}\right) \tag{35.16}$$

which is a function of θ only. Also,

$$x_{21} = x_{19} - l_1 \cos\delta + l_4 \cos(\phi_0 + \delta) \tag{35.17}$$

$$z_{21} = z_{19} + l_1 \sin\delta - l_4 \sin(\phi_0 + \delta) \tag{35.18}$$

with

$$l = \sqrt{(x_{13} - x_{21})^2 + (z_{13} - z_{21})^2} \tag{35.19}$$

so that l can be found as a function of θ, $l = f_1(\theta)$ say, by substitution for x_{21} and z_{21} in this expression. Figure 35.9 illustrates the outcome. If a small change $\delta\theta$ in θ occurs, in which the corresponding change in l is δl, the moment M corresponding to a spring/damper force $f_2(l, \dot{l})$ is $f_2(l, \dot{l}).dl/d\theta$ by virtual work. The properties of the spring/damper unit can thus be expressed in terms of an equivalent moment $M(\theta, \dot{\theta})$ about the swing-arm pivot, as

$$M = f_2\left\{f_1(\theta), \frac{df_1(\theta)}{d\theta}\dot{\theta}\right\}\frac{df_1(\theta)}{d\theta} \tag{35.20}$$

which can be fully automated.

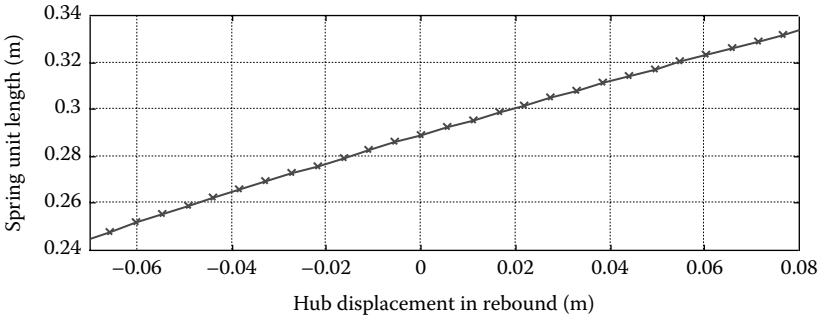

FIGURE 35.9 Spring/damper unit length to wheel displacement relationship for GSX-R1000 motorcycle.

35.4.9 Chain Drive

The chain functions as a tension link between the points p_{gu} on the gearbox sprocket and p_{wu} on the rear wheel sprocket when the engine is driving the wheel and between p_{wl} and p_{gl} when the wheel is driving the engine (Figure 35.10). Some slack or clearance is allowed between driving and overrunning, and the chain is treated as elastic and damped. The force transmitted between the relevant points thus depends on some logic, to decide between drive and overrun, and the relative angular displacements and velocities of the gearbox sprocket and the rear wheel. The points themselves need to be defined as moving points in the appropriate rotor. The point definitions are derived via a geometric analysis from [48] that follows.

From Figure 35.10, the following relationships can be deduced:

$$\mathbf{r}_{sa} = -r_{sa}\cos\theta\,\mathbf{i} + r_{sa}\sin\theta\,\mathbf{k} \tag{35.21}$$

$$\mathbf{r}_{s0} = (x_{23} - x_{11})\,\mathbf{i} + (z_{23} - z_{11})\,\mathbf{k} \tag{35.22}$$

$$\mathbf{r}_{wu} = -r_w \sin\eta_u\,\mathbf{i} - r_w\cos\eta_u\,\mathbf{k} \tag{35.23}$$

$$\mathbf{r}_{gu} = -r_g \sin\eta_u\,\mathbf{i} - r_g\cos\eta_u\,\mathbf{k} \tag{35.24}$$

$$\mathbf{r}_{wl} = r_w \sin\eta_l\,\mathbf{i} + r_w\cos\eta_l\,\mathbf{k} \tag{35.25}$$

$$\mathbf{r}_{gl} = r_g \sin\eta_l\,\mathbf{i} + r_g\cos\eta_l\,\mathbf{k} \tag{35.26}$$

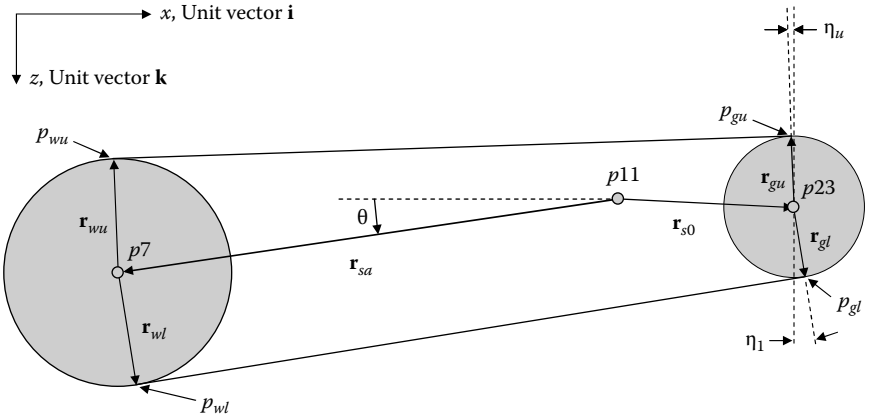

FIGURE 35.10 Geometry of chain drive with swinging-arm suspension. The point $p11$ is the swing-arm pivot center and $p23$ is the gearbox sprocket center.

The chain lines are perpendicular to the radius vectors, so that

$$(-\mathbf{r}_{wu} - \mathbf{r}_{sa} + \mathbf{r}_{s0} + \mathbf{r}_{gu}).\mathbf{r}_{gu} = 0 \tag{35.27}$$

$$(-\mathbf{r}_{wl} - \mathbf{r}_{sa} + \mathbf{r}_{s0} + \mathbf{r}_{gl}).\mathbf{r}_{gl} = 0 \tag{35.28}$$

Through some algebra, these equations yield

$$\eta_u = \sin^{-1}\left(\frac{r_g - r_w}{\sqrt{(r_{sa}\cos\theta + x_{23} - x_{11})^2 + (r_{sa}\sin\theta - z_{23} + z_{11})^2}}\right) + \tan^{-1}\left(\frac{r_{sa}\sin\theta - z_{23} + z_{11}}{r_{sa}\cos\theta + x_{23} - x_{11}}\right) \tag{35.29}$$

$$\eta_l = \sin^{-1}\left(\frac{-r_g + r_w}{\sqrt{(r_{sa}\cos\theta + x_{23} - x_{11})^2 + (r_{sa}\sin\theta - z_{23} + z_{11})^2}}\right) + \tan^{-1}\left(\frac{r_{sa}\sin\theta - z_{23} + z_{11}}{r_{sa}\cos\theta + x_{23} - x_{11}}\right) \tag{35.30}$$

expressing the angles η_u and η_l as functions of the swing-arm angle to the horizontal, θ, obtained by summing the nominal value with the displacement from nominal. For any swing-arm position, the coordinates of the points p_{gu}, p_{wu}, p_{gl}, and p_{wl} can therefore be specified.

The upper chain run is in tension if $(-r_g\varphi_g + r_w\varphi_w + \delta l_u)$ is positive, the first two terms accounting for the spinning of the sprockets and the third for the increase in separation of p_{gu} and p_{wu} due to suspension motion. Similarly, the lower run is in tension if $(r_g\varphi_g - r_w\varphi_w + \delta l_l - s_l)$ is positive, in which s_l represents the chain slack. If the upper chain run is in tension, it applies a force between the end points of the form $(-kx - cv)$ where k is the spring rate, c the damping coefficient, x is the extension, and v the extension speed. In such a case, the lower run force is zero and conversely.

For nonlinear simulation purposes, AutoSim's "ifthen" function is used to deal with the logic of determining whether the upper or lower chain run is in tension and therefore of deciding which forces to apply. For the corresponding linearization, the upper chain run only is used and the chain is considered to operate in tension or compression. It is implied that the chain slack is omitted from the linear model.

35.4.10 Speed and Steer Controllers

To maintain a desired forward speed profile, driving torque is applied to the gearbox sprocket and reacted on the main frame. The driving torque is not allowed to be negative. If braking is needed to maintain the desired speed, the front brake is used. The torque is produced by a proportional/integral control on the speed error with constant gains. The two gains required are noncritical. Effective values can easily be found by a few trials. If the integral gain is too large, oscillatory instability results. The target speed is provided as data in a table function, with time as the independent variable.

A steering feedback controller is also necessary to stabilize the machine in maneuvers in which it is not self-stable. In particular, stabilizing control allows the solution of the steady-turning equilibrium state problem by simply running a simulation to steady state. The controller devised is a proportional/integral/derivative (PID) feedback of motorcycle lean angle error to steering torque, with the lean angle target being set by an initial value and a constant rate of change. The target lean

angle must therefore be a ramp function of time. This would be easy to alter if it were considered restrictive. In fact, the PID-stabilizing controller can be used as part of a path-tracking control based on two-track vehicle practice [49]. A different approach to tracking control is considered in Section 35.7.

The steering control gains need to be speed adaptive, and they need choosing with considerable care to achieve effective stabilization. Especially difficult are cases involving very low or very high speed and high lean angles. Each of the three PID gains is linearly related to speed, as indicated by the relations

$$G_p = spg_0 + spg_1.u \tag{35.31}$$

$$G_i = sig_0 + sig_1.u \tag{35.32}$$

$$G_d = sdg_0 + sdg_1.u \tag{35.33}$$

corresponding to the control law

$$\tau = G_p(\phi - \phi_{ref}) + G_i \int_0^t (\phi - \phi_{ref})\, dt + G_d \dot{\phi} \tag{35.34}$$

where

u is the forward speed
τ is the steering control torque
ϕ is the lean angle
ϕ_{ref} is the target lean angle

Since the gains are critical only at very low and very high speeds, the constants in (3.21) through (3.23) can be chosen based on the extreme-speed behavior. Root locus analysis can conveniently be used to find values yielding good stability. Resulting gains as functions of speed for our basic motorcycle and rider, corresponding to coefficients $spg_0 = -24$, $spg_1 = -2.231$, $sig_0 = -163$, $sig_1 = 0.6154$, $sdg_0 = -48.5$, $sdg_1 = 0.6923$, are shown in Figure 35.11. These gains are tuned for 5 and 70 m/s in straight running.

35.4.11 Inputs

In addition to the feedback controls described earlier, braking torques between rear wheel and swing arm and between front wheel and lower forks can be applied in the model according to a time or velocity schedule. The brakes have been used in studies of deceleration dynamics [36]. Also, a

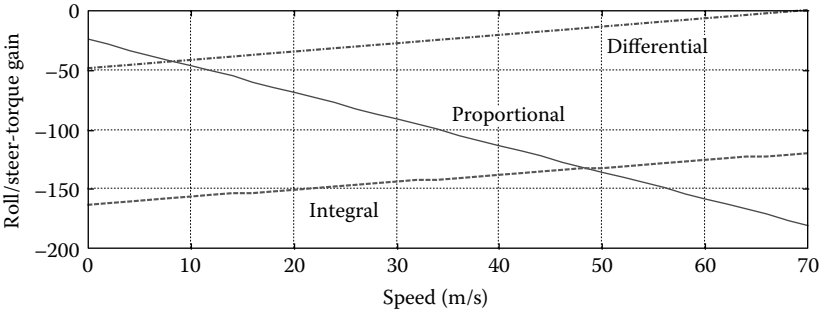

FIGURE 35.11 PID steering controller gains as functions of speed for standard motorcycle and rider.

simple longitudinal road profile is included, such that a length of road can be given a sinusoidal profile with a ramp function wavelength. The tire traverses the profiled road according to the point contact model described in Section 35.4.5, with the rear wheel seeing a version of the profile that is delayed relative to the front by the wheelbase travel time. It is implicit in this description that the road profiling is of wavelength substantially longer than the tire-to-ground contact. For short-wavelength irregularities, a more complex strategy would be needed [33].

As described in Section 35.4.10, the nonlinear simulation model is normally set up to find trim states by automatically tracking a demand for constant lean angle and slowly varying speed or for constant speed and slowly varying lean angle. The linear model, from substantially the same AutoSim source program, does not normally include the speed or steering controllers. To allow the computation of responses of the uncontrolled system to standard inputs in the linear world, those inputs to the linear model have to be defined.

Inputs included comprise driving torque to the gearbox sprocket for longitudinal control, steering torque between the steering frame and the rider upper body and rider upper body lean torque reacting on the rider's lower body for lateral control, and road profiling as a disturbance input [50].

35.4.12 Parameter Values

The full set of parameter values for the kind of model described is extensive and much work is involved in finding them. Most of the values belonging to the GSX-R1000 are listed in [47], with the remainder in [48], and they are not reproduced here. Figure 35.12 is a diagrammatic but geometrically accurate picture of the motorcycle. The figure shows eight masses each with diameter in proportion to mass represented, sprockets for the gearbox and rear wheel, and suspension details.

35.4.13 Equilibrium State Checking and Power Balancing

With the stabilizing controllers installed, the motorcycle can be run to equilibrium at any feasible speed and lean angle. To describe such an equilibrium state, force and moment balance equations can be set up, as was done in [47,50]. For health checking purposes, it is necessary that any equilibrium state yielded by the simulation model satisfies the force and moment balance conditions. As described in [47], the checking process also includes a power balance, whereby the engine power is

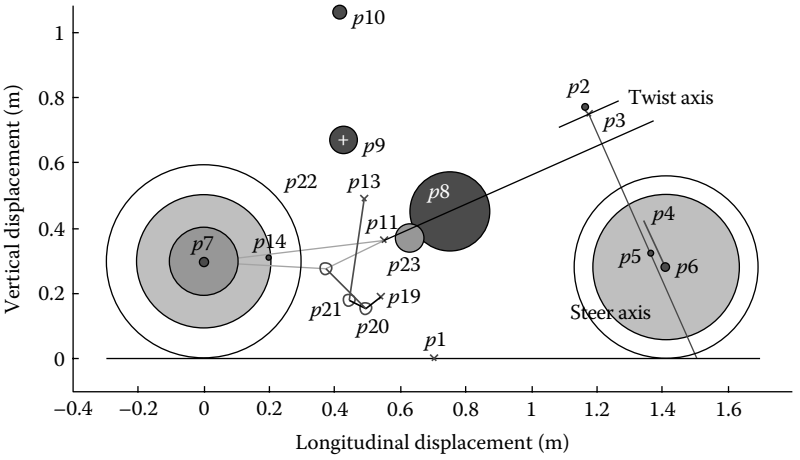

FIGURE 35.12 Pictorial representation of Suzuki GSX-R1000 machine in nominal state. Masses are shown in proportion to their magnitudes. The monoshock rear suspension and telescopic front forks are shown. The chain drive sprockets are also included at $p23$ and $p7$. $p1$ is at mid-wheelbase and is the aerodynamic force reference point.

shown to account precisely for the aerodynamic and tire losses. In steady turning, the force balance check is to ensure that the sum of the external forces is equal to the sum of the inertial and gravitational forces. The force error calculated is

$$\underline{F}_{error} = \sum_i \underline{F}_i + \sum_j m_j(\underline{g} - \underline{\omega}_j \times \underline{v}_j) \tag{35.35}$$

the first sum containing all the external forces, while the second deals with gravitational and centripetal effects. The external forces include (i) the aerodynamic lift and drag forces, (ii) the front and rear wheel normal loads, (iii) the tire longitudinal forces, and (iv) the tire side forces, including the driving force at the rear tire sufficient to maintain the steady speed. In the second term, m_j represents the mass of the jth body, $\underline{v}_j$ is the velocity of the body's mass center, $\underline{\omega}_j$ is the body's angular velocity vector, and g is the gravitational acceleration vector.

In much the same way, the following moment error should be zero:

$$\underline{M}_{error} = \sum_i \underline{l}_i \times \underline{F}_i + \sum_j \{\underline{l}_j \times m_j(\underline{g} - \underline{\omega}_j \times \underline{v}_j) - \underline{\omega}_j \times \underline{H}_j\} + \sum_k \underline{M}_k \tag{35.36}$$

where

l_i and l_j are moment arm vectors referred to the rear wheel contact point

H_j is the moment of momentum of body j about its mass center

The first sum accounts for the moments generated by the external forces listed earlier, while the second contains a part treating gravitational moments and moments of inertial forces on the body mass centers and a part accounting for the rate of change of moment of momentum of each body, with respect to its mass center. The third summation deals with aerodynamic pitching and tire aligning moments.

Each of the terms $\underline{\omega} \times \underline{H}$ is calculated as $\underline{\omega} \times \left(H_x \underline{i} + H_y \underline{j} + H_z \underline{k}\right)$, with $\underline{H}$ having components H_x, H_y, and H_z in directions denoted by the unit vectors $\underline{i}$, $\underline{j}$, and $\underline{k}$, which must be chosen so that the moment of momentum components is invariant, when the motorcycle is in a steady turn. For all the non-spinning bodies, the body reference axes satisfy this requirement. For the wheels, the parent body's reference system needs to be used and a moment of momentum term for the spin added on. For the most general case applicable here, in which I_{xy} and I_{yz} are zero but I_{xz} is nonzero [51], noting a change of sign of products of inertia is compared with the reference because [51] and AutoSim use opposite conventions:

$$H_x = I_{xx}\omega_x + I_{xz}\omega_z \tag{35.37}$$

$$H_y = I_{yy}\omega_y \tag{35.38}$$

$$H_z = I_{xz}\omega_x + I_{zz}\omega_z \tag{35.39}$$

in which ω_x, ω_y, and ω_z are the components of $\underline{\omega}$ in the $\underline{i}$, $\underline{j}$, and $\underline{k}$ directions.

Thus, for the main body, this second component of rate of change of moment of momentum, that about the mass center, is of the form

$$\underline{\omega}_{main} \times \{(I_{mainx}\omega_x + I_{mainxz}\omega_z).\underline{i}_{main} + I_{mainy}\omega_y.\underline{j}_{main} + (I_{mainxz}\omega_x + I_{mainz}\omega_z).\underline{k}_{main}\} \tag{35.40}$$

Here, $\underline{i}_{main}$, $\underline{j}_{main}$, and $\underline{k}_{main}$ denote the unit vectors $\underline{i}$, $\underline{j}$, and $\underline{k}$ for the main body. To deal with the rear wheel, its diametral inertia is added to the corresponding terms belonging to the swing

arm, its parent body, as if it were part of the swing arm. The spin is accounted for by a term $\underline{\omega}_{swingarm} \times I_{rwy}\omega_y.[rwy]$ and similarly for the front wheel, for which the lower fork body is the parent.

The power error is given by

$$P_{error} = \tau.\omega_{spin} + \sum_i \underline{F}_i.\underline{v}_i + \sum_k \underline{M}_k.\underline{\omega}_k \tag{35.41}$$

where

τ is the gearbox sprocket driving torque

ω_{spin} is its spin velocity relative to the main frame

$\underline{v}_i$ is the velocity of the point of application of force, $\underline{F}_i$

$\underline{\omega}_k$ is the absolute angular velocity of the body to which moment, $\underline{M}_k$, is applied

Describing the power associated with tire forces requires care also. The velocity involved is that of the tire tread base material [50,51], already calculated in connection with finding the slip ratio and the slip angle.

These checks on any equilibrium state are substantially independent of the full equations of motion on which the simulation model depends, and it is reassuring that they are always satisfied to a high level of accuracy.

35.5 MOTORCYCLE BEHAVIOR

35.5.1 Equilibrium "Trim" States

If the allowed motions include only small perturbations from straight running at constant speed, longitudinal and vertical motions are decoupled from the lateral motions by virtue of the motorcycle symmetry, and much understanding of the steering behavior can be obtained at this level, the lateral and longitudinal/vertical problems being considered separately.

When the motorcycle is run from low speed to high speed at very low acceleration levels, it passes through a sequence of quasi-equilibrium states. As the speed builds, the drive torque has to increase as the aerodynamic drag, lift, and pitching moment increase according to the square of the speed. The machine attitude adjusts correspondingly, as can be seen in Figures 35.13 and 35.14. Note especially the suspension system deflections increasing systematically with speed, contrasting with the assumptions of [52].

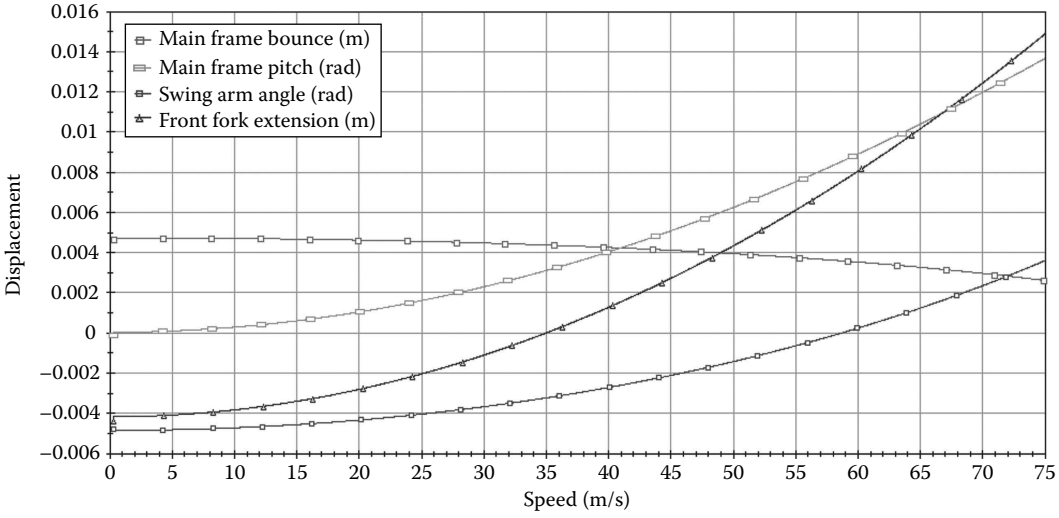

FIGURE 35.13 Straight-running attitude results showing how aerodynamic forces grow with speed and influence the posture of the motorcycle. Positive directions are downward for bounce, nose up for pitch, and rebound for the swing arm and the front forks.

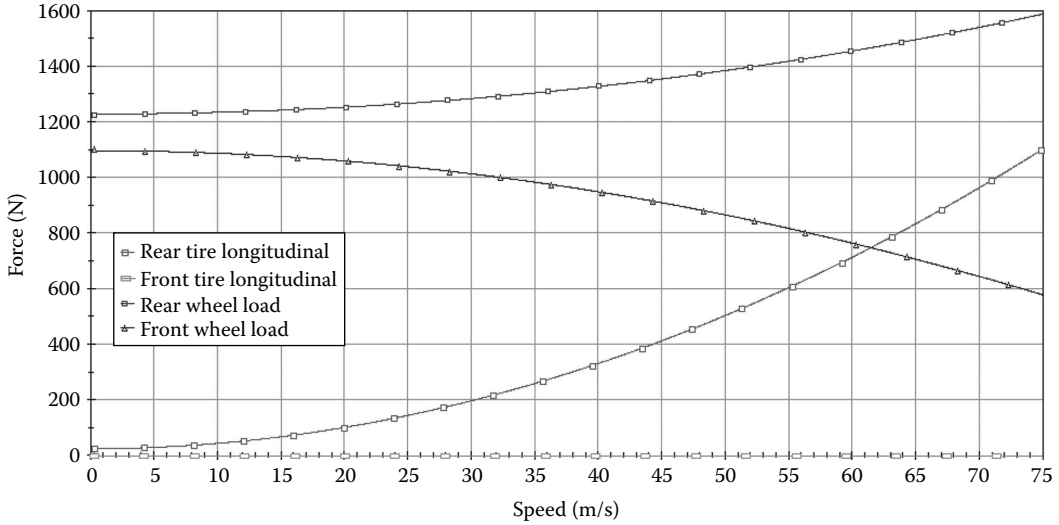

FIGURE 35.14 Straight-running attitude results showing how tire forces change with speed. Driving force is positive. In this example, the driving force at the rear tire is about 70% of the load on the tire at 75 m/s.

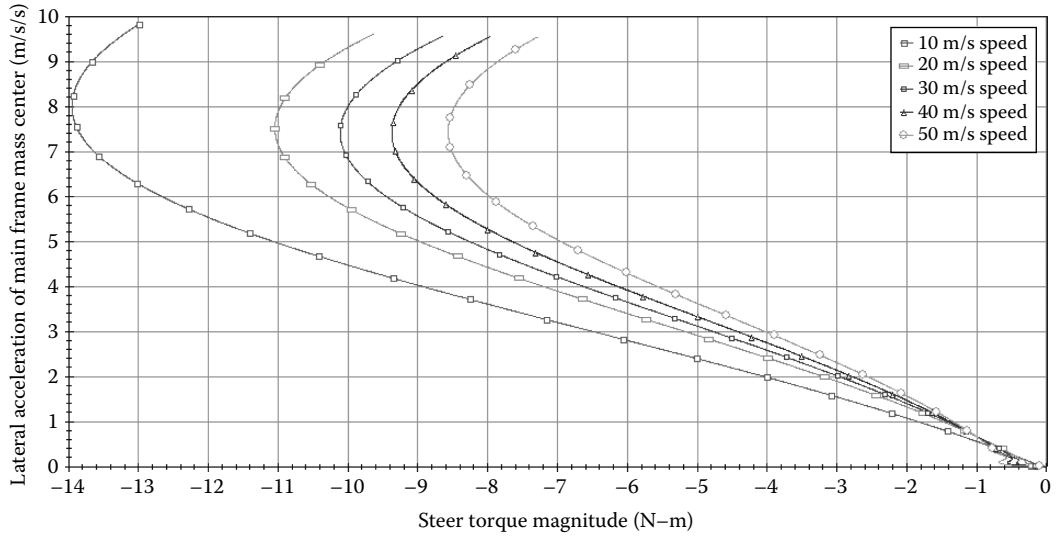

FIGURE 35.15 Steady-state lateral acceleration responses to steering torque input at a series of fixed speeds with slowly increasing lean angle. Infinite slope of a curve, occurring between 7.3 and 8 m/s/s lateral acceleration in these cases, indicates a possible point of transition from static stability to static instability.

In cornering, the speed is conveniently fixed, and the lean angle is ramped up to somewhere near the limit of the available performance space. In these cases, handling diagrams showing lateral acceleration of the main frame mass center against either steer torque (free control) or steer angle (fixed control) can be plotted. These diagrams need to be interpreted strictly in accordance with the theoretical background exposed in Chapter 2. Examples for speeds of 10, 20, 30, 40, and 50 m/s and lean angles up to 0.9 rad are shown in Figures 35.15 and 35.16. If the steer torque is regarded as the input, the steer angle is itself a response, but when the fixed-control stability properties are suitable, the rider does have the option of using steer angle as the control input, utilizing his or her own internal control capabilities to produce the required steering displacements.

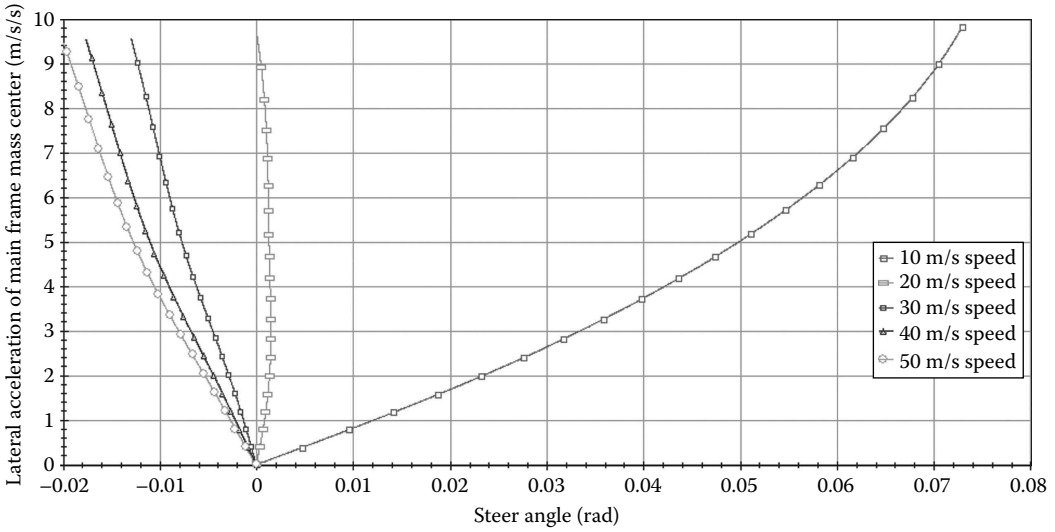

FIGURE 35.16 Steady-state lateral acceleration responses to steering angle input at a series of fixed speeds with slowly increasing lean angle.

The full spectrum of results for each of these cornering cases is complex and all the details are not shown. However, they are available to the linearization process through result files that can be read into MATLAB and utilized to evaluate the matrix elements of the linear model. The passive rider lower and upper bodies displace roughly in proportion to the main frame roll angle. The lateral displacement of the lower body is always less than 3 mm, while the roll displacement of the upper body is approximately 10% of the main roll angle. The wheel loads remain much the same throughout, but the suspensions compress, as the tire side forces grow. The front tire drag increases to about 100 N as the lateral acceleration builds toward 10 m/s/s.

35.5.2 Stability for Small Perturbations from Straight-Running Trim States

Suppose we use our linear model in straight running to calculate first the fixed-control and secondly the free-control stability properties of the motorcycle/rider system. Each process (in MATLAB) involves reading the equilibrium states for the running condition of interest, evaluating the elements of the A matrix (Equation 35.3), finding the eigenvalues and plotting those that lie within an interesting range, and moving to the next running condition to repeat the computations until the so-called root locus [35] is complete. Results can be plotted either as real parts of roots against speed or as imaginary parts against real parts with speed as the varying parameter.

Results are shown in Figures 35.17 and 35.18. In fixed control (steering system locked in the straight-ahead position), the machine system is unstable in roll at low and medium speeds, with a positive real eigenvalue of about 3.75 at the lowest speeds that slowly decreases as the speed increases. The motion belonging to this mode is akin to the divergence from the upright configuration of an inverted pendulum. The mode stabilizes at about 23 m/s. Then, surprisingly, the fixed-control motorcycle and rider are stable until an oscillatory mode with frequency approaching 3 Hz becomes unstable at about 65 m/s. Rider stabilization of the low-speed motion by steering position adjustments should not be impossible but would not be easy. The time constant of the divergent rolling motion is that of a uniform rod of approximate length 1.2 m balancing on its pointed end. However, at speeds between 23 and 65 m/s, this fixed-control motorcycle is self-stabilizing, and it appears to be entirely possible for a rider to use primarily steer angle control in this speed range. The autostabilization must arise primarily from the development of lateral forces by the tires when they run at a camber angle. As the motorcycle leans, the wheel camber and the forces generated apply a rolling moment to the system to counter the leaning.

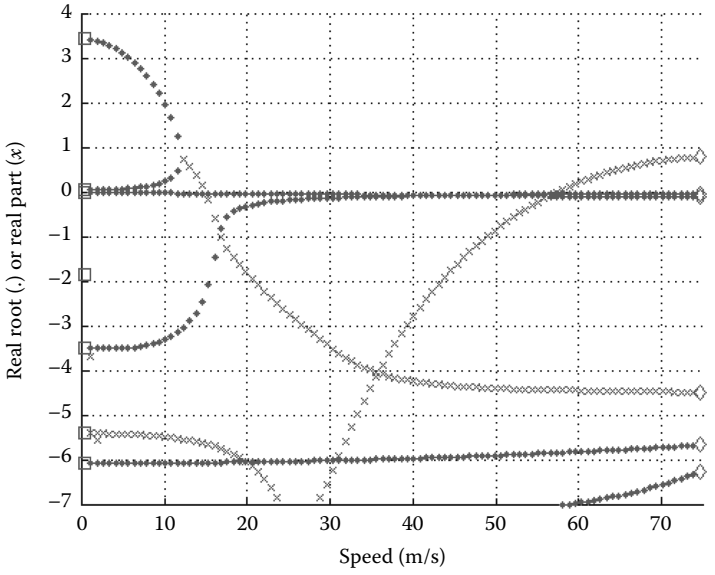

FIGURE 35.17 Eigenvalue real parts as functions of speed in the range 0.5–75 m/s for straight-running standard motorcycle in fixed control. The standard model is converted effectively to fixed control by multiplying the standard steering damper coefficient by 100. Remarkably, the fixed-control motorcycle self-stabilizes in straight running between about 14 and 57 m/s.

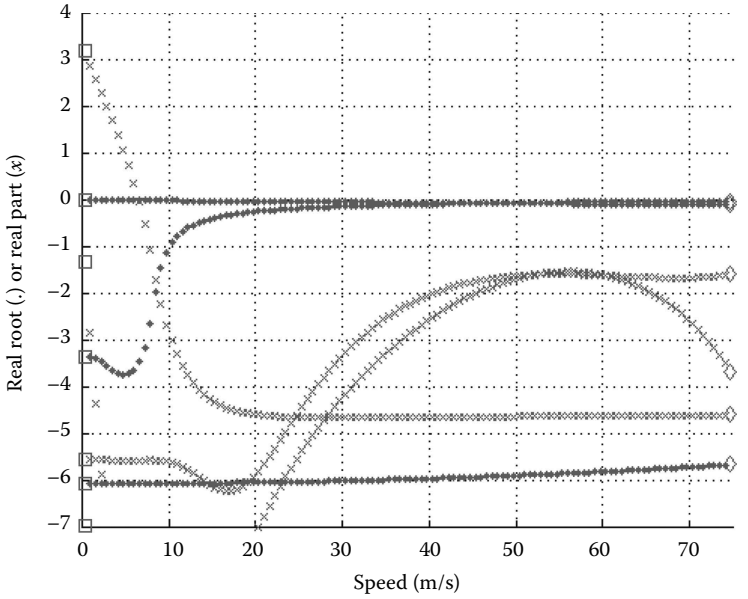

FIGURE 35.18 Eigenvalue real parts as functions of speed in the range 0.5–75 m/s for straight-running standard motorcycle in free control. The free-control motorcycle self-stabilizes in straight running at about 6 m/s.

The locus is shown again in the alternative form in Figure 35.19, along with the results of halving and doubling the frame torsional stiffness. In free control, at very low speeds, there are two positive real eigenvalues. One of these can be associated loosely with the whole machine rolling over or capsizing, as with fixed control, while the other is related to the steering system rotating from the straight-ahead nominal position to full lock under the influence of gravity. With a very small increase in speed, these two real roots become a complex conjugate pair describing an oscillatory

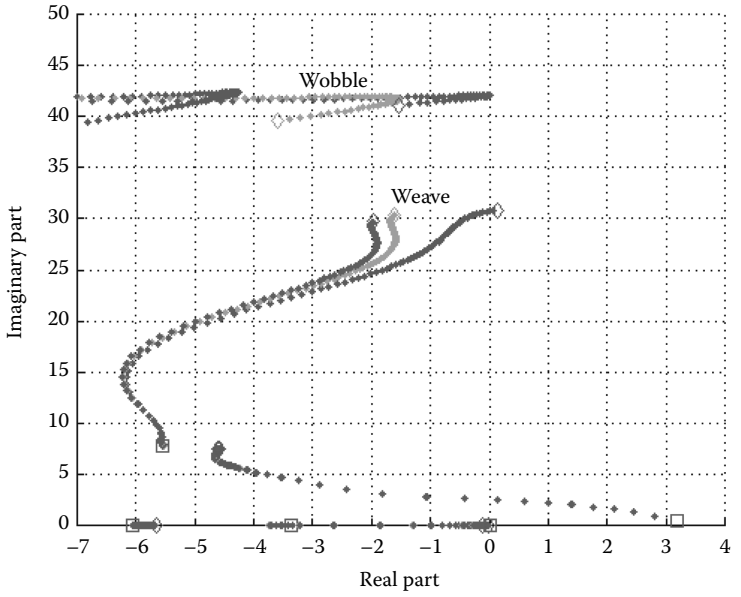

FIGURE 35.19 Root loci for the speed range 0.4–75 m/s for the standard motorcycle with frame torsional stiffness variations. The red curves show the results of halving the stiffness, while the magenta curves show the consequences of doubling the stiffness. The low-speed end of each locus is indicated by a square plot symbol, while the high-speed end is shown by a diamond.

motion of very low frequency, becoming stable at about 6 m/s (see Figure 35.18). This autostabilization of the system at relatively low speed makes the free-control properties of the motorcycle much more attractive to the rider than the fixed-control ones. It can be safely concluded that the rider's main control actuation at low speeds is by steering torque and it is very important that the steering system is free to turn at these low speeds, where the fixed-control behavior is particularly poor.

It has been suggested that the wobble mode can be viewed as involving oscillations of an isolated castor [29,53], the steering axis being fixed and the rear frame properties having no influence on the stability. The idea has been tested in practice by the Pirelli Company, who applied their "pendulum" method [54] to motorcycle front fork assemblies, finding a medium-speed wobble instability to occur regularly. The idea can be tested theoretically in the following way. The stability of the front steering frame on its own can be found by adding stiff lateral restraining springs and dampers to the point $p2$ in Figure 35.12 and to another point on the steering axis near the ground, sufficient to prevent the steer axis from moving laterally. Root loci for the restrained system are then found in the conventional way, with attention only to the wobble-mode locus (Figure 35.20). The medium-speed wobble instability is clear, showing that the location of the steering axis by the rear frame is important to the stability of the front frame and confirming that the wobble mode cannot properly be considered in isolation from the remainder of the system.

When the motorcycle frame is relatively flexible in torsion, as has commonly been the case historically, the wobble mode is minimally damped at medium speed (Figure 35.19), as with the steering axis fixed. The characteristic behavior, in a problematic case, is for the steering assembly to go into sustained low-amplitude oscillations at or near a particular speed, as long as the rider does not impede the motions of the handlebars. The extent to which the rider might control a wobble oscillation by deliberate intervention is considered in [25]. Depending on the frame compliance, the worst speed in terms of the modal damping may be that for which the front wheel rotation frequency is equal to the wobble frequency, at around 6.6 Hz, which is better avoided by design. In such a case, any imperfections in the front wheel or tire (out of round, unbalance, etc.) will contribute forcing, and the resonant response will tend to be excessive. The possible coincidence of forcing and natural frequencies is illustrated in Figure 35.21, computed for the standard machine.

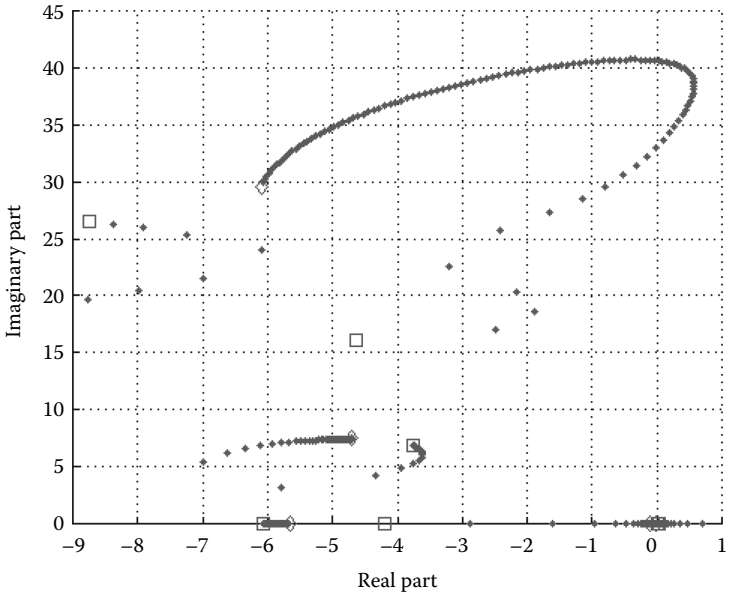

FIGURE 35.20 Root locus for standard machine in straight running with lateral stiffness and damping restraints added to the steer axis, to prevent its lateral motion. As has been shown previously [55], the wobble mode is unstable at moderate speeds, if the steer axis has no lateral mobility.

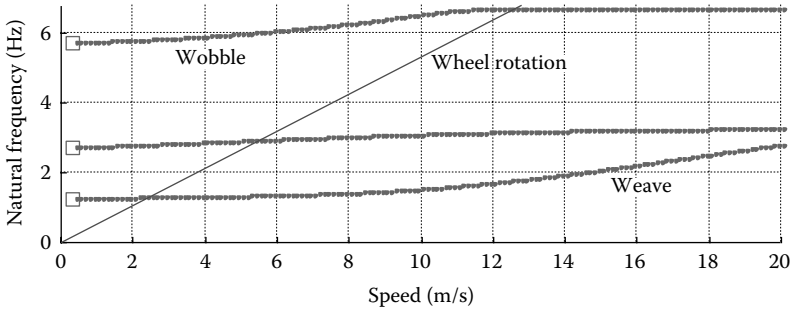

FIGURE 35.21 Typical wobble- and weave-mode natural frequencies and front wheel rotation frequency, as functions of speed, illustrating the possibility of resonant forcing of the wobble mode at moderate speed, in the case of a compliant-framed machine.

When the frame is stiff in torsion, the wobble mode is least damped at higher speeds (Figure 35.19), and it can be expected that wobbles will occur at higher speeds also. A steering damper is effective in stabilizing the wobble oscillations, but it carries a cost in terms of destabilizing the weave (Figure 35.22) and increasing the muscular effort required from the rider for steering control. There is evidence that riders have little capacity to damp out a high-speed wobble, once it becomes established to the level of a few degrees of handlebar amplitude [25]. It is dangerous due to this feature. Recent work has pointed to the possibility of a passive mechanical network being an advantageous and practical alternative to the steering damper, providing the beneficial influence of the damper on the wobble mode but also improving the weave and not implying heavy steering [56,57] (see Section 35.5.9). In the kind of network proposed, the transfer properties of the network can be shaped with frequency, such that the desirable influence of a steering damper on the wobble mode can be retained, while the deterioration of the weave mode can be avoided.

The importance of including rider compliances, tire sideslipping, and tire relaxation lags in the modeling is illustrated in Figures 35.23 through 35.25. In the first of these cases, the standard rider stiffnesses

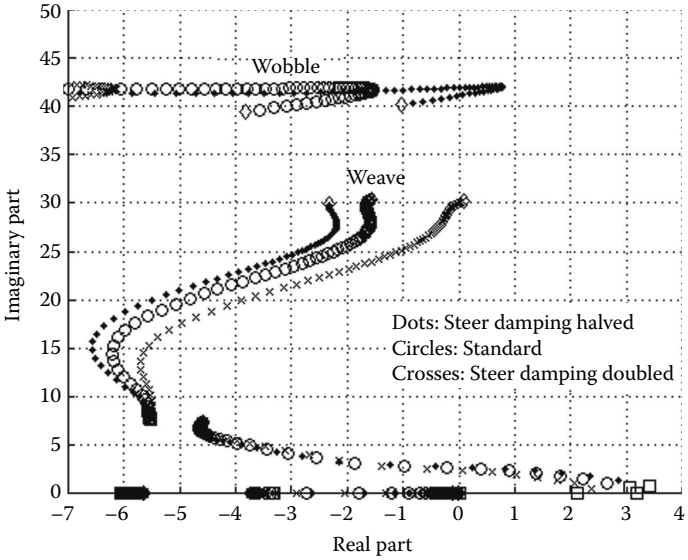

FIGURE 35.22 Root loci for standard motorcycle with steering damper coefficient halved (dots), normal (circles) and doubled (crosses). The steering damper is effective in stabilizing the wobble mode but de-stabilizes the weave mode. The low-speed end of each locus is indicated by a square plot symbol, while the high-speed end is shown by a diamond.

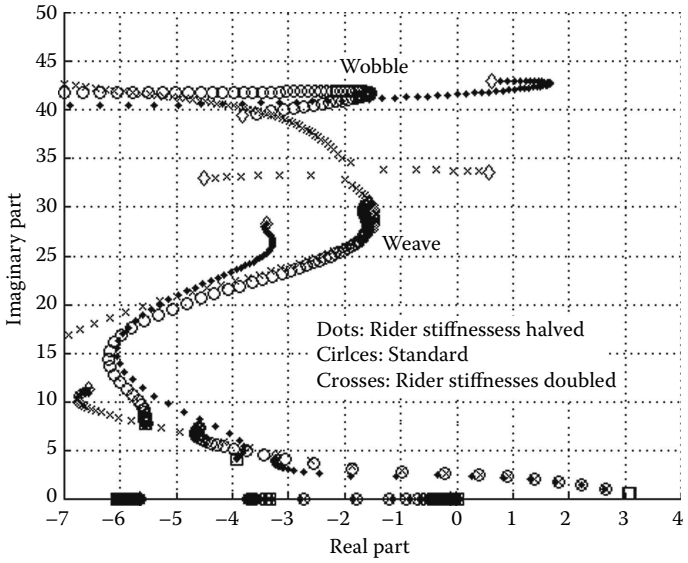

FIGURE 35.23 Root loci with rider stiffness and damping parameters varied. Both stiffnesses are halved (dots) and doubled (crosses) with respect to the nominal settings (circles). The corresponding damping coefficients are varied by a factor $\sqrt{2}$ each time. The low-speed end of each locus is indicated by a square plot symbol, while the high-speed end is shown by a diamond.

are halved and doubled, while the nominal settings, showing the same results as in Figure 35.19, are included for reference purposes. The damping coefficients corresponding to the stiffnesses altered are varied according to the square root of the stiffness adjustment factor. In the second case, both front and rear tire cornering stiffnesses are halved and doubled in the same way, while in the third case, both tire relaxation lengths are halved and doubled similarly. The stability properties of the motorcycle are

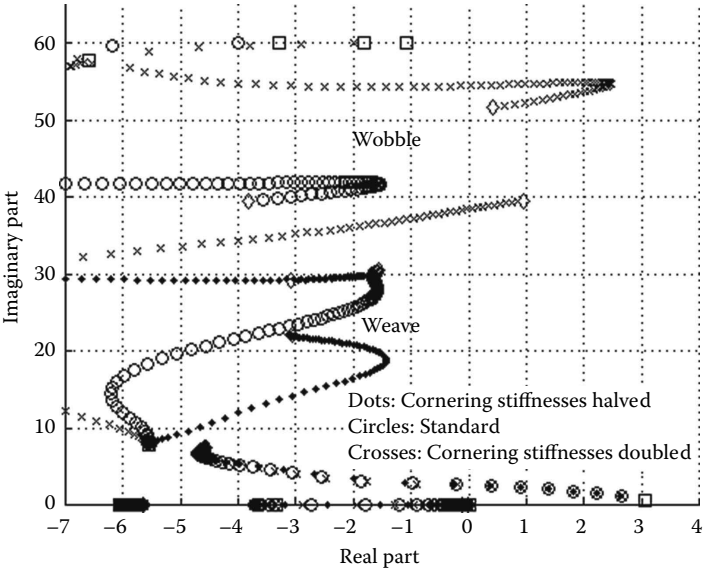

FIGURE 35.24 Root loci with tire cornering stiffnesses halved (dots), normal (circles), and doubled (crosses). The low-speed end of each locus is indicated by a square plot symbol, while the high-speed end is shown by a diamond.

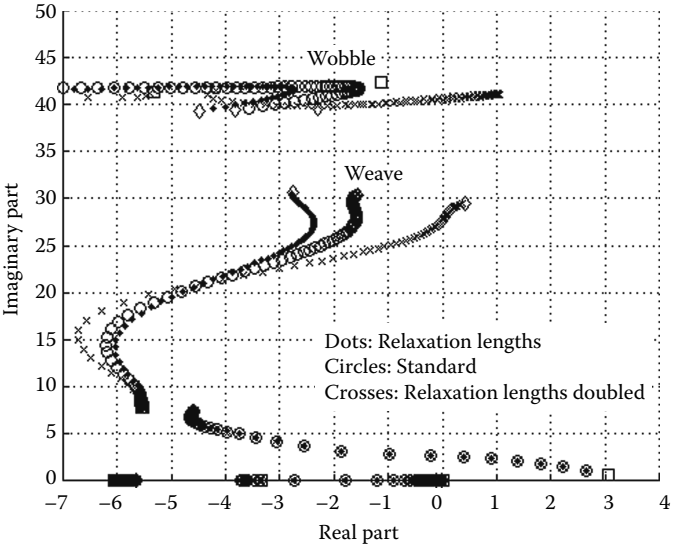

FIGURE 35.25 Root loci with tire relaxation lengths halved (dots), normal (circles), and doubled (crosses). The low-speed end of each locus is indicated by a square plot symbol, while the high-speed end is shown by a diamond.

changed grossly by such large variations in parameter values, and it is clear that the features scrutinized, namely, frame torsion and rider compliances, tire sideslipping and tire relaxation lags, must be included in models of contemporary machines to make good predictions of behavior over the full speed range.

35.5.3 Normal Modes for Straight-Running Trim States

Mode shapes are given by appropriate eigenvector columns. Examples for the wobble mode are shown in Figure 35.26 and for the weave mode in Figure 35.27. In these diagrams, "lat" means the lateral velocity of the main frame reference point, nominally coinciding with the rear tire/ground contact point; "yaw"

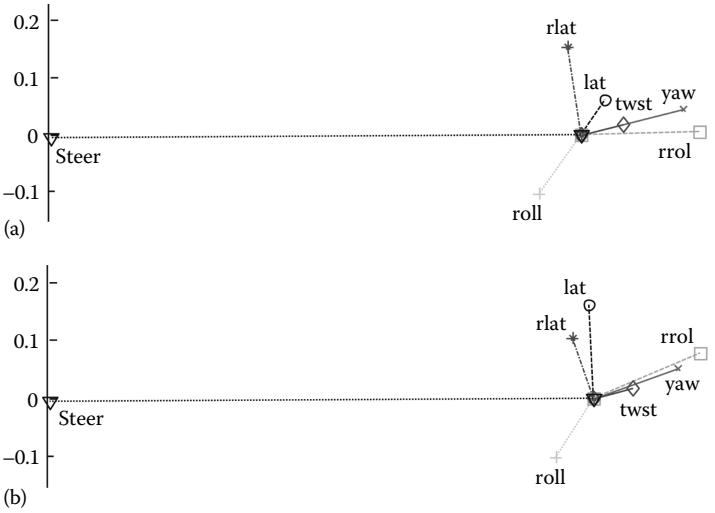

FIGURE 35.26 Wobble-mode eigenvectors for 20 (a) and 50 m/s (b). Translational velocities in m/s and angular velocities in rad/s. Corresponding eigenvalues are –7.142 ± 41.743i and –1.686 ± 41.880i.

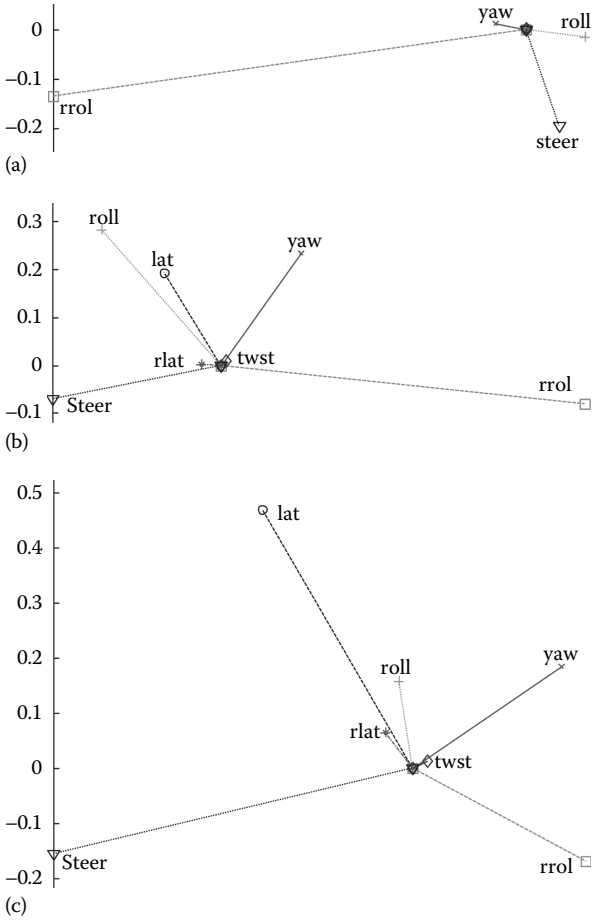

FIGURE 35.27 Weave-mode shapes for 5 (a), 20 (b), and 50 m/s (c). Translational velocities in m/s and angular velocities in rad/s. Corresponding eigenvalues are –5.575 ± 8.18i, –5.866 ± 17.35i, and –1.622 ± 27.35i.

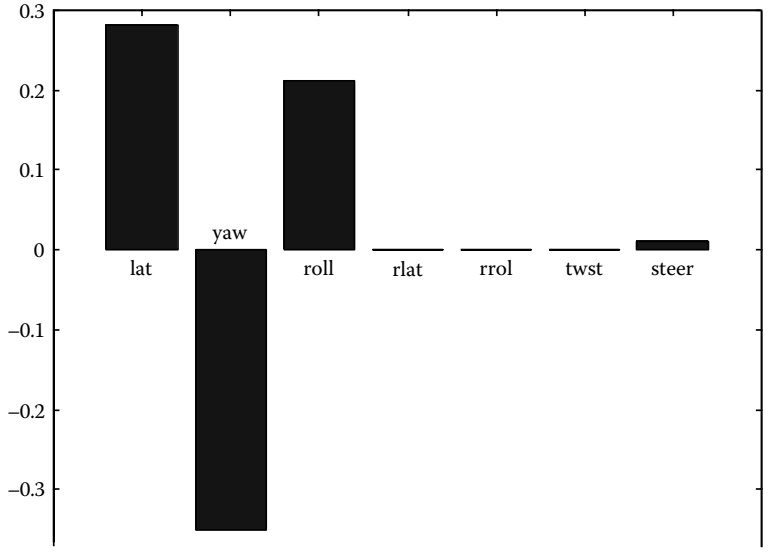

FIGURE 35.28 Capsize mode participant motions at 20 m/s. Translational speeds in m/s and rotational speeds in rad/s.

and "roll" are for the main frame; "rlat" means the lateral velocity of the rider lower body relative to the main frame; "rrol" means the rider upper body relative roll velocity; "twst" is the frame twisting velocity; and "steer" is the steer velocity relative to the main frame. The wobble mode mainly involves contrarotation of the steering system and the main frame, with significant participation from roll, rider motions, and frame twisting. The shape does not change much over the speed range. The weave mode is more variable with speed and is harder to characterize. There is always substantial rider participation, especially from rolling of the upper body. This rider participation is, of course, a consequence of the adoption of the rider model from [13], derived from excitation of a number of riders in pure roll. To the extent that the modal motions are different from this, the direct acceptance of the results is of questionable validity. The best way to represent a generic rider remains an open issue. Animation of the modes is a very useful aid to obtaining some appreciation of them (http://www.ic.ac.uk/controlandpower/motorcycles).

The capsize mode at 20 m/s, having real eigenvector elements, is depicted in Figure 35.28. The motion involves translating to the right (say), rolling to the right, and steering to the right, while the motorcycle yaws to the left. Rider and frame twisting contributions are negligible.

35.5.4 Frequency Responses in the Neighborhood of Straight Running

From the small-perturbation linear model, it is straightforward to calculate frequency responses to defined excitation, but it is not easy to interpret the results of such calculations. It was demonstrated in [3] that motorcycles are not as good as cars in responding to a sudden need to maneuver and that the skill of the rider is a substantial issue in avoiding obstacles (see [30] also). It is clear that maneuverability has some importance but it is not so clear how to define it objectively. One aspect of the problem that can be enlightened by calculation is the relative responsiveness of the motorcycle to steer torque and to rider lean torque forcing, an issue studied experimentally in [8]. Let us choose to compute yaw rate responses to steer torque or rider lean torque input. Since motorcycles only rarely operate with significant sideslipping, the yaw rate response is considered a reliable indicator of the lateral motions and the path followed.

Yaw rate responses to steer torque input for the standard motorcycle at speeds of 10, 30, 50, and 70 m/s are shown in Figure 35.29, and corresponding responses to rider upper body torque input are shown in Figure 35.30. The responses at the low frequencies of importance for rider control reduce as the frequency rises and are much reduced for higher speeds. Weave and wobble resonances

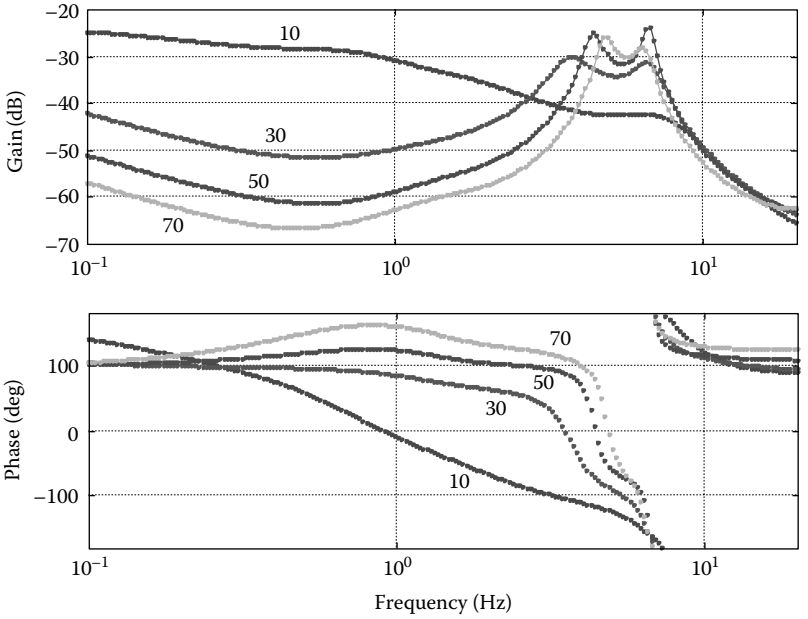

FIGURE 35.29 Yaw rate frequency responses to steer torque input for standard machine in straight running re 1 (rad/s)/(N m) for speeds 10, 30, 50, and 70 m/s.

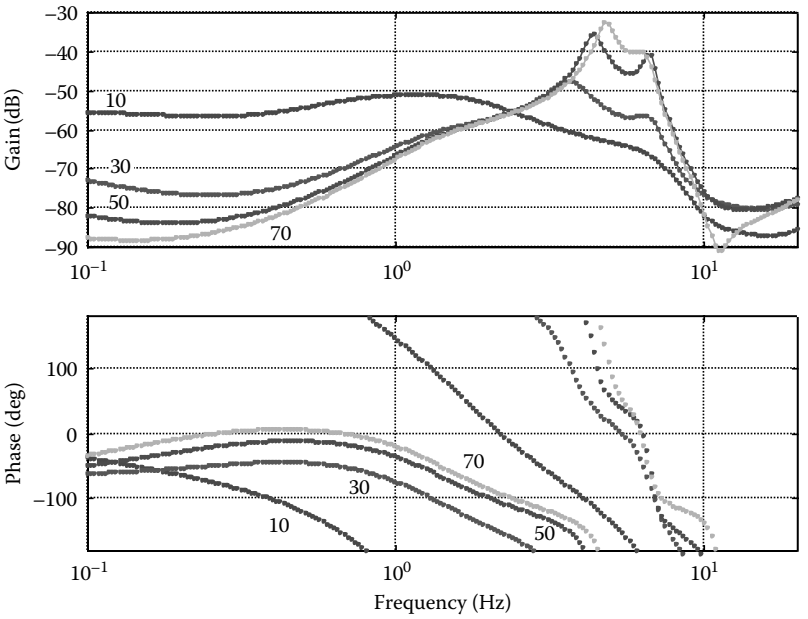

FIGURE 35.30 Yaw rate frequency responses to upper body lean torque input for standard machine in straight running re 1 (rad/s)/(N m) for speeds 10, 30, 50, and 70 m/s.

show clearly for the higher speeds. Responses to rider body torque are much less than those to steer torque, confirming the idea that steer torque control is completely dominant over body torque control. If the main frame roll inertia or the main frame yaw inertia is doubled, and the results of Figure 35.29 are regenerated, only very small changes occur. These results are not shown, since they are so similar to those of Figure 35.29. Responses to wheel rotation forcing, with various types of wheel or tire imperfection, are shown in [58], which results are not repeated here.

35.5.5 Stability in Cornering

When motorcycle motions involve large excursions from the nominal laterally symmetric state, out-of-plane movements, lateral, yaw, roll, rider lean, frame twist, and steer, become interactive at first-order level with in-plane movements, bounce, pitch, and wheel hop. Trim states from the simulation runs used to yield Figures 35.15 and 35.16 are chosen now to illustrate the stability properties in cornering. The simulations involve fixing the speed and slowly ramping up the roll angle to near limit states, so the varied parameter in the root loci is the motorcycle roll angle or, equivalently, the lateral acceleration of the main frame mass center.

With free steering, from Figure 35.15, we might anticipate a transition from statically stable to statically unstable at a lateral acceleration level of 7.3–8 m/s/s for any of the five speeds. Examples are given in Figure 35.31, for 10 m/s speed, and Figure 35.32, for 30 m/s speed, with eigenvalue real parts plotted as functions of lateral acceleration, and Figure 35.33, for 50 m/s speed, which is a root locus plot, with lateral acceleration the swept parameter. Figures 35.31 and 35.32 show the expected appearance of positive real eigenvalues at high lateral accelerations. In each case, the stability transition is represented by the real part of a complex conjugate pair of eigenvalues changing sign, but the imaginary part is less than 0.03. The appearance of the complex pair near to the stability boundary is thought to be due to numerical imprecision in finding the eigenvalues. Figure 35.33 shows only a small influence of cornering on weave and wobble roots at 50 m/s speed. Corresponding root loci for other speeds show the same feature but they are not included.

Fixed steering is represented approximately by multiplying the standard steering damper coefficient by 100. From Figure 35.17, we should expect static instability for 10 m/s forward speed and static stability for 40 m/s speed at small lean angles. Figure 35.34, for 10 m/s speed, demonstrates static instability through the lateral acceleration range, while Figure 35.35, for 40 m/s, shows no positive real roots until the lateral acceleration reaches about 7.6 m/s/s.

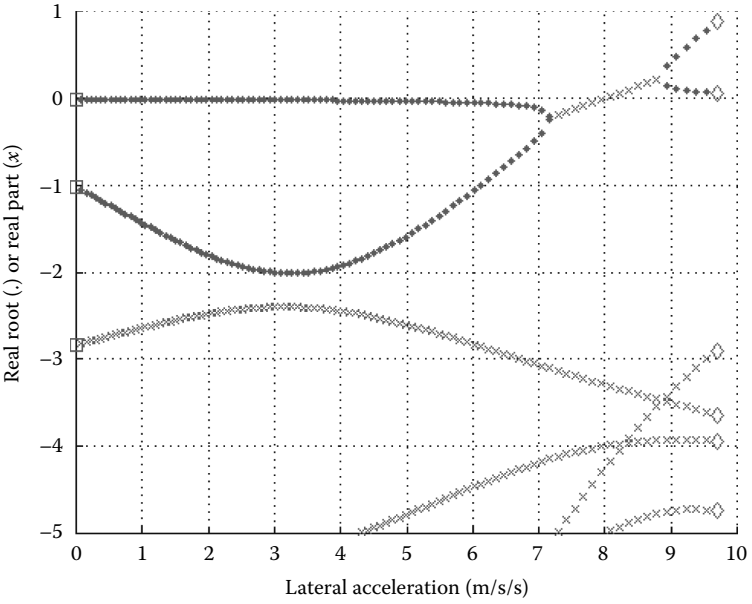

FIGURE 35.31 Real parts of characteristic roots for standard motorcycle in free control at a constant speed of 10 m/s through the full range of lateral accelerations. Dots show real roots, while crosses indicate real parts of complex conjugate roots. The crossing of the stability boundary occurs at 8 m/s/s lateral acceleration, as might be expected from Figure 35.15. The complex roots in this region are thought to be due to computational imprecision.

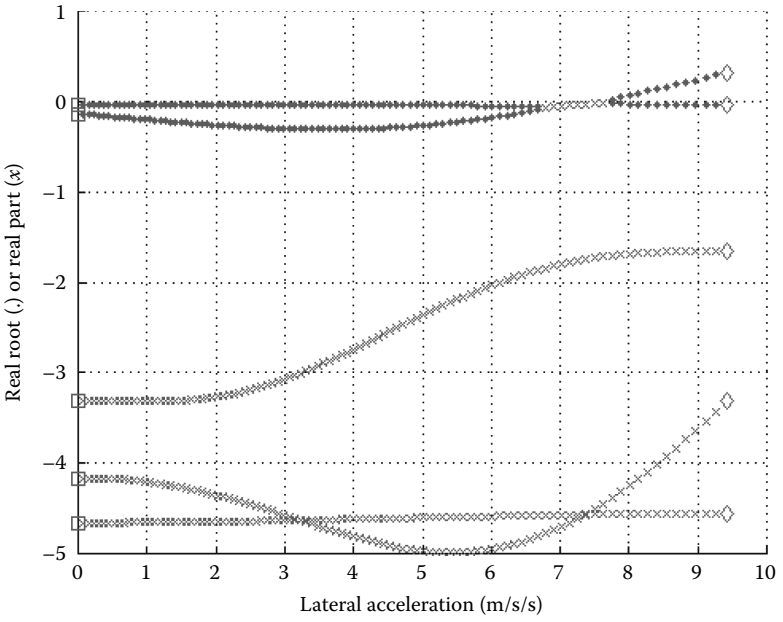

FIGURE 35.32 Real parts of characteristic roots for standard motorcycle in free control at a constant speed of 30 m/s through the full range of lateral accelerations. Dots show real roots, while crosses indicate real parts of complex conjugate roots. The stability boundary is crossed at 7.7 m/s/s lateral acceleration, again in line with Figure 35.15. Again, the complex roots near the boundary have very small imaginary parts.

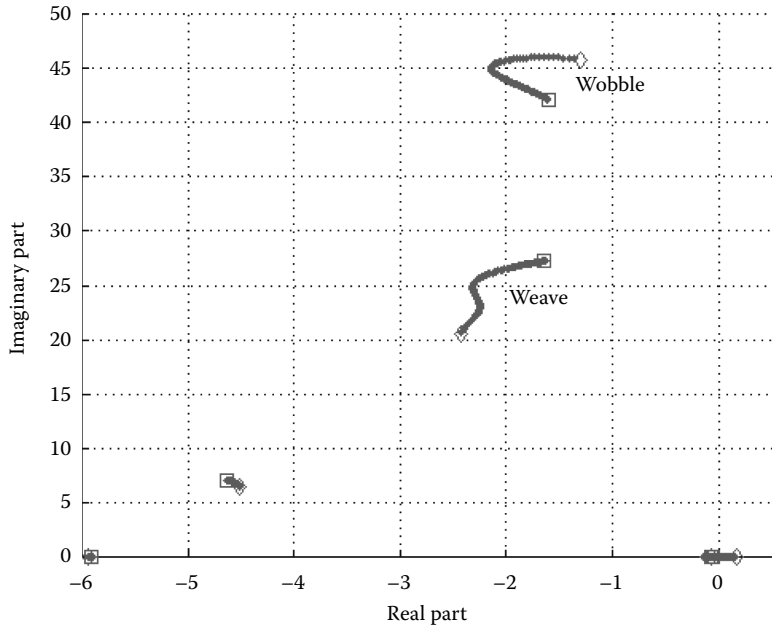

FIGURE 35.33 Root locus plot for a fixed speed of 50 m/s and lateral accelerations from 0 to 9.5 m/s/s. Squares are for zero lateral acceleration and diamonds for 9.5 m/s/s. The influence of cornering on the stability of the oscillatory modes is modest, the weave mode tending to improve with turning vigor.

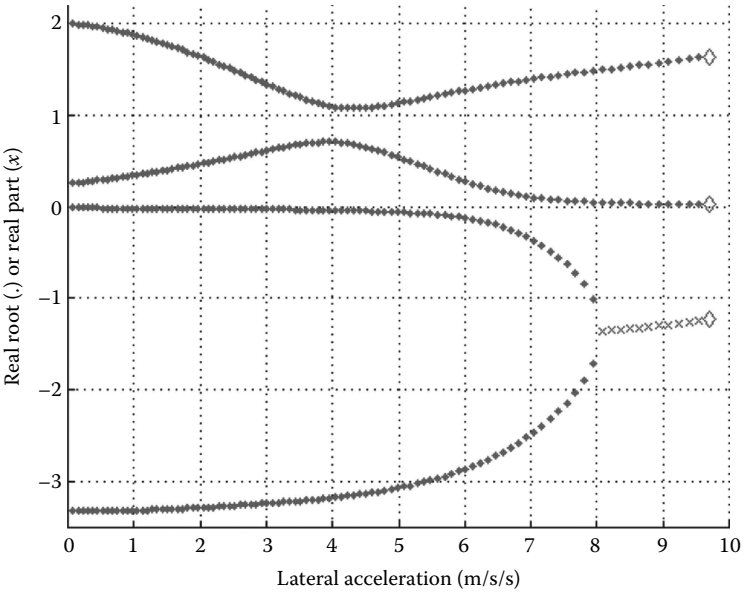

FIGURE 35.34 Real parts of characteristic roots for standard motorcycle in fixed control (steer damping*100) at a constant speed of 10 m/s through the full range of lateral accelerations. Dots show real roots, while crosses indicate real parts of complex conjugate roots. The system is statically unstable at this speed throughout the range of lateral accelerations.

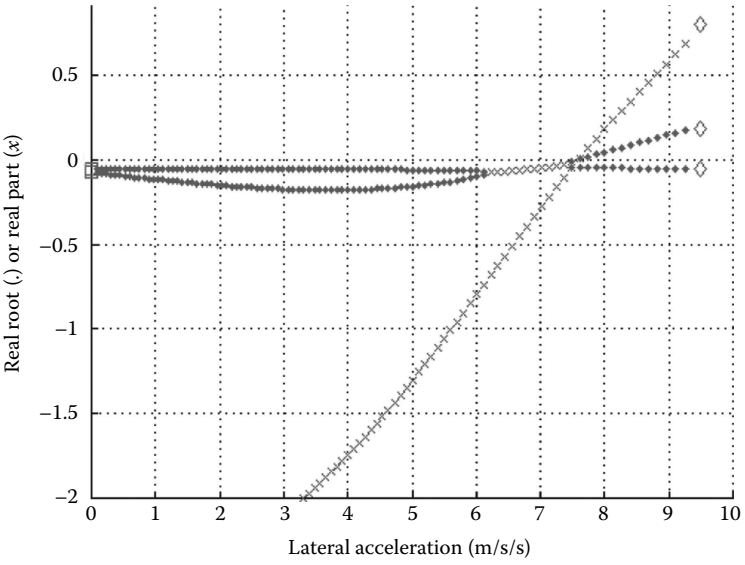

FIGURE 35.35 Real parts of characteristic roots for standard motorcycle in fixed control (steer damping *100) at a constant speed of 40 m/s through the full range of lateral accelerations. Dots show real roots, while crosses indicate real parts of complex conjugate roots. The motion becomes unstable at about 7.6 m/s/s lateral acceleration.

Root loci for the standard motorcycle for a constant roll angle of 20° and a speed range of 5–70 m/s are shown in Figure 35.36. The least stable speed for the weave mode is about 47 m/s and for the wobble mode is about 57 m/s. These running conditions will be examined from the point of view of road undulation forcing in Section 35.5.8.

The stability properties show that at low speeds, free steering of the motorcycle is essential to its controllability with reasonable effort. For higher speeds, fixed control is feasible, and it is likely that

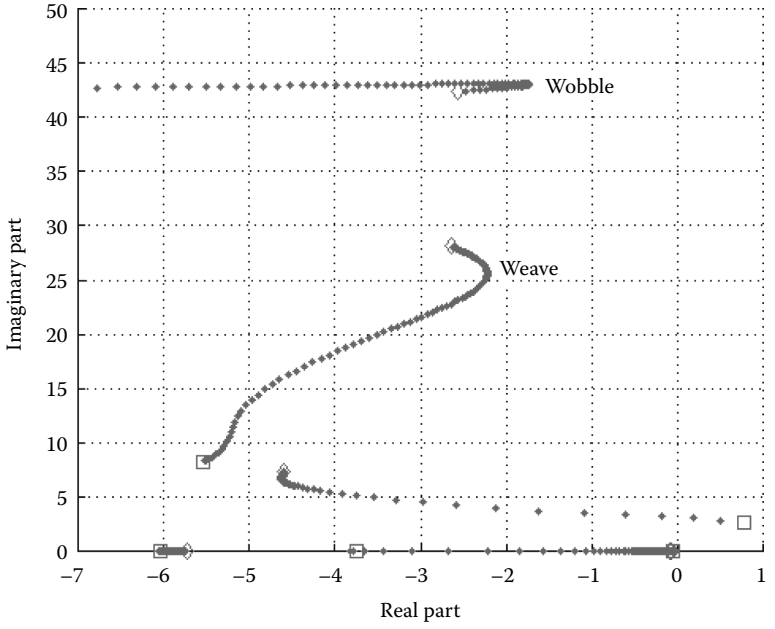

FIGURE 35.36 Standard machine root loci for speed 5–70 m/s and lean angle of 20°. Minimum damping of the weave mode occurs at about 47 m/s, while that for the wobble mode occurs around 57 m/s. Squares are for 5 m/s, while diamonds indicate 70 m/s speed.

real riders choose some convenient combination of free and fixed control, depending on machine and speed. At higher speeds, the fixed-control machine becomes oscillatory before the free-control machine does. At high speeds, the rider will again choose primarily free control. It is the stability properties in free control that matter most, since this is always the fallback option.

35.5.6 Cornering Modes

Due to the cross-coupling of in-plane and out-of-plane motions in cornering, the oscillatory modes have a more complex composition when the small perturbations occur about a turning trim state. The eigenvectors, showing the mode shapes, are just as easy to calculate as in straight running, but they are even more difficult to visualize. Again animation is potentially valuable (see (http://www.ic.ac.uk/controlandpower/motorcycles)). Cornering weave is illustrated in Figure 35.37 for 50 m/s speed and very high lateral acceleration, while cornering wobble is shown in Figure 35.38 for the same condition.

35.5.7 Road Undulation Forcing

Lightly damped oscillatory modes of motion have the potential to resonate in response to suitable regular forcing, as already mentioned in Section 35.5.2 in relation to wheel rotation forcing. Other possible sources of regular forcing are aerodynamic vortex shedding [22,59] and road irregularities [50]. It is believed that a whole class of motorcycle accidents is connected with road undulation forcing.

When a motorcycle is traveling substantially along a straight path, the coupling between road undulations and lateral responses is very weak and problems should not arise, but in cornering, the strength of coupling grows with the roll angle and sustained forcing along the curved path of the machine may lead to dangerously high response amplitudes. Resonant responses may be large for special combinations of machine speed, lean angle, and road wavelength. The speed and lean

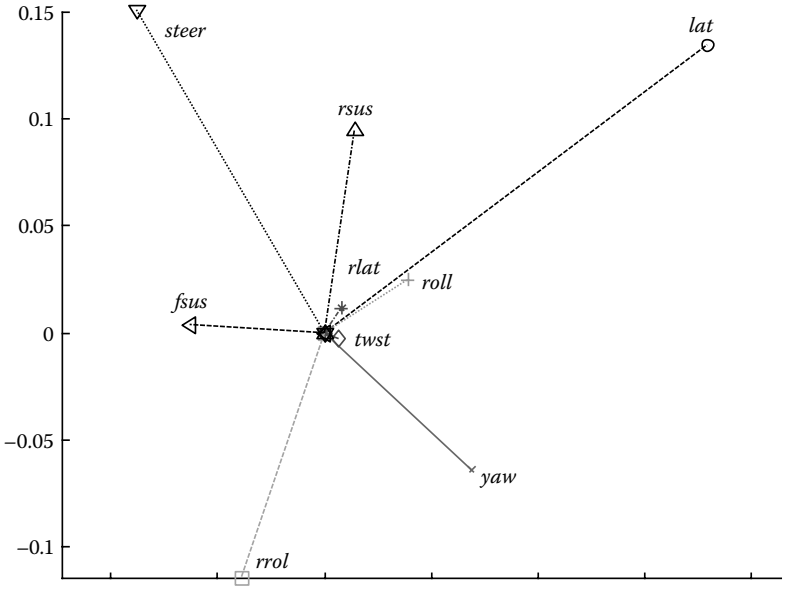

FIGURE 35.37 Weave-mode eigenvector for 50 m/s speed and 9.54 m/s/s lateral acceleration. The corresponding eigenvalue pair is –2.447 ± 20.39i. Translations are in m/s and rotations in rad/s. All the variables illustrated are velocities. "rsus" is the swing-arm angular velocity, while "fsus" is the front fork extension velocity. "rrol" and "rlat" are rider roll and lateral velocities.

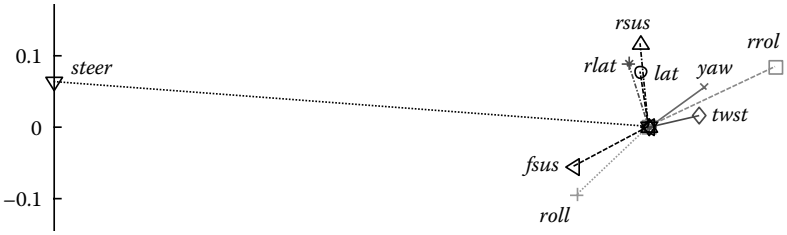

FIGURE 35.38 Wobble-mode eigenvector for 50 m/s speed and 9.54 m/s/s lateral acceleration. The corresponding eigenvalue pair is –1.278 ± 45.75i. Translations are in m/s and rotations in rad/s. All the variables illustrated are velocities. "rsus" is the swing-arm angular velocity, while "fsus" is the front fork extension velocity.

angle determine the natural frequencies, the modal damping factors, and the road forcing to vibration mode coupling strength. The wavelength governs the matching of forcing frequency to natural frequency. A detailed study of a touring machine from the early 1980s can be found in [50]. The connections with recorded accidents are also made there.

The calculation of responses to sustained road forcing was described earlier in Chapter 2 (see (2.10) in particular). In Figure 35.39, the results of such calculations for our standard machine at 20° roll angle and 57 m/s speed, where the wobble-mode damping is least, are shown. Similar results for 47 m/s, for which the weave mode is least damped, are shown in Figure 35.40. In each case, the two resonances are clear, and the 30 dB peak of the wobble mode at 57 m/s indicates that the road displacement amplitude necessary to cause a lock to lock steering response is only 16 mm. The road undulations do not need to be large to create a problem, as long as they are regular and are tuned to the machine properties at the relevant running conditions. In contrast to [50], forcing of the weave mode from the rear wheel is dominant with our standard machine, while the front wheel input is only a little stronger than that from the rear in respect of the wobble mode.

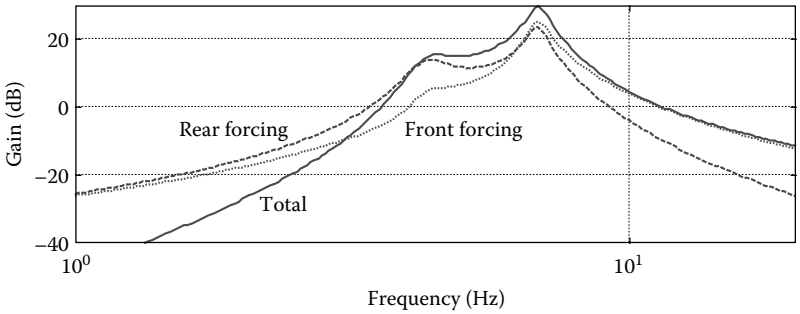

FIGURE 35.39 Steer angle frequency responses of standard bike at 57 m/s speed and 20° roll angle to road forcing in m (0 dB response represents 1 rad). In contrast to the case studied in [50], the rear wheel excitation is dominant in relation to the weave mode here.

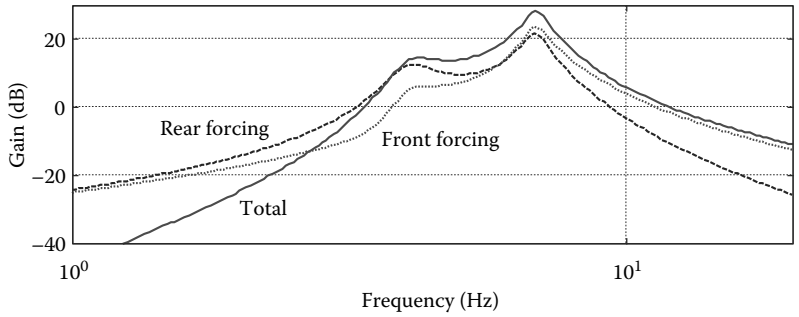

FIGURE 35.40 Steer angle frequency responses of standard bike at 47 m/s speed and 20° roll angle to road forcing in m (0 dB response represents 1 rad). The front excitation is only a little more effective than that at the rear in respect of the wobble-mode response.

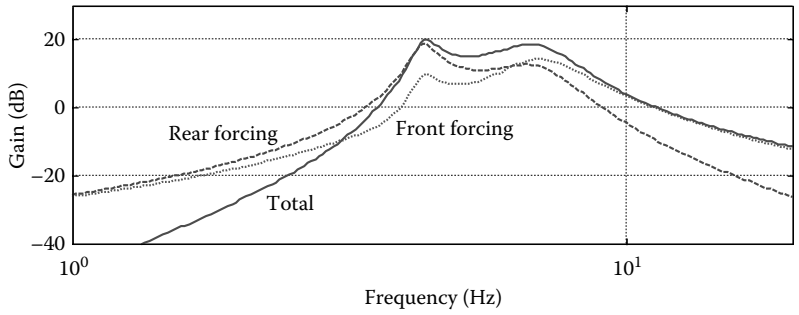

FIGURE 35.41 Steer angle frequency responses of standard bike at 57 m/s speed and 20° roll angle to road forcing in m (0 dB response represents 1 rad) with the standard steering damper coefficient doubled.

Figures 35.41 and 35.42 correspond to Figures 35.39 and 35.40, respectively, and they show the influences on the responses of doubling the steering damper coefficient. The change is effective in reducing the wobble-mode peak by about 12 dB, but it raises the weave-mode peak by about 4 dB. The steering damper is helpful to the wobble mode but damaging to the weave, as can also be seen in the root loci (Figure 35.22). The damper can be a rather critical component due to this conflict between the modal responses, and alternatives are of current research interest (see Section 35.5.9).

The possibility of nonlinear responses to road forcing being problematic arises naturally, since the motorcycle equations of motion are very complex and the terms of all orders are contained in them. Subharmonic, superharmonic, internal, and combination resonances [60] may occur. These nonlinear phenomena are potentially significant because they are likely to be outside the normal experience of riders, who

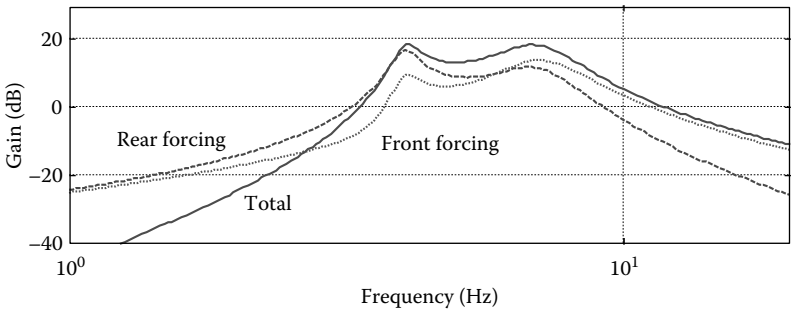

FIGURE 35.42 Steer angle frequency responses of standard bike at 47 m/s speed and 20° roll angle to road forcing in m (0 dB response represents 1 rad) with the standard steering damper coefficient doubled.

are unlikely to have learned how to deal with them, if they do occur. The phenomena have been studied by simulation and time-frequency analysis of computed motion time histories [61,62]. Large-amplitude subharmonic and superharmonic oscillations can occur, associated with forcing frequencies of twice or three times, or one-half or one-third of the weave or wobble natural frequencies, respectively. Superharmonic resonances were easier to provoke than subharmonics. Internal resonance requires whole-number relationships between natural frequencies and will not be notable unless the (linear) modal damping factors are low. Running conditions for which the wobble frequency is twice the weave frequency typically do occur, and simulations show that exciting one mode directly, by forcing at the natural frequency, can lead to a strong response in the other mode. However, the nonlinear energy transfer mechanisms appear relatively weak, and no real events can be positively associated with nonlinear behavior as yet.

35.5.8 Steering Compensation

It has been established both experimentally [15] and theoretically [22,50] (see Figures 35.22, 35.41, and 35.42) that a steering damper increases the damping of the wobble mode while decreasing that of the weave mode at high speeds. One possible way of improving on a standard steering damper is to make it speed adaptive [63], but variability according to speed does not directly address the fundamental problem. Stiff-framed machines are liable to have minimally damped weave and wobble modes at similar high speeds, as has been demonstrated earlier (Figures 35.18 and 35.19). The basic question is, "can we find an alternative to the damper, providing the same benefit to the wobble mode but not destabilizing the high-speed weave?" Searches for a passive mechanical compensator to improve on a standard damper are reported in [56,57] and for an active system for the same purpose, in [64]. In these studies, the steering damper is abstracted from the mechanical system and treated as an example of a compensator that responds to steering velocity by generating a torque between the main frame and the steering assembly (Figure 35.43). More general compensators made from springs, dampers, and inerters, the inerter consisting of a geared flywheel giving torque proportional to the relative angular acceleration across it [65], are considered by Nyquist frequency-response-based methods, followed by optimization over a wide range of operating conditions. Networks with good properties are identified, one of which is shown in Figure 35.44. This network operates like a steering damper at the wobble-mode frequency but behaves more like an inerter for the weave mode. Network parameters and frequency response properties and the influences on the root loci and road forcing responses can be seen in the references.

In the case of the active compensator, passivity is no longer a restriction on the achievable performance, the compensator may be of high order without becoming impractical, and adaptation of the parameters to operating conditions is quite feasible. The compensator design in [64] is achieved by H-infinity loop-shaping procedures [66–68], and further advantage with respect to the standard damper and the passive network is demonstrated. Work in progress is directed toward understanding of the influences of acceleration and deceleration. Also, practical evaluation of passive and active systems in the laboratory and on running motorcycles is in progress.

Appl. Mech*., in review for determination of parameter values.)

35.5.9 Acceleration and Deceleration

Many motorcycles are capable of high levels of acceleration and deceleration. Often, stoppies set the limit on what is possible in braking, while wheelies or engine power set the acceleration limits. From a steady condition, application of driving or braking brings an in-plane response directly [48], and the lateral dynamics are affected, partly by the redistribution of tire loadings and partly by virtue of the inertial influences newly introduced. Strictly, the motions cannot be analyzed by considering small-perturbation-from-trim states, since trim states require the speed to be constant. However, with appropriate reservations, frozen-time eigenvalue analysis can be used to predict behavior [36]. Acceleration and deceleration are not just interesting from an analytical standpoint; they are important practically, due to safety considerations.

First, let us examine the transient in-plane behavior when accelerating suddenly from low speed [48]. Figure 35.45 shows the standard machine traveling straight at trim at 5 m/s when a demand for 5 m/s/s acceleration occurs. The speed controller responds by applying a driving torque to the transmission sprocket, and the motorcycle attitude adjusts to the new situation. The rear tire longitudinal slip settles to just under 0.03. The main frame bounce is positive downward, and positive pitching gives a nose-up attitude. The swing-arm angle is positive in rebound. The corresponding wheel loads are shown in Figure 35.46.

Severe braking by the front wheel only from 75 m/s straight-running trim, with a deceleration demand of 10 m/s/s, is shown in Figures 35.47 and 35.48. In decelerating, the aerodynamic force system helps, but nevertheless, in this case, the front tire shear force needs to be greater than the front wheel load to achieve the deceleration objective. The front tire slip ratio reaches below −0.05, the tire getting quite near to its adhesion limit. The rear tire continues to contact the ground, the load reducing to only 200 N at one stage.

If the motorcycle brakes were applied sufficiently to cause wheel locking, the major influence on the lateral motion of the motorcycle would come from the completely changed behavior of the tires, when they stop rolling. It is easy to show, by representing the tire lateral forces for locked wheels as only marginally effective, that the vehicle will become rapidly divergent, if either front or rear wheel locks. In the former case, the rider's control mechanism is effectively removed by the wheel

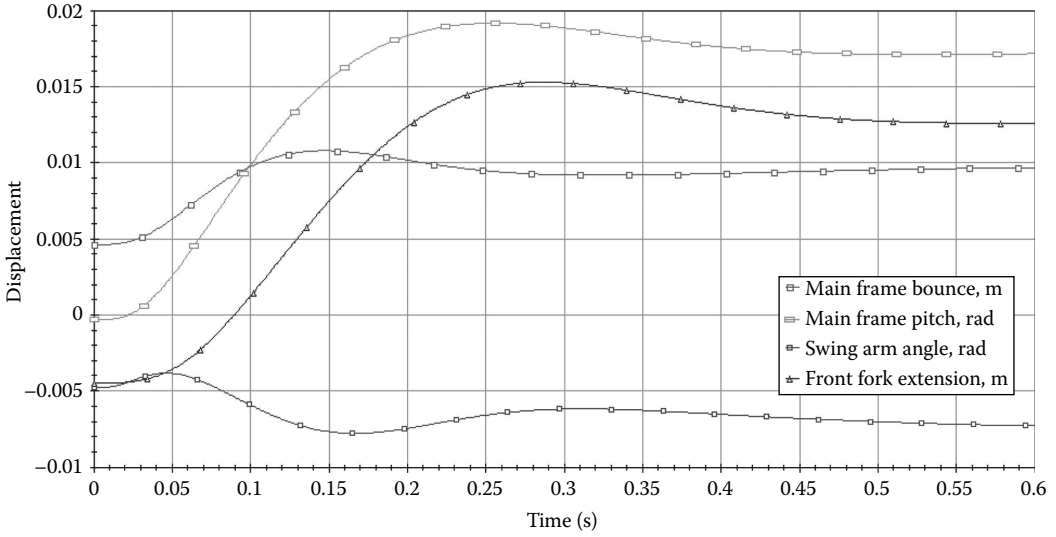

FIGURE 35.45 Motorcycle responses to step input of 5 m/s/s acceleration demand from 5 m/s straight-running trim state.

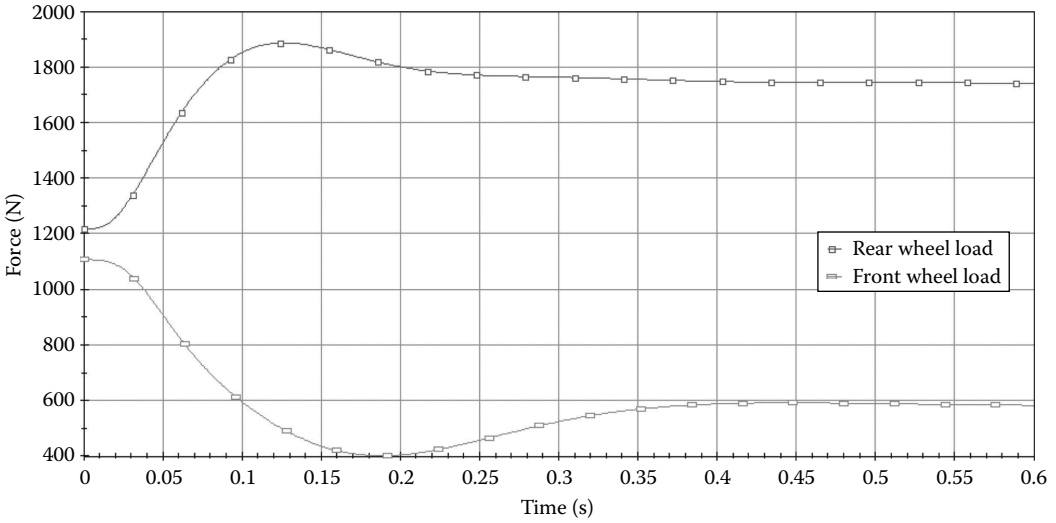

FIGURE 35.46 Rear and front wheel loads for the simulation run of Figure 35.45, showing the transfer of load from front to rear corresponding to the acceleration of 5 m/s/s. The manner in which suspension kinematics influence the transient load transfer is illustrated in (From Sharp, R.S. et al., *Advances in Computational Multibody Systems*, J. Ambrósio ed., Springer-Verlag, Dordrecht, the Netherlands, pp. 45–68, 2005).

locking. The only possible salvation lies in releasing the brake and getting the front wheel to roll again. In the latter case, control is possible through the use of the steering system to influence the front tire, but the stabilizing task is likely to be difficult. Effective antilocking systems have a particular appeal in the world of single-track vehicles, since locking wheels is so problematic.

Now, let us examine the influences of acceleration and braking on the root loci of the straight-running motorcycle through the speed range. As described earlier, the calculations can be done in either of two ways. The first way involves performing a simulation run in which the machine accelerates from low speed at a constant rate, avoiding a wheelie, to a speed determined by the engine power available, and then carrying through a root locus computation, as if the simulation

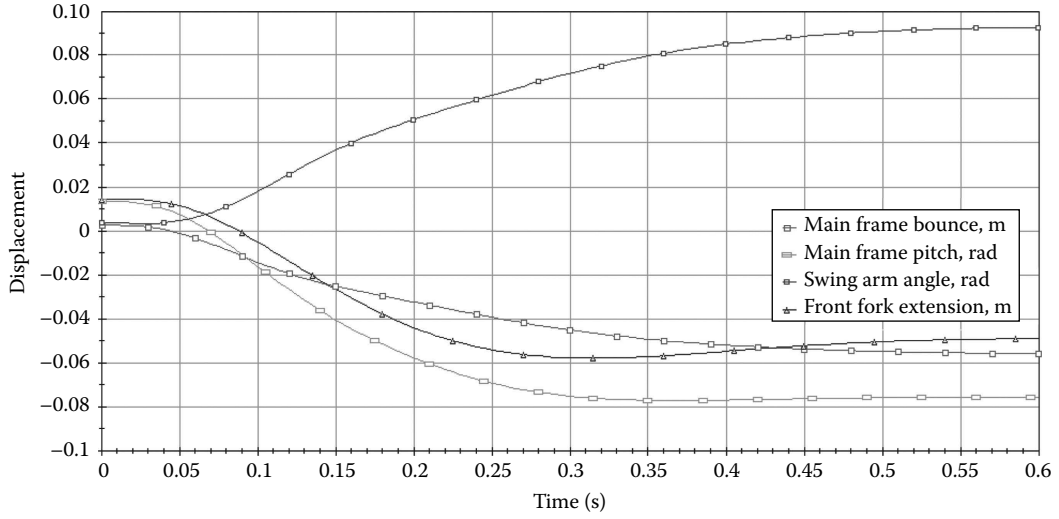

FIGURE 35.47 Motorcycle responses to step input of 10 m/s/s deceleration demand from 75 m/s straight-running trim state by front braking only.

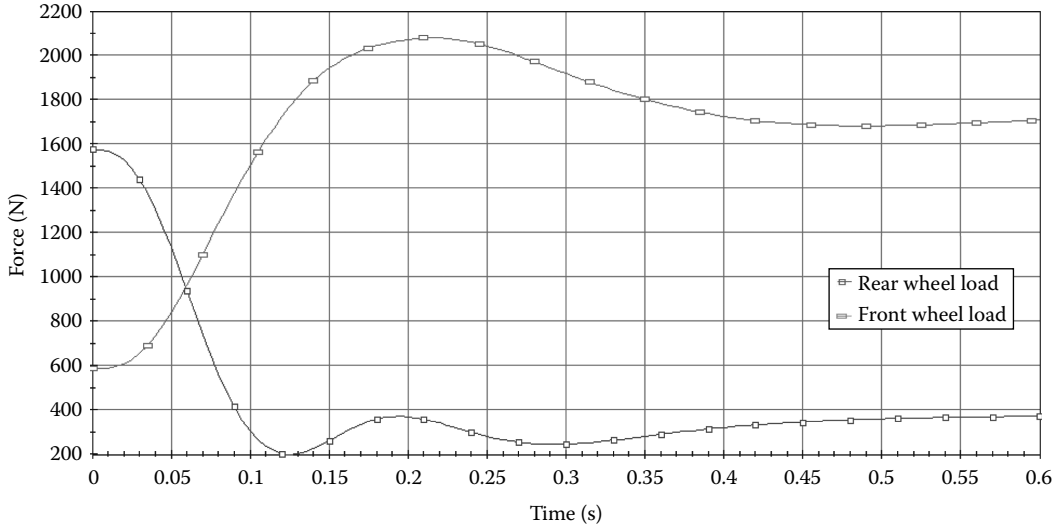

FIGURE 35.48 Rear and front wheel loads for the simulation run of Figure 35.47, showing the transfer of load from rear to front corresponding to the deceleration of 10 m/s/s. The front tire shear force is greater than the wheel load in this run. (See Sharp, R.S. et al., *Advances in Computational Multibody Systems*, J. Ambrósio ed., Springer-Verlag, Dordrecht, the Netherlands, pp. 45–68, 2005 for suspension kinematic design influences on the load transfer.)

run were a succession of trim states. This is the "frozen-time" method [36]. The second way involves the application of an artificial horizontal gravitational field, so that each mass in the system is acted on by a corresponding force opposing the (imagined) acceleration, with the simulation run to establish trim states employing only a marginal acceleration, typically 0.1 m/s/s. The purpose of the speed change is to cover the range of speeds of interest in a single simulation run, with negligible acceleration influences. Fortunately, the differences between the two methods do not have to be studied too deeply, since the root loci resulting are indistinguishable. Figure 35.49 contains frozen-time results for accelerations of 2.5 and 5 m/s/s, while Figure 35.50 shows similar results for decelerations of 5 and 10 m/s/s. Bearing in mind the different speed ranges covered,

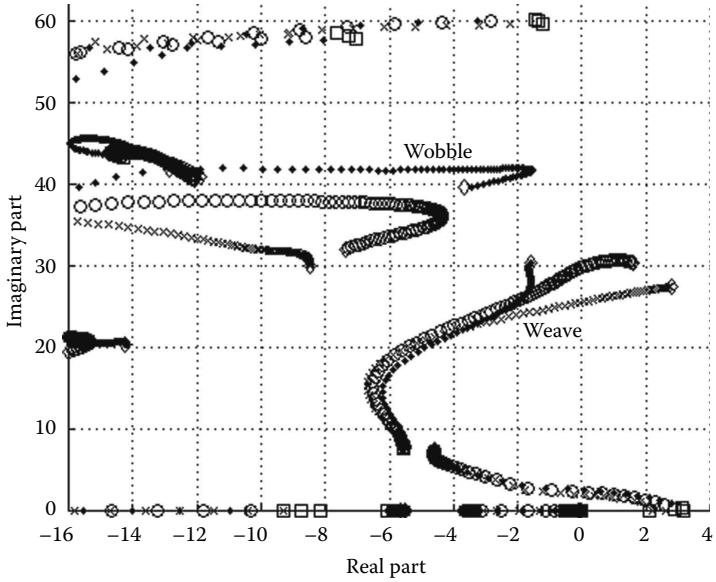

FIGURE 35.49 Root loci for straight running at constant speed from 0.5 to 75 m/s (dots), with acceleration of 2.5 m/s/s from 0.4 to 62 m/s (circles) and with acceleration of 5 m/s/s from 0.4 to 50 m/s (crosses). The speed ranges are limited by the engine power output of 88 kW. A square represents the low-speed end of each locus, while a diamond represents the high-speed end.

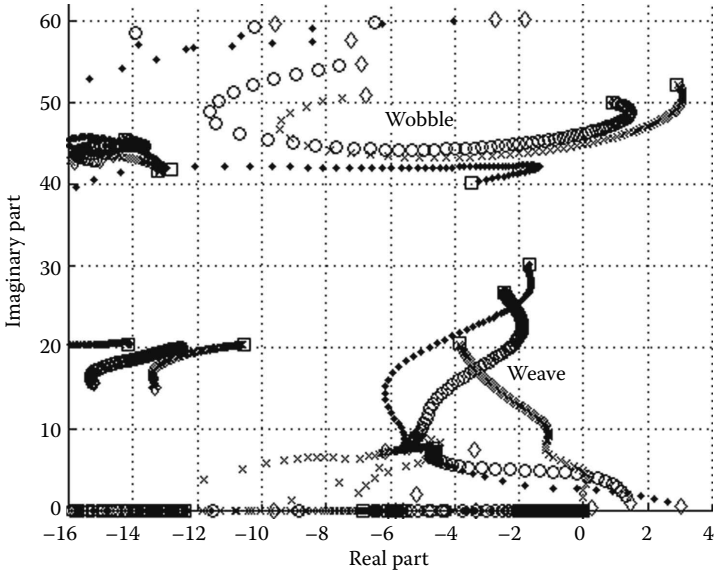

FIGURE 35.50 Root loci for standard machine in straight running at (almost) constant speed from 75 to 0.3 m/s (dots), with deceleration of 5 m/s/s (circles) and with deceleration of 10 m/s/s (crosses). A square represents the high-speed end of each locus, while a diamond represents the low-speed end.

the acceleration can be seen to destabilize the high-speed weave and to stabilize the wobble mode and conversely. The influences of acceleration and deceleration on the stability of motorcycles in cornering have yet to be studied in any depth.

If the machine is in a trim state at 20 m/s speed and 20° roll angle, a sustained steer torque of −4.9 N m is necessary to maintain the trim. The trim state is stable, so that removing the steer torque input can be expected to result in the machine coming upright and straightening course.

To show the influence of accelerating or decelerating on such a turn exit, the simulation model is set up to accelerate at 1 m/s/s by driving the rear wheel and to maintain speed or to decelerate at 1 m/s/s by braking the front wheel (Figures 35.51 and 35.52).

Accelerating at the same time as removing the trim steering torque causes the steering system to return to the zero position more quickly. The influence on the machine's roll angle is to slow down the return to straight running. It is a common experience that a motorcycle feels good when accelerating out of a turn, and these results suggest that the slowing down of the rolling-to-upright motion is the basis for the attractive feel. Skillful riders will apparently coordinate throttle and brake to obtain a smooth transition from a turn to a straight path.

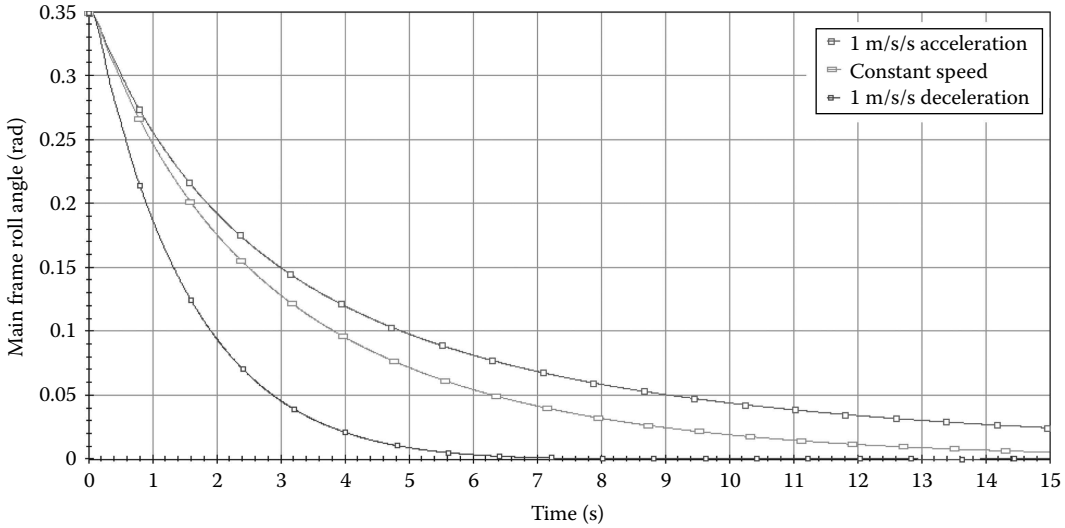

FIGURE 35.51 Motorcycle roll angle histories with 1 m/s/s acceleration, constant speed, and 1 m/s/s deceleration from initial 20° roll angle and 20 m/s speed, with trim steer torque removed.

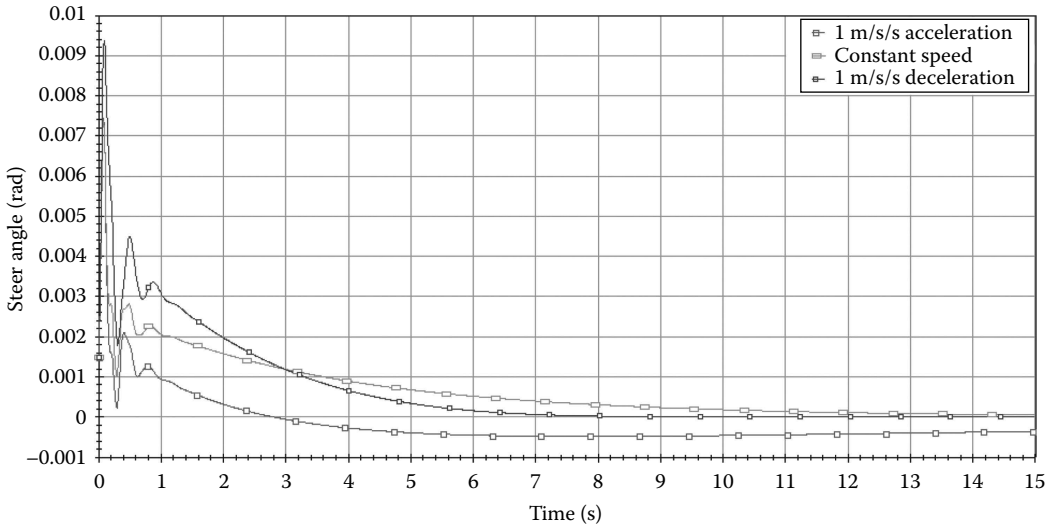

FIGURE 35.52 Motorcycle steer angle histories with 1 m/s/s acceleration, constant speed, and 1 m/s/s deceleration from initial 20° roll angle and 20 m/s speed, with trim steer torque removed.

35.5.10 Power Accounting

The power balance check calculations described in Section 35.4.13 allow the determination of all the sources of power supply and consumption in the system [47,50]. Aerodynamic losses are relatively simple, but the losses due to various aspects of the tire force and moment systems are not so obvious. Results from the standard motorcycle for a sustained 45° roll angle turn with a slow acceleration from 10 to 70 m/s, achieved in about 200 s, are shown in Figures 35.53 and 35.54. Power supplied to the drive sprocket by the engine is lessened a little by the rear tire losses before contributing to the vehicle motion. Aerodynamic losses account for a high proportion of the total power consumption. At 70 m/s, 92% of the engine power goes to propelling the motorcycle and 79% of the total is dissipated aerodynamically. The front tire rolls freely and there are hardly any losses associated with the longitudinal and lateral forces. However, the

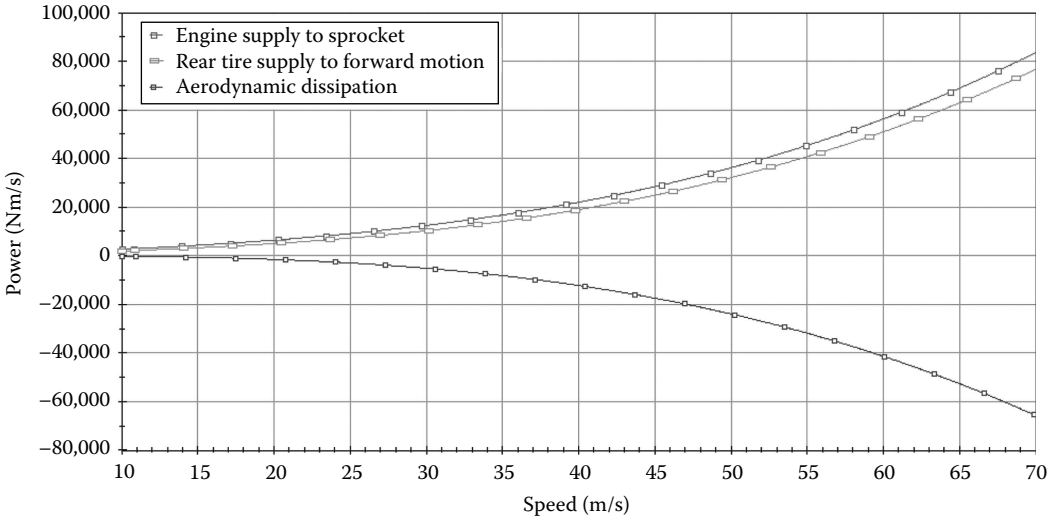

FIGURE 35.53 Power supply from engine and from rear tire longitudinal force and power dissipation by aerodynamic influences in sustained turning at 45° roll angle with 0.3 m/s/s acceleration, as functions of speed.

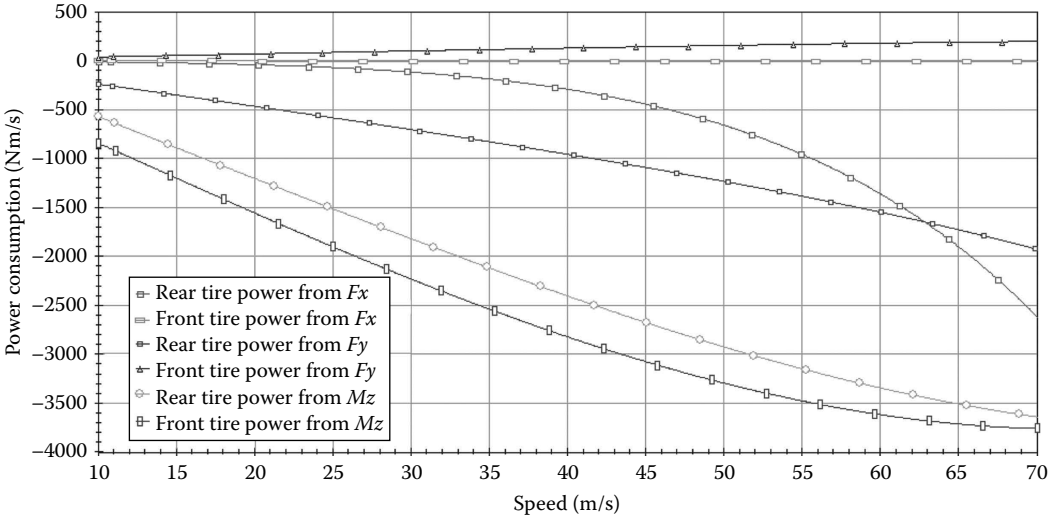

FIGURE 35.54 Tire power consumption components in sustained turning at 45° roll angle with 0.3 m/s/s acceleration, as functions of speed.

power consumption due to the front tire aligning moment builds up to about 3.8 kW at 70 m/s. The rear tire power consumption shows a typical strong dependency on longitudinal force, since the power due to *Fx* increases with force, slip, and speed, and the slip increases as the force does.

35.6 SENSITIVITIES TO CONFIGURATION PERTURBATIONS

35.6.1 Experimental Configuration Changes

Bayer [15] carried out systematic experiments to determine weave-mode damping factors for 13 different motorcycles through their speed ranges. His results are shown in Figure 35.55, in which the variations observed are indicated by the hatching lines. Three machines had only modest speed capability, which machines are designated "low-speed machines" in the figure.

Bayer also prepared a special high-performance motorcycle for testing, with the possibility to change the wheelbase by lengthening the swing arm and to vary the steering head angle and the trail. A potential problem in such testing is that unknown variations in stiffnesses will occur when the geometry is modified and these may be sufficient to spoil the interpretation of the results, when these influences are considered negligible. Results for 40 and 46 m/s show that increasing the wheelbase and using a larger steering head angle (more rake) are both beneficial. At the higher speed, increasing the trail also raised the damping factor but, at the lower speed, this change made no difference. At both test speeds, raising the steering system inertia was quite strongly destabilizing. Bayer produced a bar chart showing the main influences on the weave damping, which chart is reconstructed as Figure 35.56 (see [22] also). The key to the modifications made to the datum machine (at 36 m/s) is shown in Table 35.1. Bayer also found the wobble-mode frequency to lie between 9 and 9.5 Hz and the weave-mode frequency to rise from 2 to 4 Hz as the speed increased from 26 to 54 m/s.

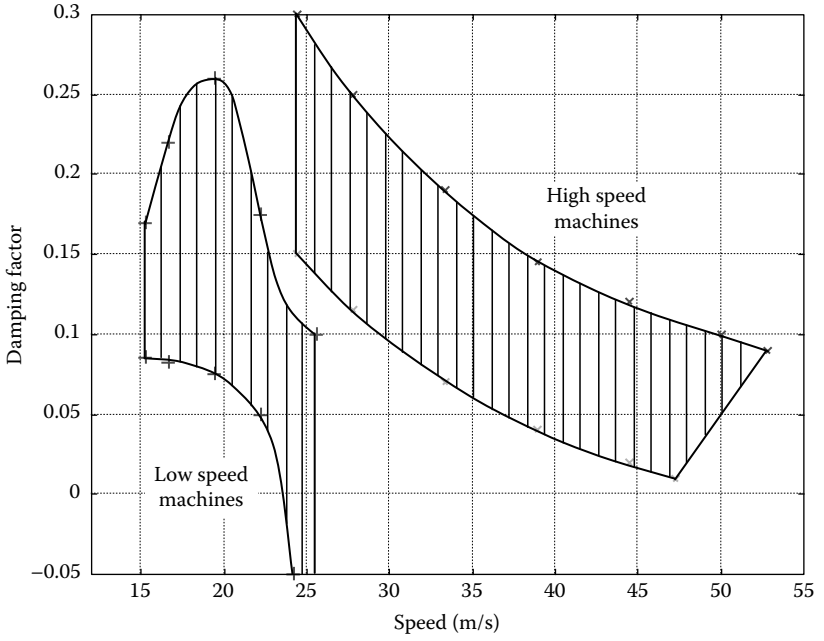

FIGURE 35.55 Weave-mode damping factors determined by experiment for 13 different motorcycles by Bayer (From Bayer, B., *Automobil_Industrie*, 2, 193, 1988). The shading indicates the spread of results obtained.

35.6.2 Theoretical Configuration Changes

Some parameter change influences on the damping factors of the weave and wobble modes for the motorcycle and rider at 60 m/s are shown in Figures 35.57 and 35.58, respectively. In Figure 35.59, corresponding variations in the capsize mode eigenvalue are given. The nominal motorcycle and rider system is the first case treated, after which one parameter is raised in turn by 10% of its nominal value. The changed parameter is depicted in short form on each chart and listed more fully in Table 35.2.

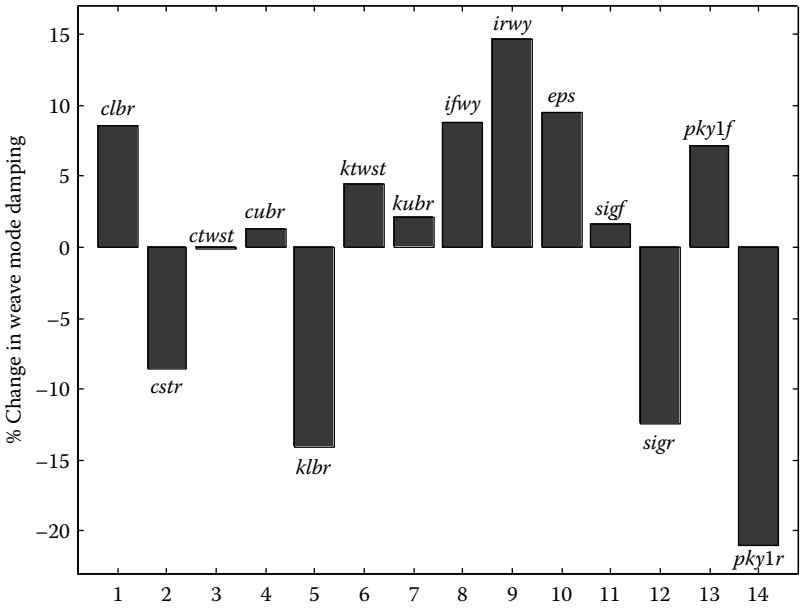

FIGURE 35.57 Bar chart showing how the weave-mode damping factor for 60 m/s speed in straight running is affected by 10% increases in individual parameter values. Variants are defined more fully in Table 35.2. The weave-mode damping factor at 60 m/s is 0.0563.

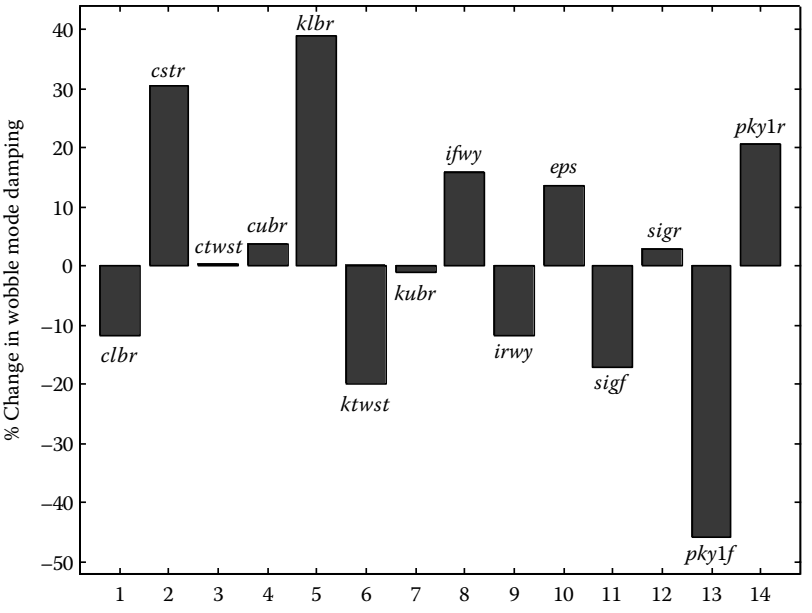

FIGURE 35.58 Bar chart showing how the wobble-mode damping factor for 60 m/s speed in straight running is affected by 10% increases in individual parameter values. Variants are defined more fully in Table 35.2. The wobble-mode damping factor at 60 m/s is 0.0384.

The weave-mode damping is quite sensitive to the rider lower body stiffness and damping, in opposing senses—more damping and less stiffness are helpful. Rider to rider variations in system behavior can be expected based on this result. The steering damper is again shown as deleterious to the weave mode. Increased spin inertia in each road wheel helps, and it follows that there is some advantage, in this context, from the convention that the engine and transmission rotors spin in sympathy

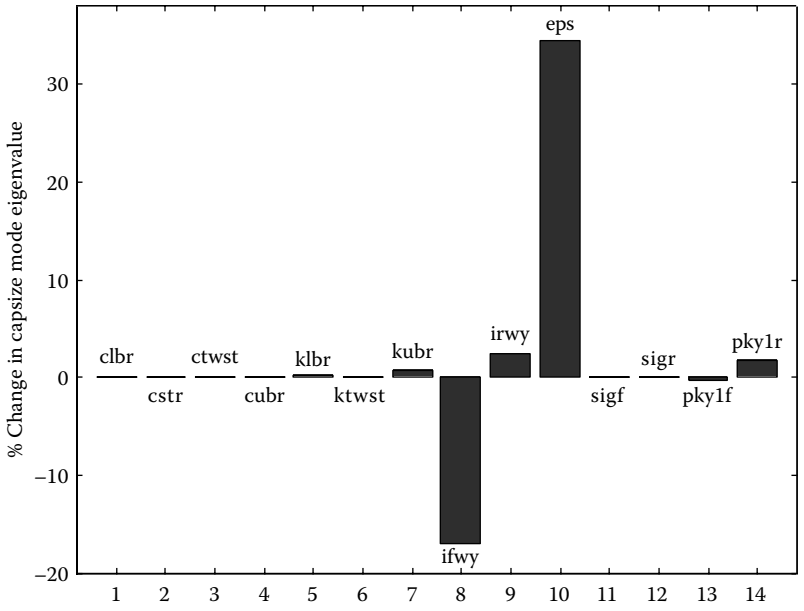

FIGURE 35.59 Bar chart showing how the capsize mode eigenvalue for 60 m/s speed in straight running is affected by 10% increases in individual parameter values. Variants are defined more fully in Table 35.2. The nominal machine has eigenvalue −0.041 at 60 m/s.

with the rear wheel rotation. An increased steering head angle is helpful. The rear tire is much more influential than the front tire, a short relaxation length and, surprisingly, a low cornering stiffness at the rear being good. The front tire cornering stiffness should be high. These results offer some insight into the weave-mode damping changes that often occur when the tires on a motorcycle are exchanged.

The wobble-mode damping is improved by increases in steer damping, rider lower body stiffness, front wheel spin inertia, steering head angle, and rear tire cornering stiffness. The damping factor is reduced by increases in rider lower body damping coefficient, frame torsional stiffness,

rear wheel spin inertia, front tire relaxation length, and front tire cornering stiffness. The last is the most influential parameter, and again, the significance of the rider lower body parameters is notable. These rider parameters act oppositely on the two oscillatory modes, as do the steering damper and the various tire parameters. An increase in the steering head angle benefits both oscillations, but it has a negative influence on the capsize mode. Note that the steering head angle is defined such that the location of key points is not affected when it is altered, which implies that the trail increases as the head angle does. The other parameter affecting the capsize significantly is the front wheel spin inertia, which should be large for stability. However, at high speeds, the steering torque needed in a transient maneuver is dominated by the gyroscopic influence of the front wheel [58], so that there would be a price to be paid in heavy transient steering at high speeds from having a high-spin-inertia front wheel. Other such sensitivity results can be found in [22].

The only direct comparison possible with Bayer's results is in respect of the steering damper addition and even this cannot be quantified, since the coefficient of Bayer's damper is not known. However, it is the case that Bayer's steering damper did reduce the weave-mode damping factor, as the theoretical results regularly show, but it only did so by a little.

35.7 OPTIMAL LINEAR PREVIEW RIDER CONTROL AND HANDLING QUALITIES

35.7.1 Motorcycle Rider Model Background

The purposes in modeling the motorcycle rider are to enable path-based simulations and to understand rider control and the matching of rider to machine better. The problem of reproducing in the virtual world the skill of a racing rider, capable of exploiting the capabilities of a high-performance motorcycle fully, is challenging. Such a virtual rider would enable the discovery of the maneuvering limits of alternative designs of systems and act as an aid to optimal design of products. The applicability to racing and product improvement generally is clear. The usefulness of a rider model depends on its computational complexity and speed of calculation and its robustness against variations in running conditions and machine design. The most practical rider model is likely to have to compromise between performance, speed, and robustness.

In the background, we know about the following features of the motorcycle riding problem: (a) The motorcycle is divergently unstable at very low speeds. The very-low-speed instability becomes oscillatory before it stabilizes, which will typically happen at about 6 m/s. After that, the system has its capsize mode near to the stability boundary. To a human rider, in this higher speed range, it does not matter much whether or not the machine is self-stabilizing, since it can be stabilized by the person without much effort in any case. (b) The motorcycle has a nonminimum phase roll response. In response to a step input of steering torque to the right, it will reach a left-hand-turn steady state, after a transient phase. (c) A motorcycle rider needs a particularly large amount of road preview [69]. If a driver of any road vehicle has too restricted a view of the roadway forward, driving is not feasible, even though the lateral position of the vehicle relative to the roadway may be quite clear. Restricted preview of the road, by fog or poor headlights, for example, makes accurate path following at reasonable speeds difficult and energy consuming. Path following by single-point preview, that is, with knowledge of the lateral location of the path at only one point ahead of the vehicle, is critically dependent on the preview distance. If the preview distance is short, tracking will be tight but oscillatory, while if it is long, tracking will be loose or sluggish, with much corner cutting. The conflict between short and long previews is avoidable by using multipoint preview, with the rider knowing effectively the whole of the relevant path at any point of a journey. How much of the path ahead is relevant depends on the vehicle dynamics. The faster are the plant dynamics, the lower will be the required preview time. (d) Steering control acts largely to yaw the relatively large longitudinal velocity component and to thereby influence the vehicle lateral position significantly only some way ahead of the current location. Due to this actuation mode, the future path requirements are a

much more useful information to the rider than are the current ones. (e) A motorcycle rider has two steering control inputs, steering torque (or angle) and rider lean torque (or angle), although there is much evidence to suggest that rider leaning is a very weak control in comparison with steering torque [8]. (f) A motorcycle rider, in common with other drivers, can choose the level of concentration to be applied to and accuracy associated with the task. Tight control is characterized by high effort and accuracy and loose control with the converse. Only in racing is tight control demanded almost the whole time. (g) The virtual motorcycle can be stabilized over a very full range of operating conditions by PID feedback of roll angle error to steer torque (see Section 35.4.10).

35.7.2 Existing Motorcycle Rider Models

The earliest effective work on modeling the motorcycle rider was by Weir, who viewed the problem as one of regulating against disturbances that could not be anticipated and following a path that could only be known at the current longitudinal location of the motorcycle [70,71]. The rider was presumed to act on some motion information and to feed it back to steer torque control to achieve the required regulation. Prior research on manual control in regulatory tasks was applied to the problem. The main results used were that the operator adopts a transfer characteristic reflecting physical attributes like information processing, decision delays, and neuromuscular delays and adjusts parameters so that the man–machine open-loop frequency response function for each closed loop is of the form

$$G_r(\omega)G_m(\omega) = \frac{\omega_c e^{-j\omega\tau}}{j\omega} \tag{35.42}$$

in the region of the gain "crossover" frequency. Here, $G_r(\omega)$ is the rider response, $G_m(\omega)$ is the machine response, ω_c is the crossover frequency, and τ is the time delay. For each loop, the rider supposedly increases his or her gain sufficiently to give the closed-loop system the desired performance, thus setting the crossover frequency. Note that when $\omega = \omega_c$, the gain is unity. Eaton's experiments with a 175 cc motorcycle, rider braced to prevent leaning, moderate speeds only, and impulsive excitation [2] allowed the identification of parameter values for a roll angle to steer torque feedback that accorded closely with the crossover theory, lending support to it. Weir also explored additional loop closures to provide heading and lateral position controls, using rider lean angle as actuation. Using this background, Lenkeit constructed a servo-rider [72], choosing roll angle over steering angle control for low speeds and roll angle to steering torque control for higher ones.

Most other motorcycle rider models are aimed more directly at path following and recognize the need for preview of the path. In [73,74], control torques are applied on rider lower body, rider upper body, and steering system, each a linear combination of roll angle and a path preview parameter. This parameter was a weighted integral over all the path ahead, containing a preview distance to be chosen conveniently. This model also was shown capable of matching experimental results. In the later paper, steering torque proportional to roll velocity was added to the control scheme, to improve low-speed operation. A brief description of a somewhat similar steering torque controller with proportional and derivative terms deriving from roll angle and terms proportional to path error and path slope, relative to the motorcycle heading, at a single preview point ahead can be found in [20].

Steer torque with terms proportional to steer velocity, roll angle error, and roll velocity was used in [75]. Single-point preview was converted into a roll angle demand, and effective gain values were found by surveying operation over speed and roll angle ranges. A fuzzy controller was devised to smoothly connect or schedule the gains, according to the operating conditions. It was found necessary to add a new term with a somewhat obscure physical basis, called a "hold" torque, to get good performance.

Notable among motorcycle rider models are those of Frezza et al. [76]. For the design of the controls, which include steer angle and longitudinal tire forces, the motorcycle is represented as having two rigid frames, joined at a vertical steering head and having pure-rolling tires. Such a machine

has its path over the ground determined by its steer angle and speed histories only. A differential equation relates the roll angle, the speed, and the path curvature. This roll angle, speed, and path curvature relation is used to constrain the solution of a nonlinear optimization problem, in which a weighted quadratic function of path error and roll angle error is minimized over a chosen preview time, subject to upper bounds on magnitudes of steer angle and roll angle. The desired roll angle is the steady-state solution of the roll, speed, and path curvature equation, with the desired values of speed and curvature being used as input to the equation. The roll error term serves to couple the longitudinal and the lateral dynamics in an interesting way. The local path immediately in front of the motorcycle is represented in a discrete form through the parameters of B splines. Therefore, the optimal solution gives these parameters and the roll angle history. The required steer angle control is derived from the optimal solution, and it is applied for a single time step, after which all the computations are repeated. The strategy can be classed as a model predictive control one, with faster computation than would be obtained by calculating with the full motorcycle model throughout. Important limitations on achievable performance associated with tire force saturation are necessarily represented as constraints, some of which appear to be decided arbitrarily. Also, applying the final steer angle and longitudinal force controls to a complex multibody motorcycle model involves faith and hope that they will function well. The authors testify to good tracking results in virtual trials but do not address speed of computation issues. Extending the preview horizon is likely to improve performance but degrade computation speed. Much compromise appears to be involved.

Another commercial rider model is that included in BikeSim [49], which uses a development of the detailed multibody motorcycle model described in [47,48]. The rider model capitalizes on the fact that the motorcycle is quite easy to stabilize over a wide operating range with PID roll angle to steer torque feedback with speed adaptive gains. With this notional control scheme in place, the path-tracking problem becomes similar to that for a car or a truck. For this class of problem, MacAdam's strategy [77] is long developed and tested. According to this strategy, a simplified linear model of the vehicle is contained within it. This linear representation is used at a particular time step to solve the optimization problem, "What is the value of the fixed steer angle that minimizes the path-tracking error over the preview horizon?" In solving this problem, account is taken of the motion state at the instant and the path in front of the vehicle, relative to the vehicle, that is, the local path, over the preview distance. As with Frezza's method, the steer angle is held for a single time step and the computations are repeated. Again, as with Frezza's method, the optimizing calculations have to be done online and they are simplified in the interests of rapidity. Again, Virtual trials are reportedly yielding good results [78].

Although the rider models described have considerable capabilities, it is thought that they are not the ultimate solution to the problem either of computing the best possible control or that of computing the fastest reasonably effective control. It is considered that optimal preview control offers something both better and faster. Only linear theory has so far been developed [79,80], but bearing in mind that the series expansion linearization method can be applied to the motorcycle operating in the neighborhood of any trim state, linear controllers that are adaptive to the operating conditions appear potentially powerful. Let us consider a foundation for linear quadratic optimal preview control theory in Section 35.7.3 as follows. In what follows, we assume constant speed and two control inputs, steering torque and rider upper body roll torque.

35.7.3 Outline of the Application of Optimal Linear Preview Regulator Theory

The view of the roadway and the vehicle motion taken is illustrated in Figure 35.60. The track centerline is presumed known relative to the fixed ground, and the vehicle motion is similarly considered in a fixed or absolute reference system. The relationship between the track and the vehicle is known, since both are known absolutely. The motorcycle is represented by its constant-coefficient linear equations of motion for small perturbations from a trim state, in this case involving straight running at constant speed. The rider exercises control by applying steer torque to the handlebars, reacted on his or her upper body, and upper body roll torque, reacted on his or her lower body.

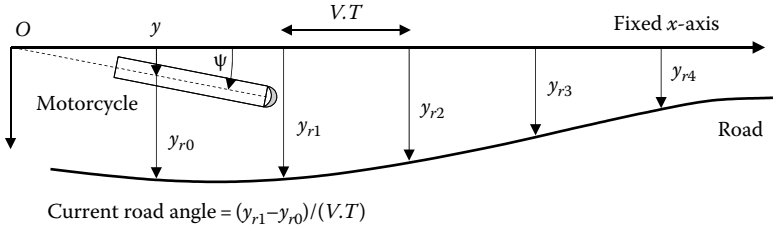

FIGURE 35.60 Representation of a motorcycle traveling along a defined path in absolute terms, with speed V and discrete time step T.

Initially, the road is presumed to follow the line of the x-axis in a general sense, so that there will be only small differences between the attitude angle of the motorcycle and that of the road. The motion is viewed in discrete time, to deal advantageously with the time delays evident in the system.

With the transition of the system through one time step, the motorcycle moves along the road by distance VT. Relatively speaking, the road moves toward the motorcycle by that distance unit. The discrete-time road dynamics are those of a shift register. The combined system of vehicle and road can be described by joining together the motorcycle dynamics and the road dynamics, which two subsystems become coupled through the path-tracking objective function, which expresses the idea that costs will be attached to differences between y, the lateral position of the motorcycle reference point, and y_{r0}, the corresponding lateral position of the track (see Figure 35.60), at each time point in a journey. Other similar measures of tracking error may also be included in the objective function, and a cost must be associated with control power, with weighting parameters to specify relative importance.

The first applications of this form of optimal linear preview control theory were to car steering control [81,82]. More background can be found in those references. An outline of the theory follows.

Suppose our linear motorcycle model of any degree of complexity has the discrete-time form

$$\begin{aligned} x_v(k+1) &= A_v x_v(k) + B_v T(k) \\ y_v(k+1) &= C_v x_v(k) + D_v T(k) \end{aligned} \tag{35.43}$$

Imagine that the lateral profile of the road is defined by discrete sample values, with values from past observations of the road ahead being stored as states of the full vehicle/road system. As the system moves forward in time, a new road sample value is read in and the oldest stored value is discarded, corresponding to the vehicle having passed the point on the road to which this oldest value refers. All the other road sample values are shifted through the time step, nearer to the vehicle. The dynamics of this shift register process are represented mathematically by

$$y_r(k+1) = A_r y_r(k) + B_r y_{ri}(k) \tag{35.44}$$

$$\text{where } A_r \text{ is of the form : } \begin{bmatrix} 0 & 1 & 0 & \cdots & \cdots & 0 \\ 0 & 0 & 1 & \cdots & \cdots & 0 \\ 0 & 0 & 0 & 1 & \cdots & 0 \\ \cdots & \cdots & \cdots & \cdots & \cdots & \cdots \\ 0 & 0 & 0 & 0 & \cdots & 0 \end{bmatrix} \quad \text{and} \quad B_r \text{ is of the form : } \begin{bmatrix} 0 \\ 0 \\ 0 \\ \cdots \\ 1 \end{bmatrix}$$

Combining vehicle and road equations together, we obtain the full dynamic system description:

$$\begin{bmatrix} x_v(k+1) \\ y_r(k+1) \end{bmatrix} = \begin{bmatrix} A_v & 0 \\ 0 & A_r \end{bmatrix} \begin{bmatrix} x_v(k) \\ y_r(k) \end{bmatrix} + \begin{bmatrix} B_v \\ 0 \end{bmatrix} T(k) + \begin{bmatrix} 0 \\ B_r \end{bmatrix} y_{ri}(k) \tag{35.45}$$

The complete problem is now in a standard discrete-time form

$$z(k+1) = Az(k) + Bu(k) + Ey_{ri}(k)$$

$$y(k) = Cz(k) + Du(k)$$

If y_{ri} is a sample from a white-noise random sequence, the time-invariant optimal control minimizing a cost function J, given that the pair (A, B) is stabilizable and the pair (A, C) is detectable [84], is

$$u^*(k) = -Kz(k), \quad \text{where} \quad K = \{R + B^T PB\}^{-1} B^T PA \tag{35.46}$$

where $J = \lim_{n\to\infty} \sum_{k=0}^{n} \{z^T(k)Qz(k) + T^T(k)RT(k)\}$ and P satisfies the matrix-difference Riccati equation

$$P = A^T PA - A^T PB\{R + B^T PB\}^{-1} B^T PA + C^T QC \tag{35.47}$$

in which Q is a diagonal weighting matrix, with terms corresponding to the number of performance aspects contributing to the cost function, and $R = \text{diag}[r_1, r_2]$, corresponding to the two control inputs, steering torque and rider upper body lean torque. Here, only one performance measure is used, $Q = q_1$ being set to represent the importance of tracking errors. r_1 and r_2 reflect the costs associated with steering torque and rider lean torque, respectively. Optimization calculations find compromises between high tracking accuracy and low utilization of steer torque and lean torque, according to the weights in the cost function.

From [82], it is also known that the optimal time-invariant control given by (35.46) is also optimal if the white-noise sequence representing the road lateral profile is low-pass filtered, to make it more realistic, and a "full" preview of the road [81,82] is available. It is implied that the white-noise disturbance assumption is not as restrictive as it might appear to be.

As in [81], the optimal control is found by partitioning the problem into non-preview and preview parts. Firstly, the non-preview, standard linear quadratic regulator (LQR) optimal control is found. Then, the state-transition matrix of the closed-loop system is applied recursively to the preview error samples to find the preview gains. The nature of the resulting optimal control is shown in Figure 35.61. There is a full-state-feedback part and a preview part, which superpose to give the optimal controls.

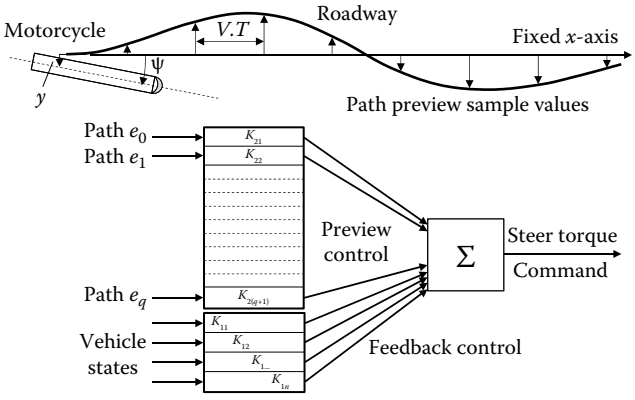

FIGURE 35.61 Illustration of the form of the optimal controls resulting from assuming a white-noise disturbance and an infinite optimization horizon. Standard LQR feedback parts and preview parts combine linearly to give the total controls.

35.7.4 Optimal Control Results

Several parameters are needed to define a particular control optimization problem. The machine speed must be specified, and the balancing between the different parts of the cost function representing use of steer torque, given by r_1; use of rider upper body lean torque, given by r_2; and tracking error, given by q_1, must be set. In addition, the number of preview points to be used needs to be decided. Many different results can be generated. Some representative cases follow. State-feedback gains are shown first in bar chart form, followed by graphs showing preview gains as continuous curves, although they are actually discrete values at the discrete-time interval of 0.02 s apart.

In Figures 35.62 and 35.63, gains are shown for speeds of 10, 40, and 70 m/s with 500 preview points, equal weights on the two controls, and a high cost on tracking errors, leading to tight control. In each case, the linearization relates to small perturbations from straight running and uses the appropriate trim state determined by simulation of the nonlinear system. As should be expected, the only nonzero state-feedback gains are associated with out-of-plane state variables. Symmetry of the straight-running condition implies zero gains for all in-plane states. Feedback gains relating to steer torque are much larger than those relating to body torque, the largest contributors, in both cases, being roll angle and frame twist angle (see Table 35.3 for a listing of the involved variables). The theory as described so far also yields feedback gains associated with lateral position and attitude angle of the machine, but these are not shown, since they become redundant when the control is transformed from global to local (see Section 35.7.5). The feedforward gains show convergence to zero as the preview distance increases, which is a long-established feature of preview control [84].

For tight control, the gains are relatively high. In this case, at 10 m/s speed, a view of the road extending only about 17 m forward is all that is necessary. Corresponding necessary preview distances for 40 and 70 m/s are 115 and 256 m, respectively. In terms of time, the necessary preview for full performance increases significantly with speed. The most useful information in the path ahead is about 8 m in front of the motorcycle at 10 m/s, 40 m ahead at 40 m/s, and at 70 m ahead at 70 m/s, around 1 s ahead in time, in each case.

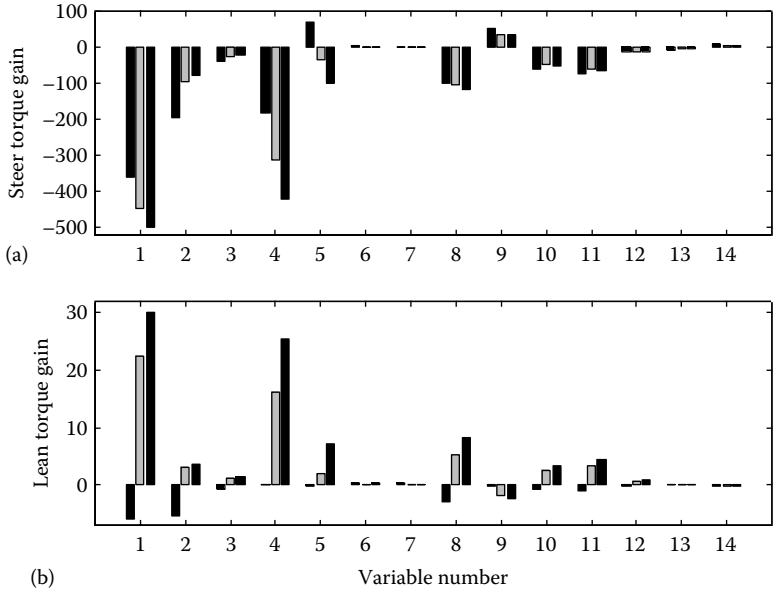

FIGURE 35.62 LQR optimal feedback gains to steering torque (a) and rider body lean torque (b) for $q_1 = 10{,}000$, $r_1 = r_2 = 1$, and speeds of 10, 40, and 70 m/s. In each group of 3 gains, the left-hand one is for 10 m/s, while the right hand one is for 70 m/s. The variables are defined in Table 35.3.

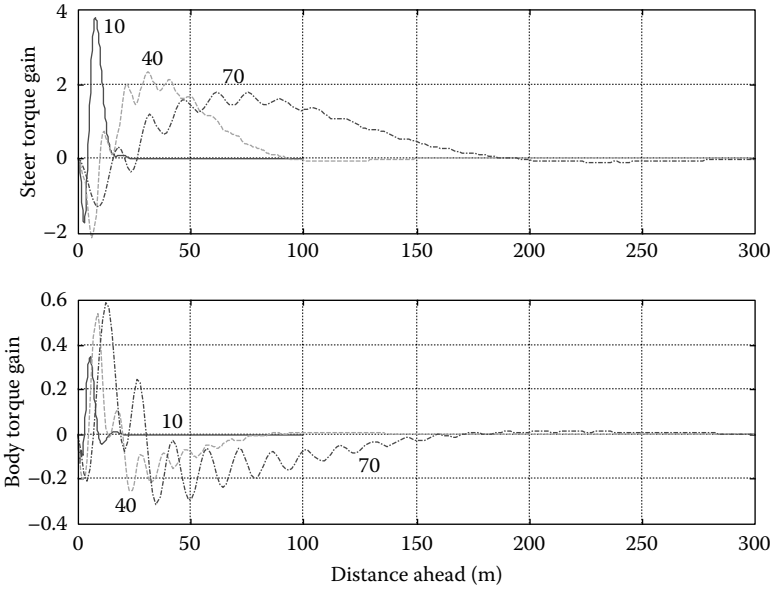

FIGURE 35.63 Preview gain sequences for standard machine system at 10, 40, and 70 m/s in straight running, with $q_1 = 10{,}000$, $r_1 = 1$, $r_2 = 1$.

TABLE 35.3
Variables Associated with LQR Feedback, with Gains Specified in Figures 35.62 and 35.64

Variable #	Variable Description
1	Main frame roll angle
2	Rider hip relative lateral displacement
3	Rider upper body relative roll displacement
4	Frame twist angle
5	Steer angle
6	Rear tire sideslip angle
7	Front tire sideslip angle
8	Main frame reference point lateral velocity
9	Main frame yaw velocity
10	Main frame roll velocity
11	Rider hip lateral velocity relative to the main frame
12	Rider upper body roll velocity relative to the main frame
13	Frame twist velocity
14	Steer velocity

Figures 35.64 and 35.65 show the contrasting results when the control is loose as represented by $q_1 = 100$. The feedback gains are less than half those for the previous tight control, although they follow a similar pattern, with the major gains belonging to roll angle and frame twist angle. The preview gains are reduced very approximately in proportion to the change in the q_1 weighting, and at each speed, the most useful path information is further ahead of the vehicle, at 15, 80, and 170 m for 10, 40, and 70 m/s, respectively, than with the tighter control of Figures 35.62 and 35.63. The inverse dynamics of the motorcycle and rider are apparent in the preview gain sequences, especially for 70 m/s speed. At this high speed, the weave mode of the machine is lightly damped (see Figures 35.18 and 35.19),

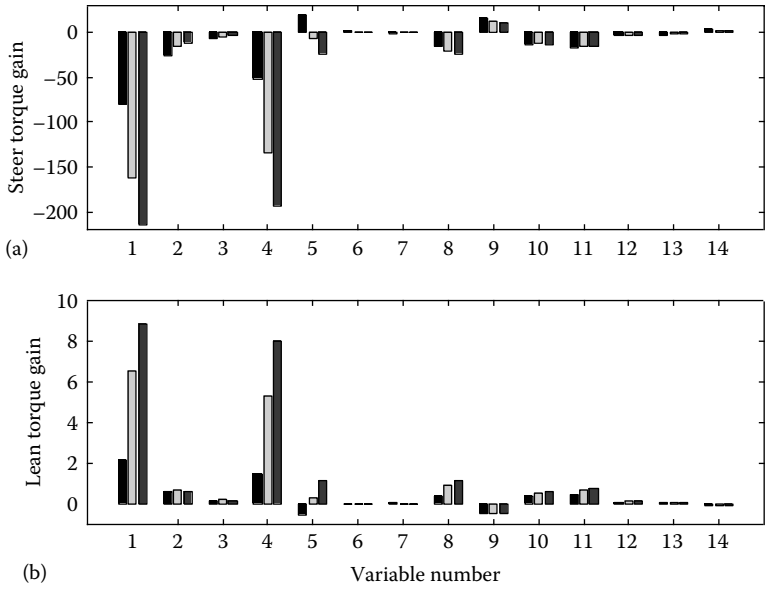

FIGURE 35.64 LQR optimal feedback gains to steering torque (a) and rider body lean torque (b) for q_1 = 100, $r_1 = r_2 = 1$, and speeds of 10, 40, and 70 m/s. In each group of 3 gains, the left-hand one is for 10 m/s, while the right hand one is for 70 m/s. The variables are defined in Table 35.3.

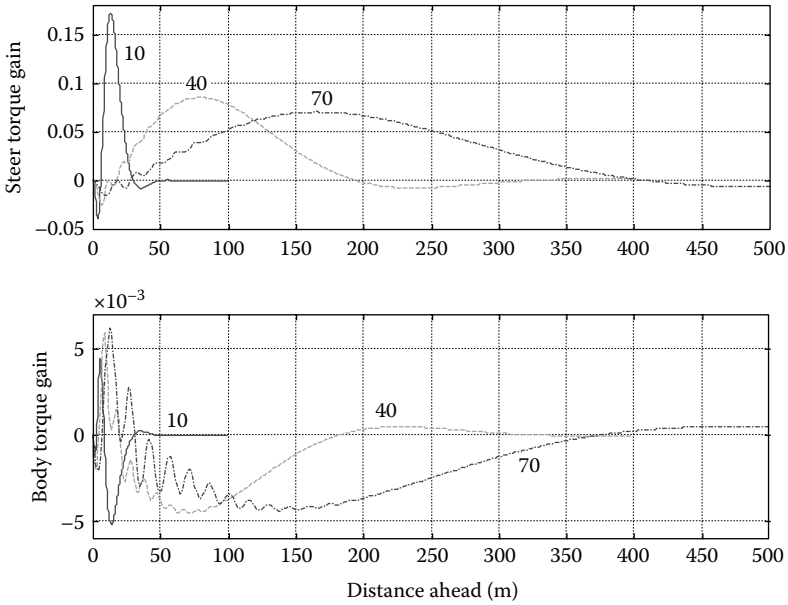

FIGURE 35.65 Preview gain sequences for standard machine system at 10, 40, and 70 m/s in straight running, with q_1 = 100, $r_1 = 1$, $r_2 = 1$.

having a natural frequency of around 4.5 Hz. The oscillations in the preview gain sequence, converted to a time basis, are at this same frequency. This frequency is likely to be well beyond the rider's control bandwidth and it seems unlikely that the mode is usable for control purposes. The main requirement appears to be that the mode is well damped.

With the rewards for additional preview diminishing as the preview increases, it is possible to estimate the preview necessary for more or less full tracking accuracy, as a function of speed,

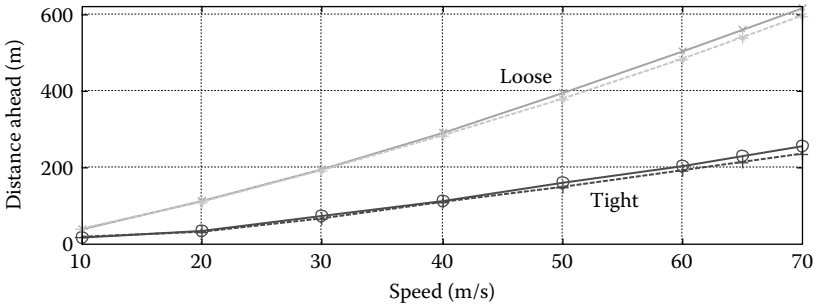

FIGURE 35.66 Preview distances required for "full" performance as functions of speed for standard machine, with tight (q_1 = 10,000) and loose (q_1 = 100) controls and equal weights on the two controls. Each solid line refers to steer torque, while each dashed line refers to body lean torque.

design, and weightings. Indeed, it seems likely that a distinguishing feature of a successful sports motorcycle, designed for responsiveness, is that its need for rider preview of the road is minimized by its design and idea developed for cars in [82]. A simple criterion of the necessary preview is that it is the distance out from the motorcycle at which 98% of the sum of the absolute values of the preview gains is encompassed within that distance. Calculating according to this criterion, for each of the controls, gives the results of Figure 35.66. Substantially, more path preview is necessary for full tracking performance when the control is loose, which result accords with common experience, and that relaxed riding is only possible if one can see the roadway a long way ahead of one's vehicle.

Other preview control law results can be found in [79,80], including some that come from the steering torque as the only control and some that place a lower weighting on the use of rider body torque than on the use of steer torque. The gains relating to steering torque are little influenced by the sort of changes referred to, while, as might be expected, lower weight on body torque leads to corresponding larger gains being found.

35.7.5 Path Tracking Utilizing the Optimal Controls

The simplest approach to path tracking is to use the optimal controls developed in the fixed reference frame as described earlier to close the loop around the motorcycle/road system and to update the state through time by repeatedly multiplying it by the closed-loop state-transition matrix. At each update, a new road sample, from the furthest point along the preview length, enters the problem as input, and the oldest preview data point leaves the problem, since it comes to be aft of the vehicle. This simple approach implies that the restriction to small angles in the linear theory of the control generation carries over into the tracking simulation. Paths that diverge substantially from the starting direction will be followed with imprecision and probably not followed at all if the path direction changes by 90° or more.

A better approach is to transform the problem to a vehicle basis. In such a basis, at the completion of each time step, the reference axes are relocated to align with the motorcycle, and the roadway is described relative to the motorcycle rather than relative to the ground [79–82]. In the repositioning of the reference axes, which are used only to describe the problem and not in any way to govern it, lateral position and attitude angle errors automatically become zero and the previewed road samples are changed from their ground-view to rider-view values. For the transformation to leave the problem unaltered, as it must to make sense physically, those two sets of changes must exactly compensate each other. It is shown in [81] that this is indeed the case. The small-angle theory now requires only that the path direction does not change radically over the preview length. Bearing in mind the relationships between vehicle speed, feasible path curvature, and required preview distance, it can be appreciated that this lesser need is invariably satisfied in practical circumstances.

Each path to be followed is designed to start with a straight section, and the preview states of the combined roadway/motorcycle system are loaded initially with zeros, to correspond with the vehicle having traveled along a straight path, before the simulation commences, for the duration of the preview. The path profile is then "seen" in the distance first, as with a rider with a full view of the road ahead. The simulation proceeds by stepping through time, using the step length 0.02 s employed for the discrete-time optimal control calculations, until a specified number of steps have been completed. At each step, the absolute position and orientation of the motorcycle are updated, and the road data in front of the machine are read in, transformed to the local view of the rider, and used to replace the old values in that part of the system state vector that corresponds to the road profile. Spline interpolation is used to obtain the local lateral road profile at the proper preview points. At the same time, the motorcycle states representing its local lateral position and attitude angle are set to zero. State-feedback and preview gains used are exactly as shown in Figures 35.62 through 35.65.

The maneuvers studied in [80,81] were a lane change and an S-shaped path. Here, we concentrate on a randomly generated path and a sharp 15° direction change maneuver, using 500 preview points in each case. The random path derives from a zero-mean white-noise sequence that is low-pass filtered by a fifth-order Butterworth filter with cutoff frequency 0.25 Hz to make it realistic but interesting [81]. Random path results are shown first, in Figures 35.67 through 35.69 for tight control ($q_1 = 10{,}000$, $r_1 = r_2 = 1$) and 20 m/s and in Figures 35.70 through 35.72 for loose control ($q_1 = 10$, $r_1 = r_2 = 1$) at the same speed. With tight control, the tracking is almost perfect, with the control torques active a little before the roadway starts to curve at about 250 m from the start. Steer and body lean torques are substantially in anti-phase, the latter being much smaller than the former. The maximum roll angle is just over 30° and the rider upper body lean angle is about one-tenth of the roll angle. The maximum steering torque is a comfortable 15 N m. Control torques and responses are a little smaller for loose control and there is some corner cutting in evidence.

Results for the direction change at 20 m/s are shown in Figures 35.73 through 35.75, generated for tight controls, and in Figures 35.76 through 35.78 for loose controls. Precise tracking of the direction change would require high-frequency control inputs. Such a maneuver consequently distinguishes well between tight and loose control. With reduced cost associated with tracking errors,

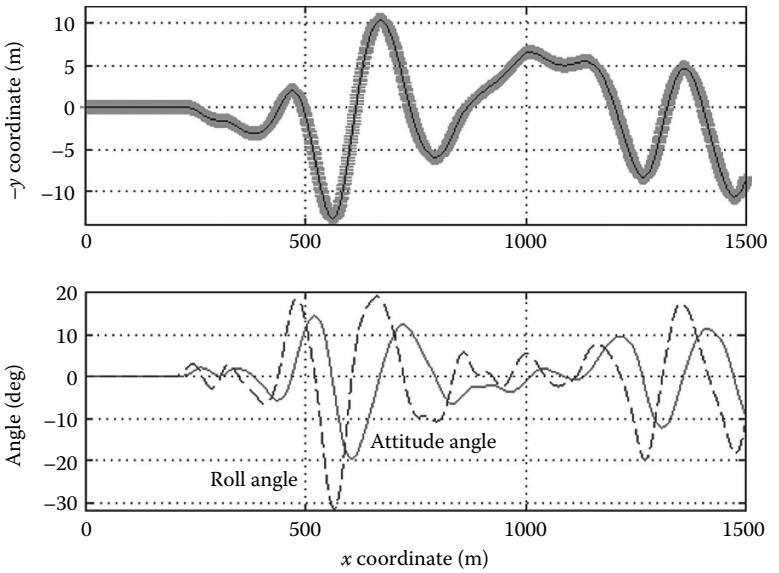

FIGURE 35.67 Random path-tracking results for the standard motorcycle/rider system with tight control ($q_1 = 10{,}000$, $r_1 = r_2 = 1$) at 20 m/s. In the upper part, the roadway is depicted by crosses, while the motorcycle path is shown by the line. The path is defined by sample values at 1 m intervals, obtained by low-pass filtering a zero-mean random sequence with a fifth-order Butterworth filter with cutoff frequency 0.25 Hz.

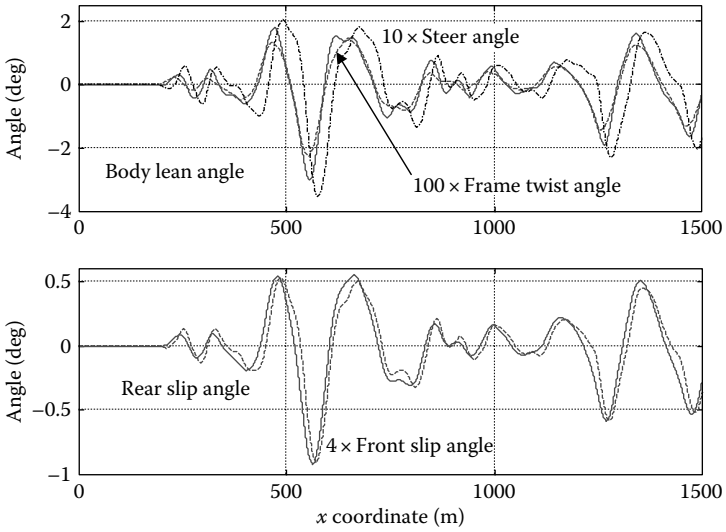

FIGURE 35.68 Random path-tracking results for the standard motorcycle/rider system with tight control at 20 m/s, from the same run as shown in Figure 35.67. The rider's upper body relative roll angle is shown by a solid line, the scaled frame twist angle is dashed, and the scaled steer angle is dash dotted.

more corner cutting occurs and the control inputs are applied further ahead of the road features. The control inputs themselves are much reduced in magnitude but are spread over a longer time. Peak values of the motion variables are much reduced. For the most accurate tracking, the pre-direction-change countersteering is left late and the front tire is made to develop substantial side force by sideslip. Rider lean control still provides only a small influence on the motions, but this influence is greater than for more relaxed riding. The theory is naturally representing the characteristics of the expert rider and the novice as revealed experimentally by [30]. Also, the theory is illustrating how the rider is able to use his or her knowledge of the motorcycle dynamics to determine an effective preview control plan. As the machine dynamics change due to speed or road condition changes, the rider clearly has a need to alter the plan in sympathy, for the control to remain effective.

35.8 CONCLUSIONS

This contribution has been based on the view that motorcycle handling dynamics is a subset of a man–machine problem, in which the rider is an important element. The motorcycle is a great deal simpler than the rider and we can know about it with much greater certainty. In principle, the motorcycle can be modeled and its behavior can be predicted with some accuracy, provided that the parametric data are sufficient.

The whole topic has been divided into chapters covering rider properties, dynamic theory, modeling needs, behavior, sensitivities of behavioral changes to variations in parameters, and rider control. The behavior considered has included steering-fixed and steering-free operation, steady-turning equilibrium, linear stability and modal properties for straight running and cornering, frequency responses to steer torque, body lean torque and road vertical profile forcing, nonlinear responses to road forcing, and the influences of acceleration and deceleration. Weave and wobble modes are important in the discussion. The value of steering dampers in respect to the wobble and their bad influence on the weave are shown, and a more general steering compensator is mentioned. Force, moment, and power balancing are put forward as valuable processes in the proving of complex multibody models. Quite new work on rider control with full road preview is included. It has been shown how one general and advanced system model can be used as a vehicle for generating a wide range of behaviors.

Research on passive and active steering compensators is ongoing and studies of rider control and handling qualities are far from complete. These appear to be the most interesting and potentially fruitful areas for future investigations. A definitive wisdom on how riders of different stature contribute to the motorcycle structural dynamics has not yet emerged.

ACKNOWLEDGMENTS

Support for the author's work by the Engineering and Physical Sciences Research Council is gratefully acknowledged. Also, the writer has gained much from his discussions on the various topics covered with his colleagues David Limebeer and Simos Evangelou.

36.1 COMFORT AND DISCOMFORT

Vehicle comfort is a known customer want and receives increasing attention as a strong sales argument. Over the past decades, several factors have changed: The basic function of cars is no longer a discriminator between the brands. Customers expect a higher level of driving quality even for smaller cars, sports, or off-road vehicles. The average customer spends more time in the car. Higher traffic density and speed increase the driver's workload. The average age of the driving population is increasing, at least in Europe [28] and the United States. Additionally,

many vehicles are used as working place. All of the aforementioned facts are good arguments for cars with increased level of comfort.

36.1.1 Definition and Theories

What is comfort? Here are a few definitions found in lexica and the literature:

Merriam–Webster [17]: "Pronunciation: \'kəm(p)-fərt\ Function: transitive verb Etymology: Middle English, from Old French conforter, from Late Latin confortare to strengthen greatly, from Latin com- + fortis strong"

Wikipedia [37] (translated): "Comfort can be described as the absence of discomfort. Discomfort means noticeable unpleasant sensations. Basic assumption is an ongoing comparison between actual sensation and previous experiences. The current situation will not be considered as unpleasant as long as there is no discrepancy between sensation and expectation for the specific context. Deviations will be noticed, which means that comfort depends on the expectations of the observer. …" Zhang et al. [40] proposed a 2D scale. Positive aspects of "liking" are associated with comfort. Negative aspects of "suffer" are associated with discomfort. Comfort and discomfort can be present at the same time. Bubb [4] also promotes the 2D scale and in addition suggests a general sequence for the discomfort aspects.

"Absence of discomfort" does not really provide a guideline to create a comfortable vehicle design. The 2D scale can explain why customers are willing to accept a certain level of discomfort and still like a vehicle, but it is very important to separate comfort from other positive attributes such as quality impressions [11] and performance feel. One attempt using a positive definition could be: "Comfort is the result of correct ergonomic design and additional convenience features." The correct ergonomic design will avoid discomfort, and the convenience features are able to create positive emotions that can be associated with comfort. Even with this short definition, comfort will remain multidimensional and very subjective.

The definition in Wikipedia includes a threshold theory that has been widely observed. If the unpleasant sensation exceeds a certain limit, it will become a discomfort. Different aspects of comfort are present at the same time, and the occupants of the vehicle will combine their individual sensations to a single score that is mainly determined by the worst comfort discipline. This is the "bad tooth theorem." If one tooth hurts, the typical patient will not be in the mood to consider 27 good teeth and come up with an average pain score. Recent health surveys in Europe indicate an increasing prevalence of back pain [3]. It is very likely that this kind of health problems will shift the priorities of the consumer toward comfort.

Coming back to the vehicle, this results in several consequences:

1. All comfort aspects must be considered simultaneously.
2. A comfortable vehicle has a good performance in every comfort discipline.
3. Designing for comfort requires deep knowledge of the human physiology.

36.1.2 Aspects of Comfort

The comfort aspects work toward three main functions: support, protect, and delight.

Based on the classical definition of ergonomics, vehicle design should support the user and make the driving as easy as possible. This includes a proper seating position with postural support under all conditions, a sufficient range of motion, a well-balanced pressure distribution, logically clustered and readable instruments, easy to reach steering and pedals, operational forces in the right range, and large enough door openings. However, the expectation of the passenger can be significantly different from the driver. While the driver needs to be "connected" to the vehicle in order to fulfill the driving task, most of the passengers tend to put more emphasis on the smoothness of the ride. Yet in both cases, sitting in the vehicle is just one of the possible situations. A comfortable vehicle supports all operations within the normal range of usage, for instance, loading/unloading, drinking coffee, or reading a map.

Driving a vehicle implies all kinds of exposures. Noise is generated in the engine compartment, through the tires, the wind, and from other traffic. Vibrations are present over a wide range of frequencies. Sudden impacts generate inertial forces in the body. The occupant needs to be protected from the weather, dirt, and pollution. A comfortable vehicle is essentially a little cozy survival space, a home on wheels.

Like in any other home, a nice atmosphere and entertainment would not hurt. This is absolutely consistent with the Latin roots of the word "comfort" because these are measures to "charge the human battery." From the physiological point of view, "charge" might even be a better word than "delight." Delight features can be used to strengthen a brand image. However, a bunch of features without proper ergonomics does not deliver a comfortable car. The absence of delight features does not create discomfort but might bring it earlier to the attention of the driver.

36.1.3 Ergonomic Rules and Laws

The driver has to watch the traffic, find his or her way, follow the street, control the speed, switch gears, use the brakes, operate controls, and sometimes even perform additional tasks in parallel to remain part of our information society. This is real work. Looking at the vehicle as a workplace, several rules and evaluation criteria can be used in the traditional sense of ergonomics [24]. The human body has not originally been designed to drive a car. In early days, many technical restrictions forced the driver to adapt to unnatural conditions behind the steering wheel. Nowadays, the car can be designed to accommodate the human. A good workplace design always takes into account the balance between capacity and demand [20]. Capacity in this context is the human ability to sustain a certain amount of physical and mental workload. Demand is the required workload to fulfill the specific task. Considering the vehicle as a workplace can explain why subjective comfort perception of the same vehicle can be so different between users.

Comfort requires a positive and stable physical and mental state, which can only be obtained if the demand is lower than the capacity. In a driving situation, the demand can vary significantly, depending on the vehicle design, weather conditions, traffic, speed, road conditions, or additional tasks. The interindividual capacity varies significantly with age, strength, size, weight, intelligence, and education to name a few. Even the intraindividual capacity is subject to a remarkable variation and depends on factors such as health state, sleep, mood, stress, time of the day, or taste of the coffee in the morning. Sometimes an uncomfortable vehicle is perceived as comfortable because it has only been evaluated in situations where the capacity was high and the demand low. Just imagine you own a nice old sports car that you only drive on Sundays when the weather is perfect, the roads are empty, and you have had plenty of sleep and a good breakfast and pick a scenic route. The same car might feel terrible on a dark and foggy Monday morning in heavy traffic under time pressure after a short night.

Many design rules for workplaces can be applied directly to vehicle design. Some ergonomic books are listed in the references [13,22,24]. The biggest difference between vehicles and standard workplaces is the unavoidable vibration of the body. Therefore, vibration exposure in particular should be considered during the vehicle development.

The EU directive 2002/44/EC [8] defines minimum safety and health requirements for workplaces. If a vehicle is used as a workplace, this directive applies for vehicles as well. The vibrations of the body as a whole are measured in accordance with ISO standard 2631 (1997). The hand-arm vibrations are measured according to ISO 5349 (2001). While the hand-arm vibration exposure should not be an issue in vehicles, whole-body vibrations, however, might become relevant under certain circumstances. Unfortunately, the vibration exposure depends on many factors and not all of them belong to the vehicle design. Road condition, driving behavior, human body mass, individual seating position, or muscle tension cannot be prescribed by the development engineer. Looking at the vehicle, vibration damping cannot be assigned to a single component or subsystem. It is an overall vehicle performance requirement, involving tires, wheel size, suspension, vehicle mass, body stiffness, carpet, the seat, and to some extent the steering column. The main drivers are, however, the suspension and seat.

ISO 2631 metrics are root mean square (RMS) or vibration dose value (VDV) of the weighted acceleration during a given time span. Other metrics are reported in Section 31.2.1. Comfort of off-road vehicles is dealt with in Chapters 12 and 34:

$$\mathrm{VDV} = \left[\int_{t=0}^{T} a_w^4(t)dt \right]^{0.25} \quad \text{with } a_w(t) = c(f) \cdot a(t)$$

and

$$c(f) = \begin{matrix} 0.4 \\ f/5.0 \\ 1 \\ 16/f \end{matrix} \quad \text{for} \quad \begin{matrix} 0.5 < f < 2 \text{ Hz} \\ 2 < f < 5 \text{ Hz} \\ 5 < f < 16 \text{ Hz} \\ 16 < f < 80 \text{ Hz} \end{matrix}$$

Further exposure must be prohibited if RMS or VDV exceeds their exposure limit value (ELV) for the daily exposure: $\mathrm{RMS_{ELV}} = 1.15 \frac{\mathrm{m}}{\mathrm{s}^2}$, $\mathrm{VDV_{ELV}} = 21 \frac{\mathrm{m}}{\mathrm{s}^{1.75}}$.

LIST OF SYMBOLS

a	Acceleration
a_w	Weighted acceleration
$c(f)$	Frequency-dependent weighting factor
f	Frequency

36.2 HUMAN BODY

Obviously, it would be far beyond the scope of this chapter to explain, in detail, the human anatomy and physiology. However, vehicle comfort involves the vehicle and the human. Engineers and designers should, therefore, know some basic facts about the human body (see [20,23,25,32]).

36.2.1 Body Size

The first comfort-related development task is the dimensional layout of the vehicle interior, the so-called people package. It can be very difficult to use a car that does not accommodate the user's body size. Potential issues can be visual obstructions, problems to reach pedals or controls, uncomfortable joint angles, and collisions with parts of the interior, such as steering column shroud or headliner. In particular, the seat design is very sensitive to the body dimensions.

In ergonomics, it is common practice to work with percentiles, for instance, the 5th, 50th, and 95th percentiles. The 5th percentile is small; only 5% of the population is smaller. The 50th percentile represents "Joe average," whereas 95% of the population is smaller than the 95th percentile. A design that works well for the entire range between the 5th percentile female and 95th percentile male will probably not create issues in real-world usage. Unfortunately, there is a significant geographical variation of body sizes (Figure 36.1).

Additionally, there is a drift toward larger body sizes of about 1 cm per decade [9]. The reference sizes of the percentiles need to be updated and projected to the planned production period of the vehicle.

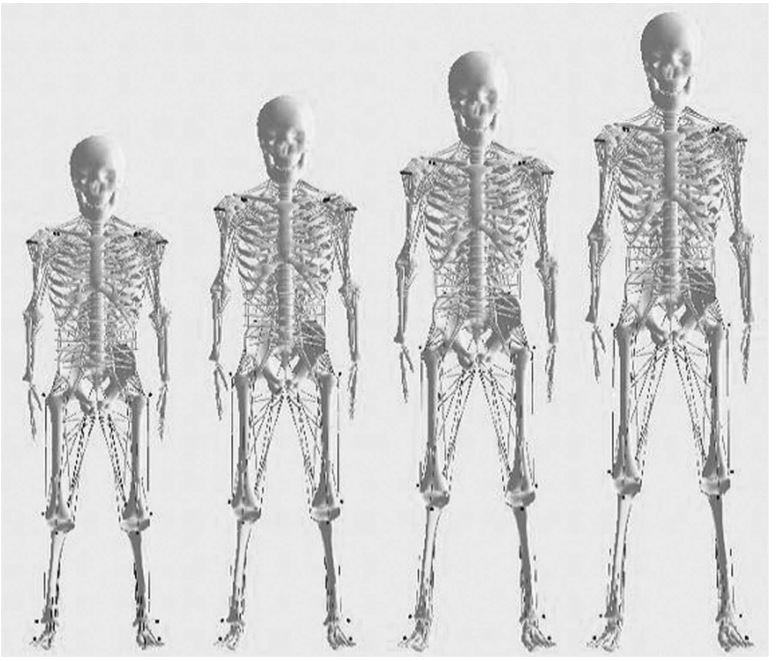

FIGURE 36.1 Scaled model of the human body, 5% female, 50% female, 50% male, and 95% male. (Plot generated by Ford Research and Advanced Engineering, Cologne, Germany.)

36.2.2 Resonance Frequencies

Why are resonance frequencies so important? Resonances of the human body can cause various kinds of discomfort [10] (Table 36.1). In many cases, the customers are not irritated by nor do they even feel the vibration but suffer from the resonance of internal organs. A very critical range lies between 3 and 6 Hz.

There is normally a resonance frequency range for different body parts due to people having different proportions and weight. Obviously, not all people with the same size automatically

TABLE 36.1
Human Body Resonances

Excitation Frequency (Hz)	Human Body Response
3–4	Strong resonance in the cervical vertebrae
3–6	Resonance of the stomach
4	Peak resonance of the lumbar vertebrae
4–5	Resonance in the hands (difficult to make aiming motions)
4–6	Resonance in the heart
5	Very strong resonance in the shoulder girdle
5–20	Resonance in the larynx (voice changes)
5–30	Resonance in the head
10–18	Resonance in the bladder (urge to urinate)
20–70	Resonance in the eyeballs (difficult to see)
100–200	Resonance in the lower jaw

Source: Kroemer, K. and Grandjean, E., *Fitting the Task to the Human*, Taylor & Francis, Philadelphia, PA, 1997.

have the same weight. Similarly, the damping behavior of the vehicle seat depends on weight and proportions of the occupant as well.

36.2.3 Human Locomotor System

Compared to the past, today's usage of the human locomotor system has changed dramatically, too fast for the evolution to follow up with an optimized version of the "Homo sedens" (sitting human). As a result, using our body that has been optimized for the traditional life, dominated by physical activity, we experience discomfort in static seating positions with poorly distributed muscle tension. In many cases, this even leads to significant pain or reduced muscular performance [3]. Sport teachers and gym managers have already noticed that the current lifestyle of younger people has led to reduced average maximum muscle forces.

Therefore, it is important to analyze all driving tasks with respect to the muscular activity. This is a real challenge because the human locomotor system consists of more than 200 bones, connected with various kinds of joints and more than 600 muscles that can be considered as independent actuators [25]. Adding all degrees of freedom in the human skeleton, the total number will be significantly smaller than the number of skeletal muscles. In mathematical terms, this means that the equation system is indeterminate. In physiological terms, this means that the human body has several options to recruit the muscles and still fulfill the same movement task [20]. Many muscles cross two joints, others only one joint. Tendons are in place to optimize the effective lever arms and introduce wrapping points in the line of action, if a simple straight line would not be ideal for the human body. A complex system of ligaments is needed to utilize different bones and allow for the right amount of movement. For instance, the knee joint would almost fall apart without ligaments since the contacting bone surfaces of the femur (long bone of the upper leg) and tibia (long bone of the lower leg) are not congruent.

Typical driving comfort issues related to the locomotor system are:

1. *A lack of postural support in the seat*. The muscles become overloaded after a certain time and cannot stabilize the body any more. This leads to fatigue and higher loads on the passive locomotor system. Problems with cartilage (e.g., vertebral disks) and ligaments are resulting long-term consequences.
2. *Muscular effort is too high to perform the task*. This could, for instance, apply to liftgates or mechanical handbrakes. It is more of an issue for elderly people as they often, simultaneously, have limitations of the joint movement range.
3. *Muscular efforts are too high to fulfill a task over the required time*. This applies for all control tasks such as steering and pedal operation. After just one hour, the maximum muscle force drops down to less than 10% of the short-term maximum force. Therefore, even low activation levels can become critical.
4. *Activation levels are too low or have the wrong characteristics in order to fulfill the control task*. These issues are a little more complicated because the goal is not simply to reduce the effort. The driver is part of the man–machine control system, at least until autopilots become standard in our vehicles. Using the current vehicle layout, the entire control communication (steering, shifting, braking, accelerating) relies on the human locomotor system's input. The control communication is bidirectional: The driver submits commands through mechanical forces or torques, and the vehicle gives feedback through the same control elements (a mathematical formulation can be found in Mitschke [18]). Unfortunately, the driver moves during driving (probably the original reason to use the car) resulting in dynamic loads, on the same extremities that are used to operate the controls.

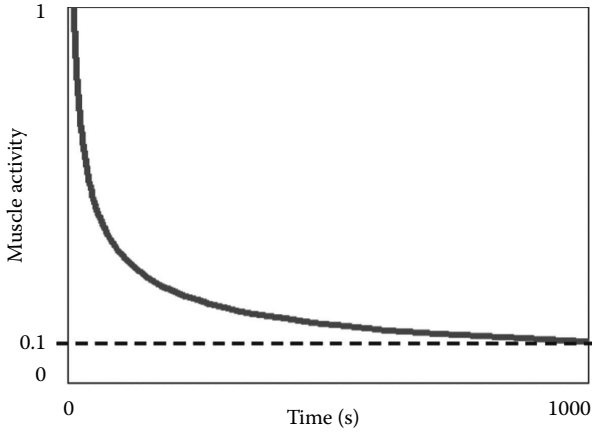

FIGURE 36.2 Muscle fatigue (50% slow-twitch fibers). The maximum force can only be developed for a short time due to metabolic constraints. Slow-twitch fibers are optimized for endurance; fast-twitch fibers are optimized for peak force [15]. (Ford plot using data from Niemi, J. et al., *J. Biomech.* 29, 451, 1996.)

The human locomotor system is fully equipped with biological strain gauges in the muscles, joint position sensors, accelerometers, force sensors in the skin, and a clever kind of "gyro" to trace the head rotation [23]. Without such mechanisms, it would be completely impossible to walk or perform other movement tasks. Recent developments of robots have exposed the difficulty of walking. It took decades until machines could balance themselves on two legs and move forward in a controlled manner. Driving a car takes advantage of the sophisticated control features that our body offers. In a sense, we become a part of a symbiotic man–machine system (Figure 36.2).

36.2.4 Heat Balance

The human body needs to keep the core temperature in a very tight tolerance band. A sophisticated temperature regulation performs this task automatically, using either increased metabolism for heating or sweating/respiration for cooling or blood vessel diameter changes in combination with heart rate changes to concentrate or spread the blood flow within the body. The optimum temperature range is affected by the humidity, differs between individuals, and depends on the clothing worn. For dry air, the temperature range is larger compared to wet air, and women typically like higher temperatures than men. The regulation process is not noticeable until it exceeds a certain level and then it not only becomes noticeable, but it may eventually cause fatigue due to the massive physical effort required. In addition to discomfort, a poor temperature stabilization in the vehicle can even cause sickness or increase the reaction time of the driver.

The heat balance in a vehicle is influenced by many external factors such as ambient temperature, sun radiation, moisture, and wind speed. Compared to regulating the temperature in a house, the task is a little more difficult in the vehicle because the driver produces more heat than the passengers, the cabin air volume is small, the heat capacity of the car interior is low, the heat production of the car itself varies, and the individual body regions are exposed to a different heat transfer situations. Unfortunately, it is difficult for the human body to react locally to different temperatures. For instance, sweat production cannot be controlled individually for the front and rear parts of the body's trunk. Two independent strategies are available for the car designer: (1) Maintain the perfect climate in the car. (2) Support the natural thermoregulation of the human body, for example, the seat covers a significant heat exchange area of the human body and should have a sufficient water vapor permeability.

36.3 COMFORT EVALUATION

36.3.1 Subjective Rating

Subjective rating is the oldest method to evaluate comfort and will probably continue to survive for some time. As mentioned earlier, the human body is fully equipped with hundreds of biological sensors. Experienced evaluators essentially use these sensors in order to detect small differences in design, which are not yet measurable.

Many different evaluation schemes have been reported in the literature, and it is beyond the scope of this chapter to come up with a complete review or guideline. However, some basic rules should be mentioned:

1. *Clear definition of the evaluation criteria and precise description of the evaluation conditions.* Comfort is multidimensional. This means that several independent criteria need to be defined and separated from each other. For each criterion, there should be one critical task or boundary condition where the differences between good and bad design are evident. Many criteria require real driving exercises on the test track. Pure showroom evaluation is not appropriate.
2. *Reference vehicle.* It is much easier to compare two vehicles than rate a single vehicle without any reference. The reference vehicle needs to be in a controlled condition over the time of usage.
3. *Descriptive rating scale.* The rating scale should be clearly defined and not too fine. It is important that all evaluators have the same understanding of a particular rating level.
4. *Customer-oriented weighting.* The multidimensional comfort rating needs to be combined to one total score for each vehicle. A representative picture can only be obtained if all important comfort aspects are captured and weighted according to the customer preference for the particular vehicle type.
5. *Trained evaluators.* Subjective vehicle evaluation is like wine tasting. The evaluator needs much experience, the ability to focus on specific aspects, and the ability to separate the differences caused by boundary conditions from the difference in performance.
6. *Sufficient evaluations.* Even trained evaluators do not always come to the same conclusion. However, a smaller number of observations are needed, compared to regular customers. For a proper comfort evaluation, it is necessary to cover a certain range of the population with a number of selected evaluators because in some comfort aspects like vibration damping, postural, or lateral support, the comfort performance depends on the occupant size.

For design optimization, it can be helpful to use bimodal scales instead of 1D scales. For instance, a seat can be too wide or too narrow. Just rating the seat width on a scale from 1 to 10 would not give guidance on how to improve the design.

36.3.2 Test Methods

Test methods typically focus on one specific comfort aspect, for instance, vibration damping or seat pressure distribution. A complete comfort assessment would require a massive test program. The advantage of tests over a subjective rating is a well-defined output that in many cases can directly be used to detect design weaknesses. However, most of the comfort-related tests involve human test subjects, which is a real drawback in terms of repeatability and reproducibility.

36.3.2.1 Human Motion

Motion analysis has a long history in biomechanics. Originally used in clinical applications such as gait analysis, the same methods have now started to migrate into the vehicle development. Motion analysis is helpful to investigate how people perform operation tasks such as ingress/egress [12]. Depending on vehicle design parameters such as door opening height or step over height, many

FIGURE 36.3 Strain gauge goniometer to measure joint angles. (From Siebertz, K. et al., The strain gauge goniometer, a new sensor to measure dummy joint angles under crash conditions, *SAE World Congress 2000*, in: *Safety Test Methodologies*, SAE 2000, Special Publications, Warrendale, PA, 2000; Photo from Ford Research and Advanced Engineering, Cologne, Germany.)

people change their movement pattern completely. Motion analysis also builds the backbone of further biomechanical analysis with computer-aided engineering (CAE) models. Motion analysis typically works with a simplified rigid body model and tries to replicate the kinematics in terms of joint angles or joint center movement.

The simplest way to record movement is videotaping or a series of digital photos. Markers should be used to identify prominent points, if possible joint locations or bony landmarks [38]. Skin movement and loose clothing are critical. A 3D reconstruction requires at least two independent unobstructed views, which can be difficult to obtain inside the vehicle. A full-blown motion tracking works with a set of four or more synchronized cameras to make sure that at least two views are available at any time. The redundancy also reduces errors due to optical distortion. In the past, many competing systems were on the market, mostly optical, some based on ultrasound, working with active or passive markers. Video-based systems and infrared-based systems with passive markers seem to be preferred.

For single joints, it is always a good option to use goniometers that are taped on the body. They deliver joint angles directly and work rather reliably. Using this technique for the whole body requires a special suit (in all body sizes that are to be investigated) (Figure 36.3).

Small movements of the human spine can be recorded noninvasive with a posture monitor, using ultrasonic sound waves to detect small distance changes between eight sensors that are taped on the skin.

36.3.2.2 Seat Vibrations

Vehicle seats can dampen the car body vibrations quite effectively. It is easy to measure seat track vibrations with regular accelerometers [1,10]. However, seat cushion vibrations depend not only on the seat but also on the occupant. A simple rubber pad with integrated accelerometer can be placed on top of the seat cushion to record the seat cushion accelerations. The rubber pad increases the contact area and is flexible enough to follow the seat shape. Hydro-pulser tests can also be very helpful for seat development. In this case, the seat is mounted on a rig and accelerated according to the measured accelerations from the seat track on the road test. In both cases, the human test subject is used more or less as passive dummy, just to load the seat. Several vibration dummies have been proposed so far to overcome this shortage, but there is no common automotive standard yet.

Most of the studies reported in the literature focus on vertical vibration of the seat pad, and it is common sense that these correlate to a subjective vibration comfort perception. However, it is debated to which extent the seat back and the other directions of the vibration contribute to the total picture. Beyond 30 Hz, the seat does not vibrate as a total system, but there are noticeable local effects, caused by resonances or modal vibrations.

Such comfort evaluations are mainly concerned with the following numerical results: (1) absolute vibration in terms of RMS or VDV and (2) ratio between seat cushion acceleration and seat track acceleration. Obviously, the amount of vibration depends on the road conditions. It is, therefore, important to use well-known roads, for example, on a test track.

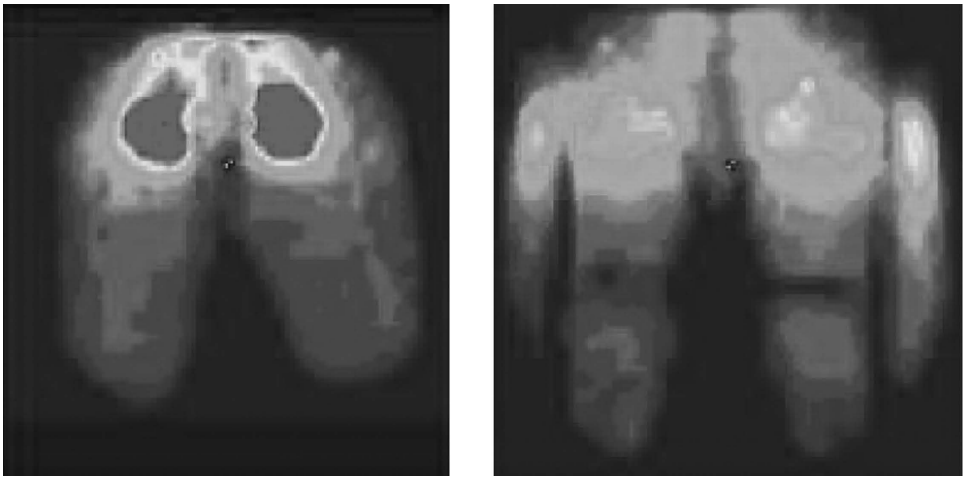

FIGURE 36.4 Seat pressure distribution of a canteen chair (left) vs. a vehicle seat using the same test subject. The canteen chair has been designed (on purpose?) for short-term usage. (Plot generated by Ford Research and Advanced Engineering, Cologne, Germany.)

36.3.2.3 Seat Pressure Distribution

Since the human body is equipped with a large number of pressure sensors, the occupants are very sensitive to the contact pressure. For example, pressure hot spots, high-pressure gradients, or small contact areas cause discomfort [16,33]. There is always a trade-off between body support and uniform pressure distribution. Without a certain pressure, there is no way to transmit the required support forces to the body, especially under dynamic conditions (Figure 36.4).

Many design weaknesses of seats, therefore, can be detected with the measurement of the seat pressure distribution. Unfortunately, the pressure distribution for the same seat can look totally different, depending on the occupant. A seat evaluation, therefore, requires measurements with a variety of people. Seat indenter with special "natural-shaped" padding is under development, but there is no standard yet.

Pressure distribution measurement has been around in biomechanics for decades [30]. An early application was the treatment of diabetic feet with custom-made shoes to optimize the pressure distribution [2]. Modern pressure mapping systems use several hundred pressure sensors per mat, can work with two mats at the same time, and record more than 10 frames per second. A high sampling frequency is helpful for dynamic measurements on test tracks, for example, to check the lateral support or bottoming out on bumpy roads.

36.3.2.4 Electromyography

The muscular force cannot be measured directly, but for many muscles, it is possible to record the electrical activity. Electrodes placed on the skin above the muscle can detect small changes of the electric potential compared to areas further away to the muscles [6]. This is called surface electromyography (EMG). A more precise measurement can be obtained using needle electrodes that are placed directly in the muscle. However, this causes discomfort in itself and, therefore, does not help to evaluate comfort. Surface EMG has a long history in clinical and sports applications because it is the only noninvasive way to obtain test data related to muscular activity. EMG is the indispensable tool to generate the validation data for further CAE studies with biomechanical models (Figure 36.5).

The signal post-processing depends on the goal of the study. For single movements such as pulling a handbrake, the signal would be rectified and filtered to estimate the muscle force. For long-term evaluations of repetitive movements or static activity, it is interesting to see the power spectrum, knowing that fatigue results in a reduction of the high-frequency signal content. Modern EMG

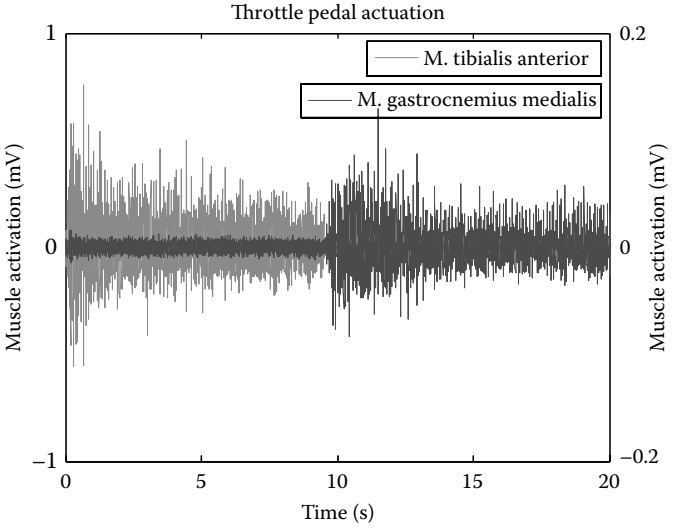

FIGURE 36.5 EMG raw signal of an accelerator pedal actuation. After 10 s (in this case), the antagonist muscle takes over. (Plot generated by Ford Research and Advanced Engineering, Cologne, Germany.)

devices work with 8 or more channels, but the test engineer should keep in mind that too many cables will affect the movement of the test subjects.

36.3.2.5 Climate

Conventional measurement techniques are used to record temperature, moisture, radiation, and air speed. Climate dummies measure the heat transfer at specified body regions with temperature-controlled segments. Unfortunately, there is no common industry standard, and the climate dummies do not work well in hot conditions.

Thermal seat comfort mainly depends on the water vapor permeability because evaporation of sweat is the dominant cooling mechanism of the human body [34]. Component test according to ISO 11092 or DIN EN 31092 can be used to optimize seat covers and reduce the number of climate chamber tests with test subjects. The component test uses a so-called skin model to generate a controlled water evaporation. The water vapor is then guided through the test sample. A high permeability correlates to a high evaporation rate that can be measured quite simply by the power consumption of the evaporation device (Figure 36.6).

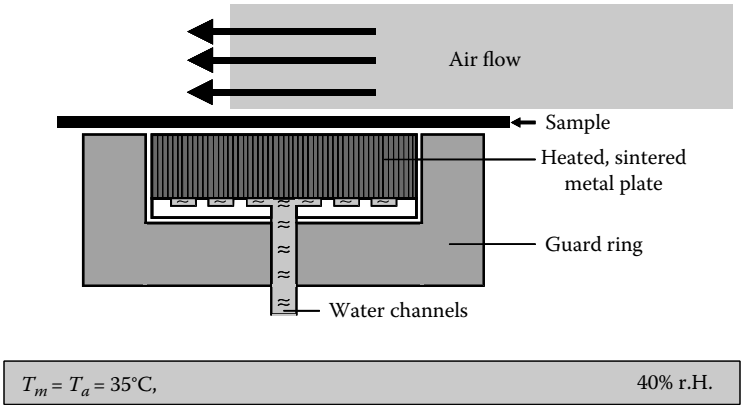

FIGURE 36.6 Skin model according to ISO 11092. (Sketch generated by Ford Research and Advanced Engineering, Cologne, Germany.)

36.3.2.6 Others

Discomfort and fatigue affect several body reactions. Some of the body reactions can be measured quite easily, for instance, the heart rate or the electrical conductivity of the skin. Eye motion tracking, including the blink frequency, is another example.

36.3.3 CAE Models

Compared to other automotive applications, CAE-driven comfort prediction is a very young branch with a low level of standardization throughout the industry. Due to the different comfort aspects and the complexity of the human body, it is not possible to include the entire comfort prediction into one single model. There will always be dedicated models for posture analysis, vibration analysis, or analysis of muscle loads, to name a few. A complete documentation of all proposed modeling strategies would fill at least one book. Some examples will be shown here, without claiming that this is a complete overview.

36.3.3.1 Kinematic Models

Kinematic models such as Ramses [26] use a segmented rigid body representation and determine the joint angles for a given posture. Based on experimental data, a comfort index can be derived from the joint angles. Design optimization in this case is equivalent to optimization of this comfort index. The method can be applied for static seating positions and movement sequences, for example, ingress/egress or pedal operation [36]. Recent studies include a strength model with "torque potatoes" [27].

36.3.3.2 Inverse Dynamic Models without Muscles

Rigid body models using inverse dynamics deliver the required joint torques and forces to fulfill a predefined motion task, taking all external loads into account [39]. Joint reactions have no direct physiological meaning since the human body does not work like a robot, but obviously there is a strong correlation between muscular effort and joint torques. These models are valuable for comparisons and trend predictions. The downside of the inverse dynamics approach is the large amount of required input parameters, which are sometimes difficult to obtain.

36.3.3.3 Inverse Dynamics Models Including Muscles

Adding the muscles to inverse dynamic models means that the modeling effort increases by about one magnitude. For a full-body simulation, several hundred muscles need to be taken into account, each of them with a specified line of action and strength properties [21]. Optimization criteria need to be defined as well because the number of unknowns exceeds the number of equations [29]. The main advantage of this fully developed model is the high bio-fidelity, meaning that the calculated results have a real physiological meaning. Compared to models without muscles, the required test data are the same, assuming a segmented rigid body approach (Figure 36.7).

36.3.3.4 Forward Dynamic Models to Simulate the Human Body Impedance

These models are more or less a virtual vibration dummy and can be used for seat development [5]. A good representation of the human body with respect to the vibration impedance allows the prediction of the seat vibration transmissibility. Obviously, the seat needs to be modeled as well, typically in a functional description with nonlinear springs and dampers. Forward dynamics means that the movement is calculated as a result of all acting forces. The main drawback of these models is the description of the mechanical coupling between seat and occupant. Typically the model focuses on vertical vibrations only.

FIGURE 36.7 AnyBody car driver model (Ford). (Plot generated by Ford Research and Advanced Engineering, Cologne, Germany.)

36.3.3.5 Forward Dynamic Models to Simulate the Vibration of the Human Body

These models are used to calculate the propagation of the seat vibrations into different parts of the human body [7,35]. This is important for further definitions of critical vibration doses or to investigate how people can operate vehicles under vibration exposure. The main advantage is a real analysis of the dynamic behavior in the human body, giving additional information over pure test data. However, these models are highly complex and require advanced modeling of the deformable body parts as well as a representation of the muscular tension, including all anatomical properties.

36.3.3.6 FEM Prediction of the Seat Pressure Distribution

These models focus on the seat pressure distribution under static load. The main task is the proper representation of the seat–occupant coupling including the foam and deformable body tissue [14,19].

36.4 CONCLUSION

When dealing with vehicle comfort, it is very easy to get lost in the exploration of fragmented details. Priorities need to be set during the vehicle development process in order to cover all the aspects of comfort. The future goal will be to replace subjective ratings with reliable test methods or with CAE methods that do not require hardware. Limited resources might force the development teams to accept simplifications when they combine the results coming from different approaches. Knowing that the customer perception of comfort is nothing less than a total score of many independent performance criteria, a good overview and the clever synthesis of the fragments will be crucial. For the engineer, this requires an open mind since the machine is just one part of the man–machine system. Even psychology comes into play as perceptions of different senses need to be orchestrated to a pleasant comfort symphony.

37.1 INTRODUCTION

A conceptual target of desirable vehicle performances can be (1) *enjoyable in driving*, (2) *clean feel to steer*, (3) *easy to control*, and (4) *safe to maneuver*. This concept is substantially based on (a) *comfort*, (b) *agility*, (c) *precision*, and (d) *safety*. As a category of vehicle dynamics, the performances are specifically represented by *handling* and *ride*. Nowadays, they are finally evaluated only by a professional driver's subjective assessment through numerous tests, even though test and assessment methods are varied dependent on each automotive or tire company. Even within the same company, the methods may be different depending on each test engineer.

Subjective assessment has traditionally been carried out by specially trained engineers or technicians but not vehicle dynamists. Since in general they do not have extensive vehicle dynamics knowledge, a fundamental vehicle dynamics concept on the subjective assessment has not been fully established. In order to successfully characterize the performances, this concept should be fundamentally understood. It should be noted that *without his or her own experience in subjective assessment, anyone does hardly understand other's subjective assessment*.

Each test engineer has his or her own subjective test and assessment techniques that have been built through various practices done by expert trainers, seniors, and himself or herself. In reality, most test engineers just know how to make subjective rating on the performances. However, they cannot express their perceptual feeling using a scientific language. That is why there has always been an untouchable barrier in the development of vehicle dynamics. During the last half century, vehicle dynamics has been developed to play a role for better handling and ride performances [1–10]. Compared to other technologies, however, the vehicle dynamics has been contributing not much.

For subjective tests to assess handling and ride performances, any practical documentation is seldom founded in public. Fortunately, ISO international standard provides very well standardized procedures for various handling objective tests [11–17]. However, ISO international standard or any other documentation for practical ride objective tests is not available in public yet. Instead, ISO international standard 2631-1 presents measurement methods for periodic, random, and transient whole-body vibration affecting health, comfort, and motion sickness [18].

Some studies provided numerous correlation approaches between objective measurement and overall handling perception [19–21]. Crolla et al. performed a comprehensive study to make handling assessment using a combined subjective–objective approach [22]. Norman and Farrer separately carried out practical approaches for the objective evaluation of on-center handling performance [23,24]. Salaani et al. did a nice study for the experimental appraisal of steering feel for on-center and off-center driving [25]. Some other works tried to practically correlate between the objective measurement and the subjective assessment of transient steer characteristics [26–28].

Numerous studies objectively evaluated ride quality using human discomfort perception [29–35]. Ushijima et al. practically studied a correlation between the objective measurement and the subjective assessment of impact harshness [36]. Some other works also carried out for the objective evaluation of the impact harshness using only vibration effect [37,38]. Amman et al. considered sound and vibration contributions to the human perception of the impact harshness [39].

When we are talking about handling performance, several words are alternatively used such as straight line, steering, cornering, and stability [40–43]. The handling performance is believed as the combined characteristic of a vehicle and a driver. In reality, its subjective assessment is generally affected by a driver's assessment capability and preference. It is very important that this performance is assessed with the least influence of the driver himself.

The subjective assessment and subjective test given in this handbook are very practical ones commonly used in a homologation process of a car or a tire by many automotive and tire companies worldwide. Here, the subjective assessment and subjective test are tried to be standardized based on their physical concepts. As a tool to make the subjective assessment, the subjective test is described. For each subjective test, its basic concept, test procedure, and driving condition are explained. Even if its concept is agreed with that of other test methods, its procedure and/or condition may be possibly different from the others.

For the purpose of well organizing the subjective assessment, the handling and ride performances can be primarily grouped in five *capabilities*. Each capability is categorized into correspondent *characteristics*. Similar to the subjective assessment, the subjective test is principally classified in five *maneuvers*. Each maneuver is composed of several *tests* with specially designed procedures.

As a supplemental method to the subjective test, objective test is presented to obtain objective measurement data eventually used for a vehicle dynamics analysis. Using vehicle dynamics variables extracted from the measurement data, the vehicle dynamics analysis is discussed to explain the subjective assessment. For that purpose, (a) *subjective assessment variables*, (b) *objective measurement variables*, and (c) *physical perception variables* are defined here.

In order to subjectively assess each characteristic of handling and ride performances, the subjective assessment variables are perceptually evaluated. The objective measurement variables are employed in order to objectively describe vehicle motion representing the characteristic. The physical perception variables are physical variables that test engineers actually perceive. Eventually, these variables can be expressed in terms of the objective measurement variables.

37.2 SUBJECTIVE ASSESSMENT

SAE J1441 explains a 10-point subjective rating scale for vehicle handling [44]. However, it does not give how to make subjective assessment. In practice, most of automakers and tire companies are using this scale.

In this handbook as shown in Figure 37.1, the handling and ride performances of a vehicle are grouped by five *capabilities* such as (1) *straightability*, (2) *steerability*, (3) *controllability*, (4) *stability*, and (5) *comfortability*. Each capability is specifically categorized into several *characteristics*. The nomenclatures of the characteristics given in Figure 37.1 have been traditionally employed to express their perceptual concepts but not their scientific definitions [40–43]. Their names may be not suitable in engineering sense and also a little different depending on each user. All characteristics are supposedly independent from each other, while they are cross affected by their causes. Even different characteristics may share the same cause.

The straightability is a straight-running ability without any significant lateral deviation from the straight path regardless of free or fixed steering. The steerability is a steering capability to achieve intended steering reactions with preferred effort and better comfort of steering. During any vehicle maneuver, easiness to control a vehicle in following an intended path is the controllability. The stability is the convergence characteristic of vehicle behavior even beyond grip limit. The comfortability is the ride comfort characteristic of a vehicle running over uncomfortable, uneven, or irregular roads.

The straightability is primarily affected based on the reaction of front tires due to external disturbances either with free or fixed steering. The response of the front tires against a series of steering applications and the following-up capability of the rear tires against the behavior of the front tires determine the steerability, controllability, and stability. The roll and pitch motions of a sprung mass are also critical factors to affect the stability as well as the controllability.

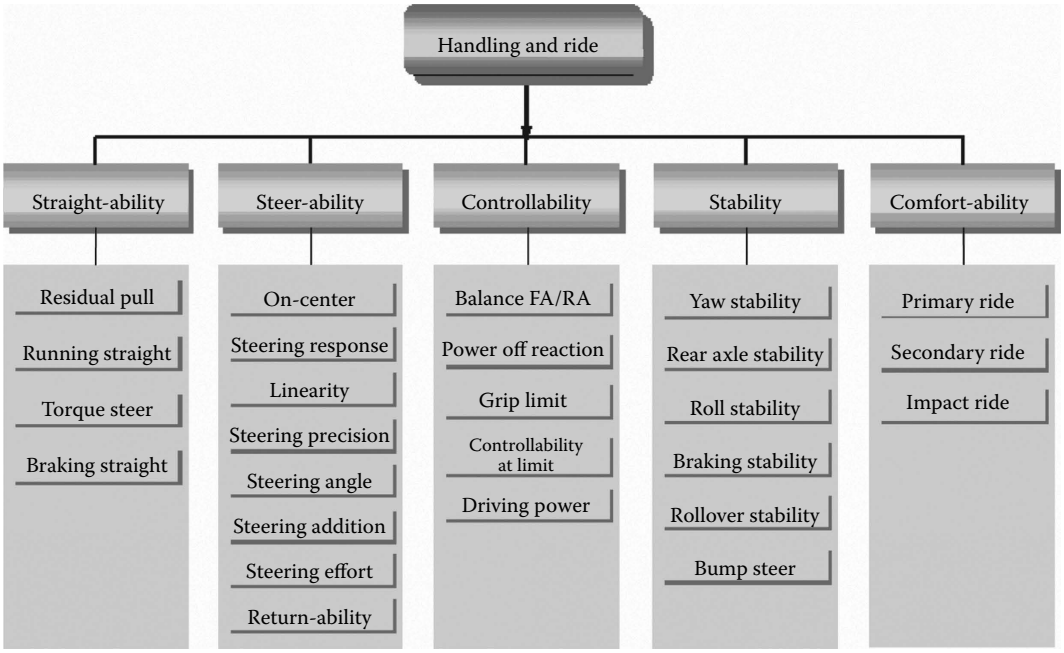

FIGURE 37.1 Subjective assessment on handling and ride performances.

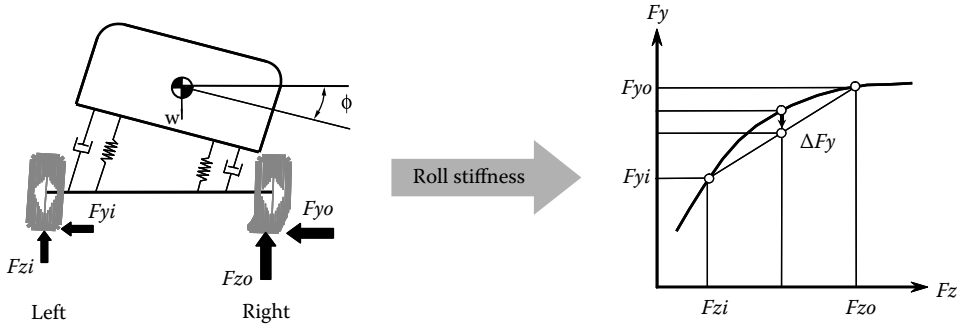

FIGURE 37.2 Lateral load transfer from inner tires to outer tires.

Roll resistance produces a load transfer from inner tires to outer tires while cornering, and then it reduces total cornering force at each axle (refer to Figure 37.2). This reduction of the cornering force not only causes grip reduction but also changes the grip balance between front and rear axles. This balance principally determines the steer characteristic of a vehicle such as transient understeer and oversteer. In case it causes too much understeer or/and oversteer, it deteriorates handling performance due to poor controllability and even bad stability.

While powering on in straight ahead as shown in Figure 37.3a, a front axle loses some grip due to a front-to-rear load transfer. On the other hand, a rear axle gains more grip. With a front-wheel-driving vehicle running on low-friction road, powering-on operation deteriorates even more front axle grip based on a so-called friction ellipse concept. In the situation of powering on in a turn (refer to Figure 37.3b), a vehicle behaviors much more understeer, which makes a driver more difficult to control the vehicle to follow an intended path.

During powering off or braking in straight ahead, a rear-to-front load transfer reduces rear axle grip, while front axle grip gains more as shown in Figure 37.4a. In a turn, a rear-wheel-driving

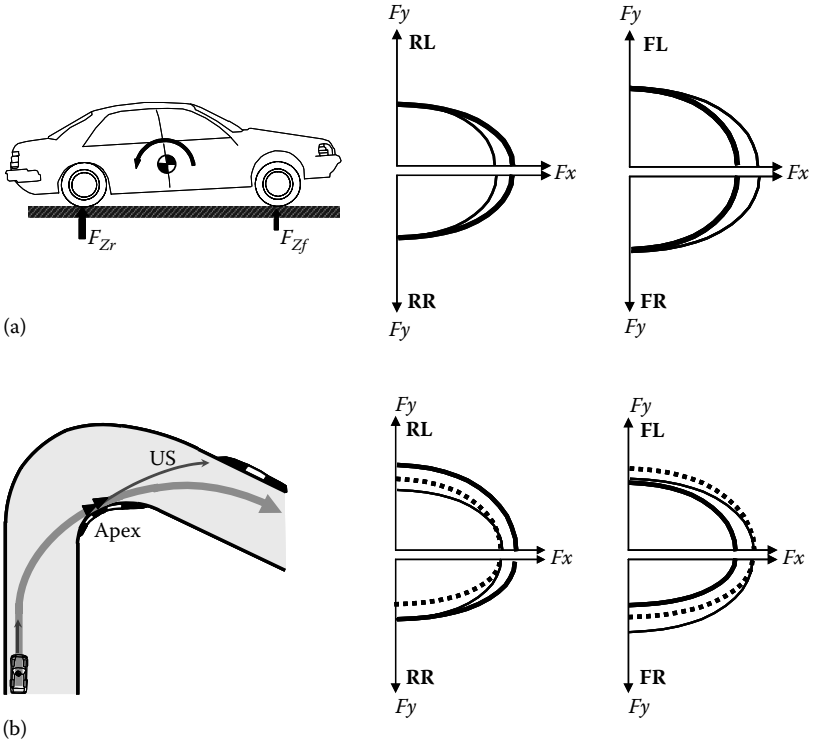

FIGURE 37.3 Longitudinal load transfer and tire force changes due to (a) power on in straight ahead and (b) power on in a turn.

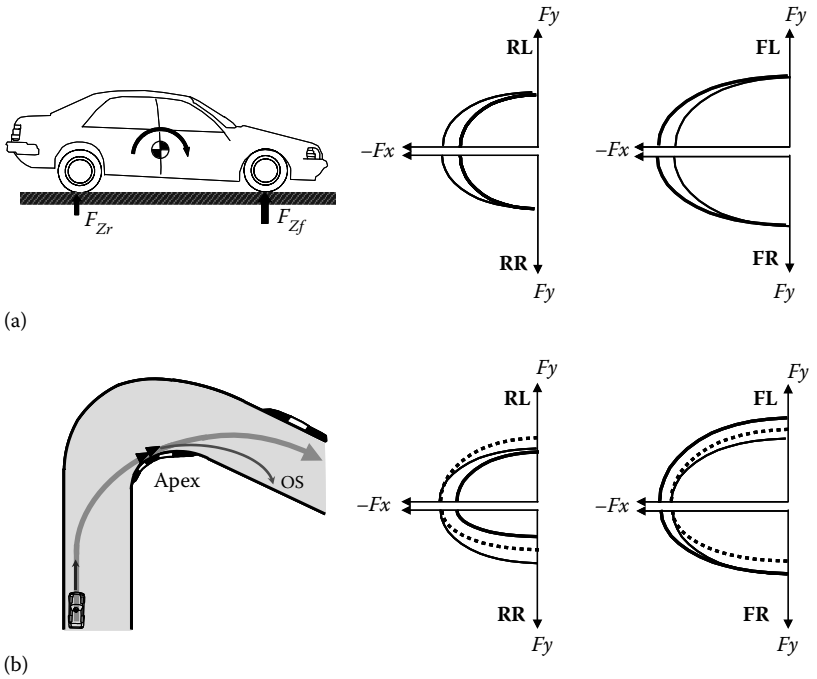

FIGURE 37.4 Longitudinal load transfer and tire force changes due to (a) power off or braking in straight ahead and (b) power off or braking in a turn.

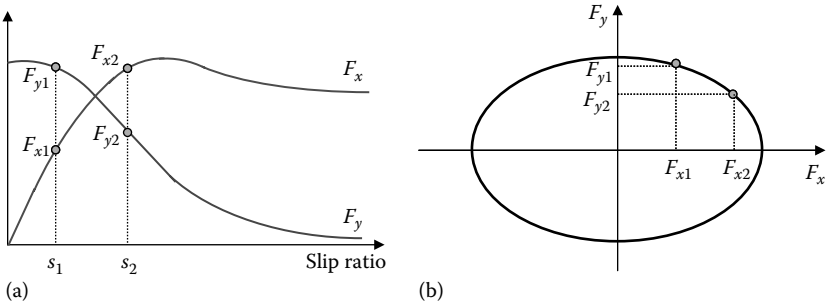

FIGURE 37.5 Friction ellipse concept. (a) Lateral force against longitudinal force and (b) friction ellipse.

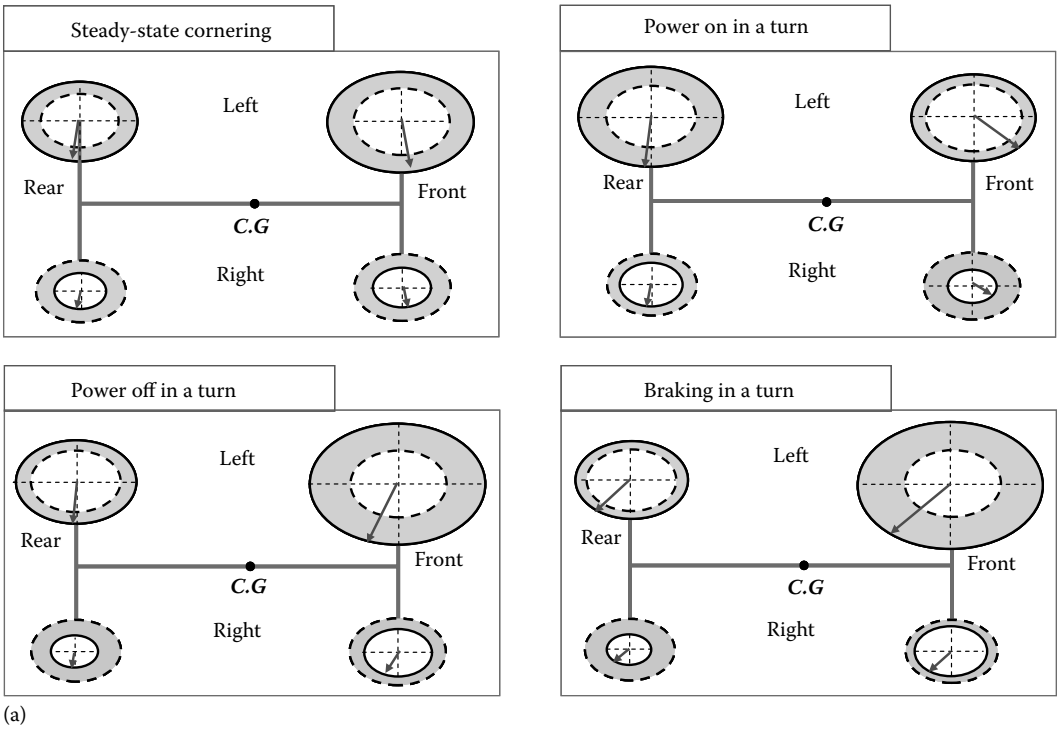
vehicle running on low-friction road deteriorates even more rear axle grip based on the friction ellipse concept (refer to Figure 37.4b). Sometimes it produces big oversteer beyond control limit in a turn so that it is easy for a normal driver to get into an accident.

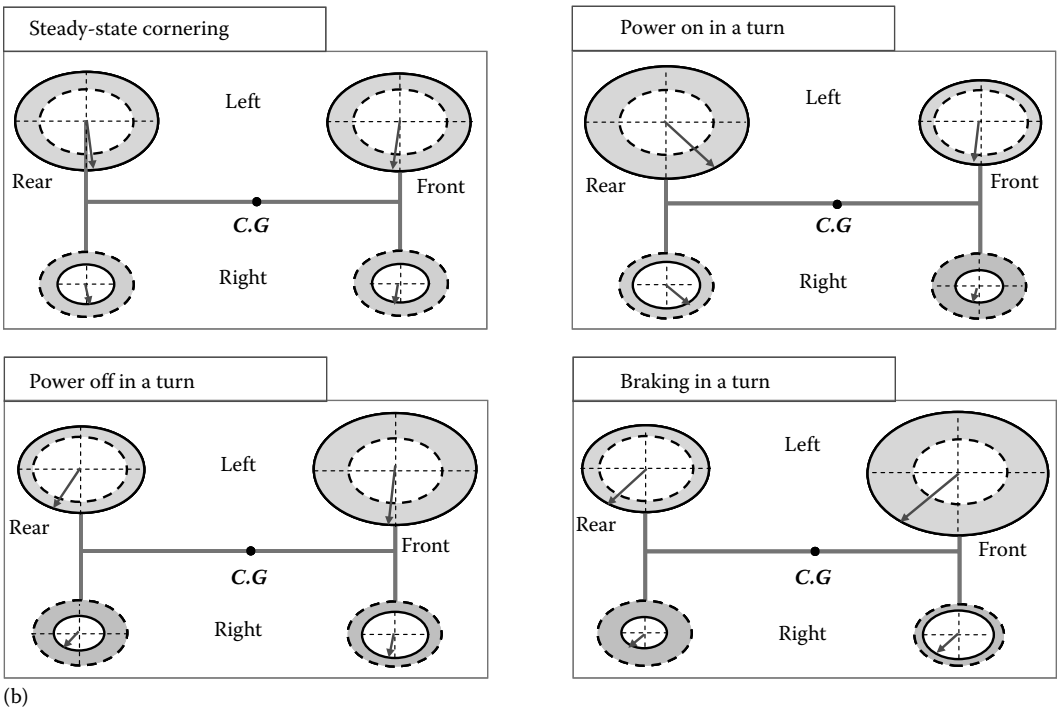
An application of power on, power off, or braking operation to a tire having lateral slip in cornering increases longitudinal force in magnitude. Instead, it reduces lateral force in magnitude due to the generation of longitudinal slip in addition to the lateral slip as shown in Figure 37.5a. The maximum potential of the resultant tire friction force is observed to be limited by about an ellipse (refer to Figure 37.5b). This phenomenon is called the friction ellipse concept. Figures 37.6 and 37.7 illustrate the friction ellipses of all tire forces of a vehicle in a right turn on high-friction road (dry surface) and low-friction road (wet surface), respectively.

When test engineers carry out their subjective assessment, they make their judgment using *subjective assessment variables*. Through special trainings, self-trainings, and test experiences, up to nowadays, test engineers learn these variables just in forms of feeling but not in physical forms. The test engineers believe that all these variables are tactically, visually, and audibly perceived during various subjective tests. However, they do not directly sense all of these variables. Instead, in reality, they do perceptually measure *physical perception variables*, which are discussed in detail later.



As the subjective assessment variables regarding steering behavior, *steering handwheel angle* is visually measured, and *steering handwheel torque* is tactically sensed. The amount of required steering handwheel angle is used as a guideline for steering gain. The same amount of the steering handwheel angle is applied to evaluate the steering responses of different vehicles. The strength of reacted steering handwheel torque is estimated for steering effort.

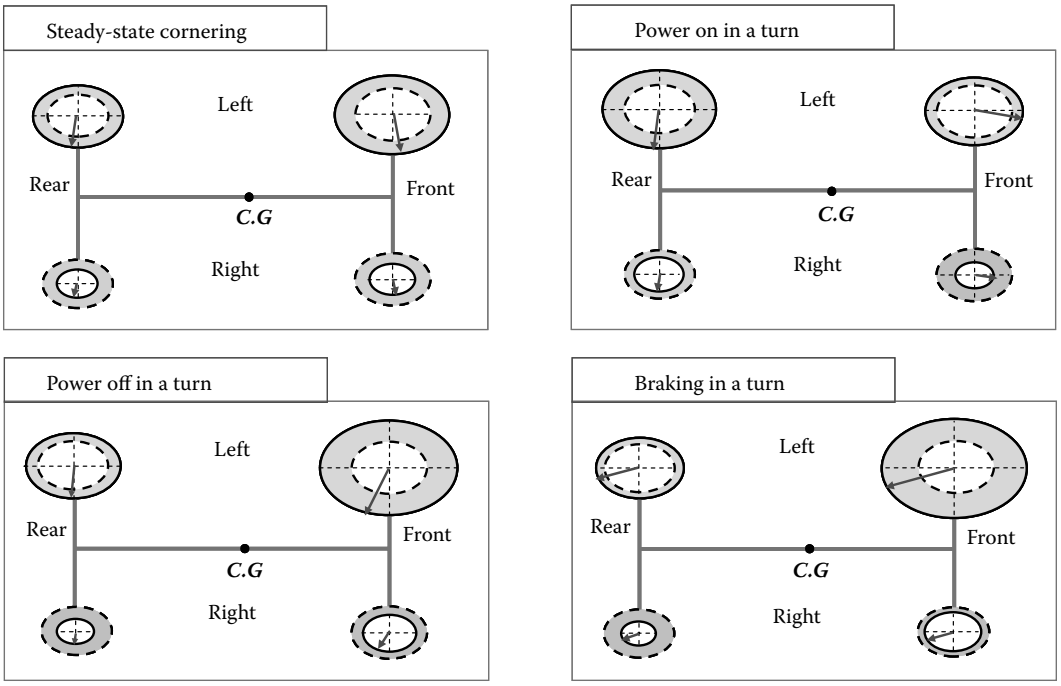
As the primary subjective assessment variable on vehicle cornering or lane-changing behavior, *vehicle path* in addition to *vehicle speed* is subjectively evaluated during straight running, cornering, lane changing, or severe lane changing. On top of that, *vehicle attitude* is also subjectively assessed. In this handbook, the vehicle attitude is defined with respect to vehicle moving direction. Therefore, the vehicle attitude stands for *vehicle nose-in attitude relative to vehicle path at an instant*.



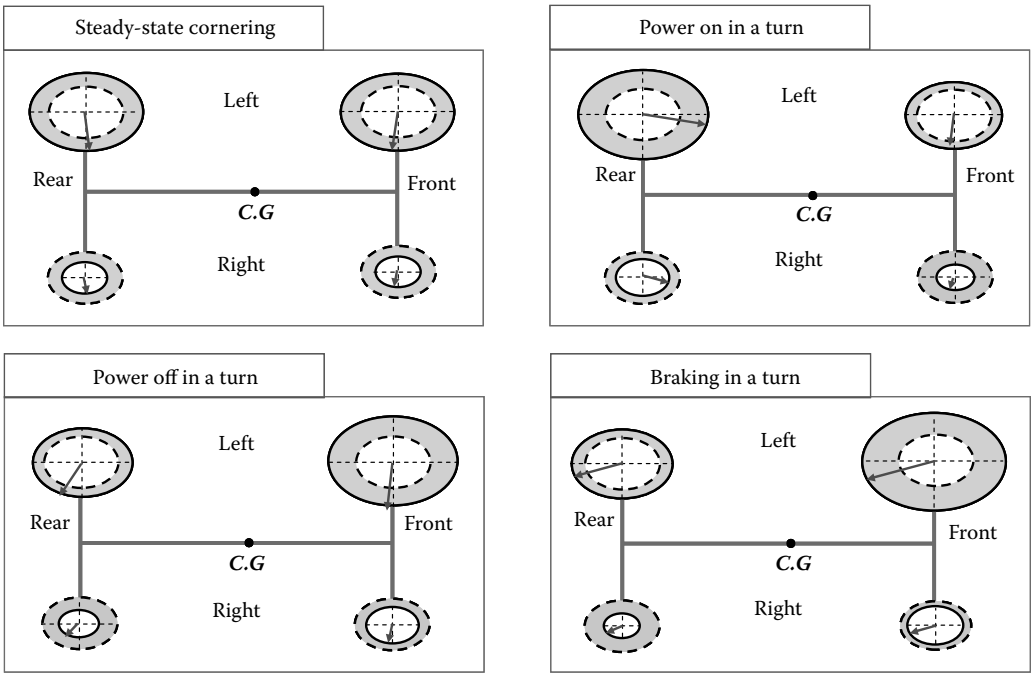
For roll stability and rollover stability, *vehicle body motion* is sensed through both driver body feel and visual observation. In order to subjectively assess comfortability, the vibratory motions of sprung and unsprung masses are tactically sensed. In addition, tire impact shock is tactically and audibly preserved.

37.2.1 Straightability

Regardless of any disturbance in driving condition, straightability to make a vehicle run in straight ahead is more often called straight-line stability. This nomenclature is just a traditionally used perceptual one but not from its physical definition. The straightability usually represents *comfort*, but in



(a)



(b)

FIGURE 37.6 Friction ellipses of all tire forces of a vehicle in a right turn on high-friction road (dry surface). (a) Front wheel driving and (b) rear wheel driving.

(a)

(b)

FIGURE 37.7 Friction ellipses of all tire forces of a vehicle in a right turn on low-friction road (wet surface). (a) Front wheel driving and (b) rear wheel driving.

the worst case, it is related to *safety*. In general, it is assessed through the perceptual evaluations of its four characteristics such as (a) *residual pull*, (b) *running straight*, (c) *torque steer*, and (d) *braking straight* (refer to Figure 37.1).

37.2.1.1 Residual Pull

Residual pull is the lateral drift characteristic of a vehicle caused due to residual steering torque. It is subjectively or objectively assessed by the magnitude of lateral drift from straight path after about 100 m driving with free steering at constant speed (usually 100 kph) as shown in Figure 37.8. It confirms the proper design of a steering system, suspension setup and tire matching, and their manufacturing uniformities. While long driving, a residual pull problem makes a driver feel tired due to the residual steering torque. Furthermore, with free steering, it may cause an accident in the worst case.

37.2.1.2 Running Straight

Running straight is a straight-running ability without any drift, wander, or sloppiness with fixed steering at constant speed as shown in Figure 37.9. It illustrates the design sensitivity of steering and suspension systems against road irregularity or wind disturbance. Its problem with long driving also makes a driver feel tired due to continuous steering corrections.

37.2.1.3 Torque Steer

Torque steer is the lateral drift characteristic of a vehicle produced by an unbalance of traction torques between left and right driving wheels, when powering on in straight ahead with fixed steering. It is subjectively evaluated with the lateral drifting motion of the vehicle moving to an adjacent lane with full power on and back to the original lane with power off as shown in Figure 37.10. Smaller lateral drift is desired for better torque steer.

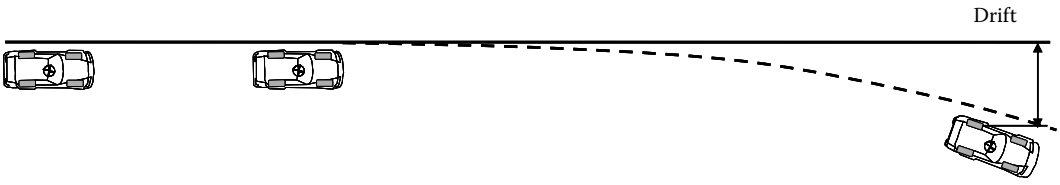


FIGURE 37.8 Residual pull.

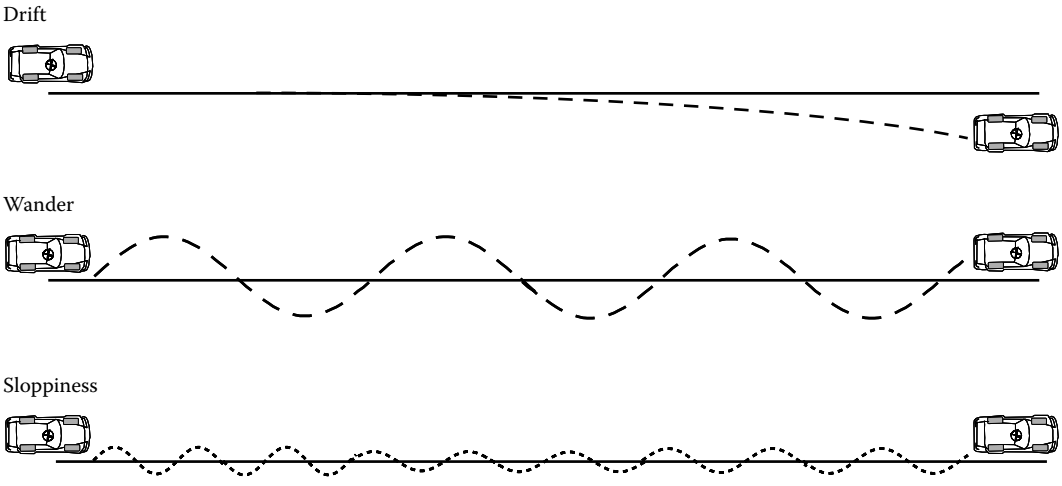

FIGURE 37.9 Running straight.

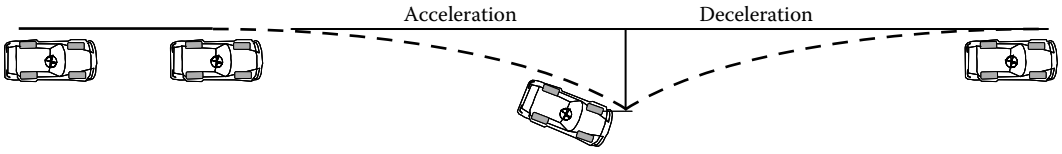

FIGURE 37.10 Torque steer.

37.2.1.4 Braking Straight

Braking straight is a straight-braking ability without any disturbance of vehicle attitude or path, when a vehicle instantaneously stops completely. It is subjectively assessed by the deviation of vehicle attitude or path during full braking with hands-on steering. No deviation of vehicle attitude or path is pursued for good braking straight.

37.2.2 Steerability

The major aims of steering behavior to be achieved are (1) *comfort*, (2) *agility*, and (3) *precision*. The steering behavior is represented by steerability categorized in eight characteristics such as (a) *on-center feel*, (b) *steering response*, (c) *linearity*, (d) *steering precision*, (e) *steering angle*, (f) *steering addition*, (g) *steering effort*, and (h) *returnability* (refer to Figure 37.1). The steerability is subjectively assessed with steering handwheel torque and vehicle path as output in response to an input of steering handwheel angle. Depending on the zone of a steering input, the steerability is specified as shown in Figure 37.11.

On-center feel, linearity, and steering addition are mild transient steering characteristics. On the other hand, all others are transient characteristics.

37.2.2.1 On-Center Feel

On-center feel is a comprehensive perception on (1) *steering torque* and (2) *vehicle path change* in response to a very slow steering input at and around the center of steering. Figure 37.12 presents the on-center steering torque represented by (a) *friction*, (b) *hollow band*, (c) *compliance*, and (d) *steering feedback*. The vehicle path change (or vehicle turn) is perceived against steering handwheel angle to assess (a) *dead band* and (b) *steering gain* as shown in Figure 37.13. The on-center feel must be clear and exact; otherwise, a driver feels nervous. Since the desirable magnitude of the on-center steering torque is dependent on each customer, it is one of the important items determining a vehicle concept.

The steering friction is initial steering torque at the center of steering. In principle, the least steering friction is desirable. However, it is practically not easy to be achieved. The improvement

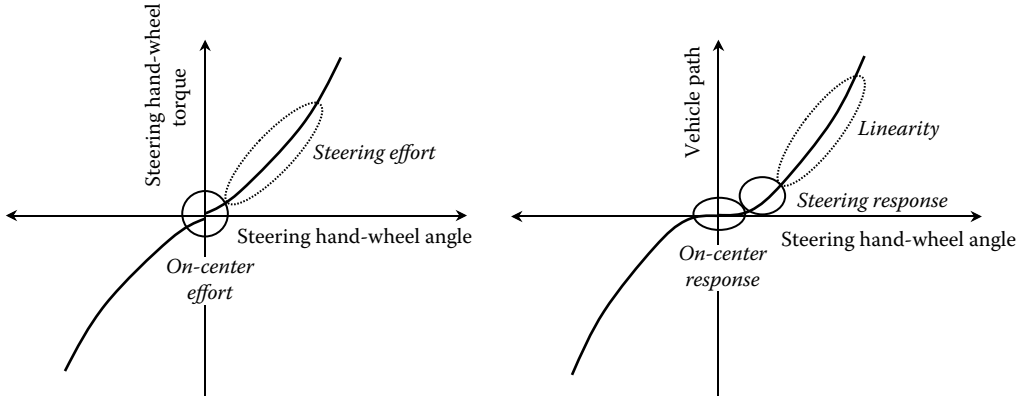

FIGURE 37.11 Steering handwheel torque and vehicle path specifying steerability.

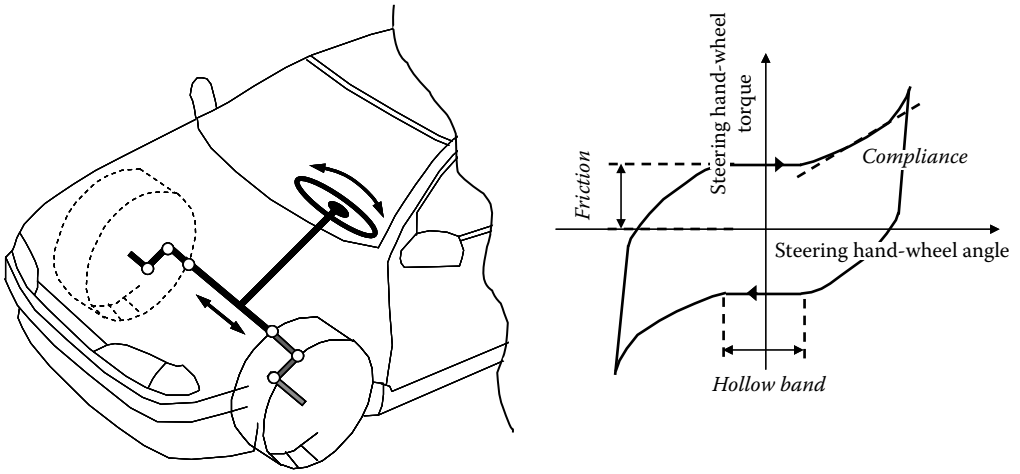

FIGURE 37.12 On-center steering torque.

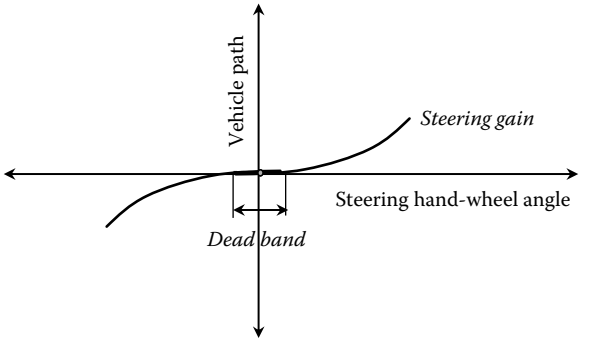

FIGURE 37.13 On-center steering response.

of the steering friction may cause some other drawbacks on steering sensitivity. In the case of big friction, it seriously hurts steering behavior.

With a little steering application from the steering center, the hollow band is sensed as the band of steering looseness caused due to no steering torque generation in addition to the friction. No hollow band is generally pursued. Otherwise, the steering effort is felt just loose around the steering center with a hollow band. In case the hollow band is significantly big, it causes too much time delay of steering response with consequent sudden vehicle path change.

The compliance is assessed with the perception of progressive steering movement against a continuous and smooth incremental steering application from the steering center. The ideal target of this perception is just like the feeling of spring compression. A proper mechanical terminology for this property should be "*stiffness*." However, "*compliance*" may be traditionally used to express the perceptual feeling of the compression.

The dead band is just the band of no vehicle path reaction generated in response to a miniature steering application from the steering center. When no dead band exists, steering corrections are always required corresponding to road irregularity and wind change. It bothers a driver to do so at every instant. On the other hand, a big dead band provokes too much time delay of steering response. It consequently produces rapid vehicle path change, which gets on a driver's nerves.

The steering gain represents a perceptual measure of an output-to-input ratio. It is assessed depending on how big the initial path change of a vehicle is generated from the steering center.

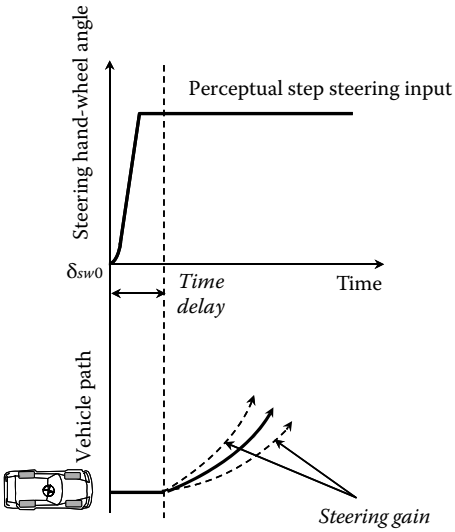

FIGURE 37.14 Off-center steering response.

It requires a proper degree of the sharpness of the vehicle path change (or vehicle turn) depending on a driver's preference, that is, not too big or not too small.

The steering feedback is feedback information transferred to a steering handwheel from tires through a steering system. In the case of good steering feedback characteristics, a driver can feel an interaction between tires and road surface. Then, it helps the driver to predict upcoming road condition. In practice, it is not easy to achieve a great level of the steering feedback characteristic.

37.2.2.2 Steering Response

Steering response is an overall subjective measure of time-dependent vehicle path change against a transient steering input. Figure 37.14 shows the vehicle path versus steering handwheel angle containing (a) *time delay* and (b) *steering gain*. Both time delay and steering gain represent the subjective quality of *agility* of the vehicle path change in time. The steering response is assessed while off-center steering both in straight ahead and in a turn.

The time delay is just a time lag until the first movement of directional change of the vehicle path. Less time delay is usually felt better. The steering gain represents a subjective measure of steering response how fast the initial movement of direction change is developed after its start of generation. It requires a proper degree of the sharpness of the vehicle path change depending on a driver's preference, that is, not too fast or not too slow.

37.2.2.3 Linearity

Linearity is a perceptual impression on the linearity characteristic of trajectory of vehicle path in response to a gradually incremental steering input. Figure 37.15 shows the profile of vehicle path to describe the linear tendency of steering gain. Any change of vehicle attitude is additionally perceived.

Good linearity characteristic requires the linearly progressive change of the vehicle path against the gradually incremental steering input. In addition, it is naturally required constant vehicle attitude. When there exists any disturbance of the vehicle path or attitude, in other words, it is assessed badly.

37.2.2.4 Steering Precision

Steering precision is an overall subjective impression on how accurately a vehicle follows an intended path with a series of steering maneuvers. While path following, the easiness to control the vehicle also affects subjective rating. It is usually evaluated as the characteristic of *precision* or *line*

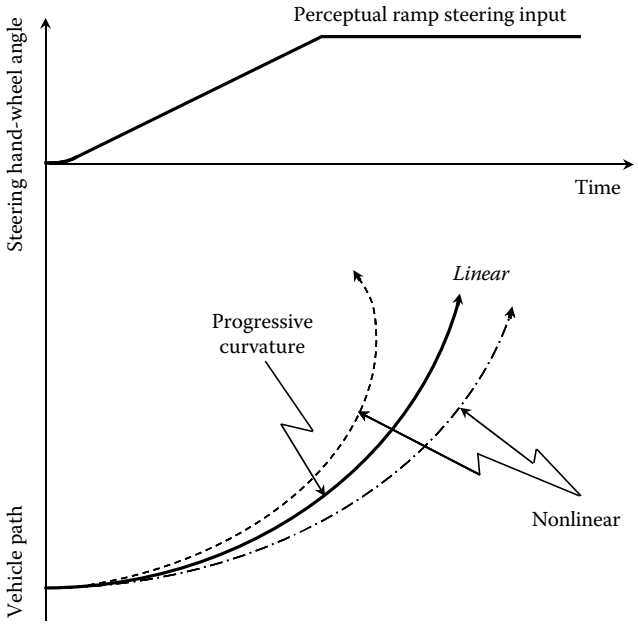

FIGURE 37.15 Linearity.

trace when path following in a handling circuit. In addition, it is judged with the accuracy of lane changing and severe lane changing.

37.2.2.5 Steering Angle

Steering angle is a subjective evaluation of an output-to-input ratio. It is assessed by the amount of steering application to get the same path. In general, the smaller the angle, the better. For example, Figure 37.16 shows the steering gains of a vehicle equipped with two different tire sets. Tire A has faster steering response but needs more steering angle to get the same path change than Tire B. The steering angle is evaluated while off-center steering both in straight ahead and in a turn.

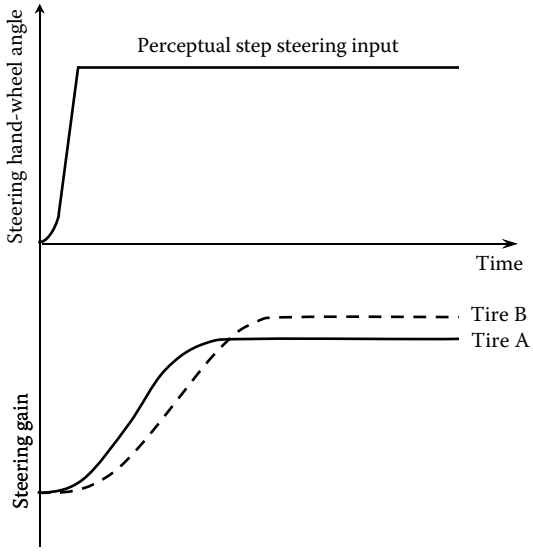

FIGURE 37.16 Steering angle.

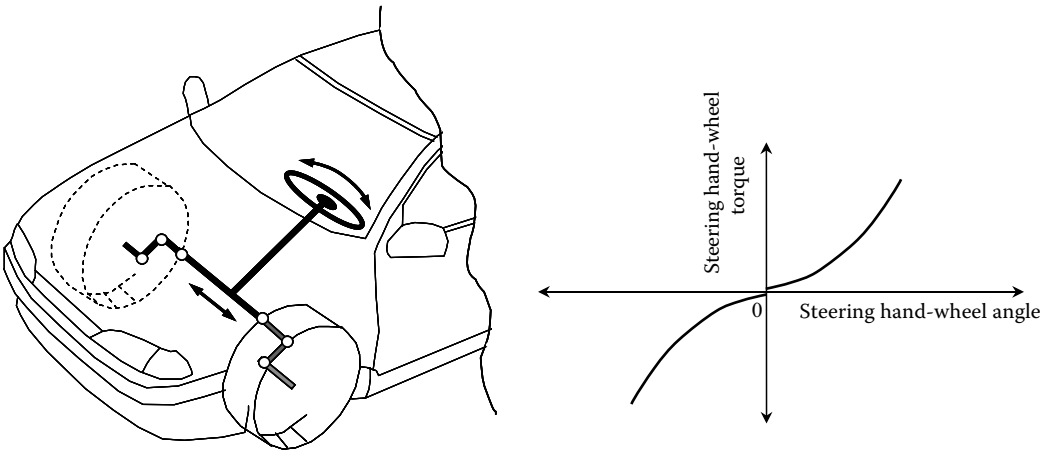

FIGURE 37.17 Steering effort.

37.2.2.6 Steering Addition

Steering addition is a perceptual indicator of additional grip produced when an extra steering input is applied at grip limit in a turn. In this situation, some path change is subjectively assessed. An understeer behaved vehicle usually requires better steering addition characteristic to come back to the intended path in a corner. In general, the more additional grip, the better.

37.2.2.7 Steering Effort

Steering effort is a subjective measure of steering handwheel torque required to change the direction of vehicle path. As shown in Figure 37.17, it should not be too loose or too tight but appropriate for the best *comfort*. The steering effort is assessed through off-center steering both in straight ahead and in a turn.

37.2.2.8 Returnability

Returnability is a perceptual evaluation of quickness and precision of steering handwheel movement returning to its neutral position primarily just after a flick steering input is applied and immediately released (refer to Figure 37.18). It represents the ability of tires to make the steering handwheel come

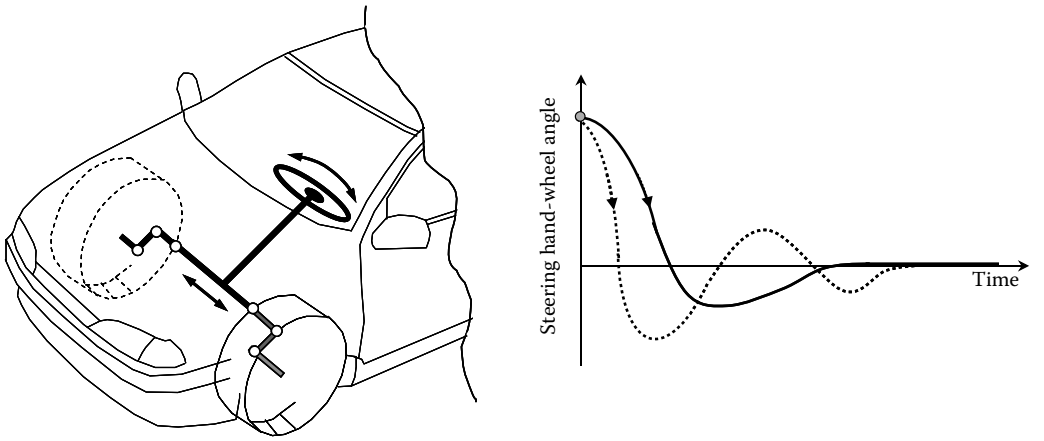

FIGURE 37.18 Returnability.

back directly and smoothly to the steering center after flick steering as well as while exiting a corner. Less oscillation of the steering handwheel and the smoothness of its movement are desirable.

37.2.3 Controllability

Controllability is a psychological assessment of easiness to control a vehicle in following an intended path in a handling circuit or while lane changing. This capability is basically dependent on the grip capabilities of front and rear axles as well as a grip balance between them. The controllability is composed of its five characteristics such as (a) *balance FA/RA*, (b) *power-off reaction*, (c) *grip limit*, (d) *controllability at limit*, and (e) *driving power.*

37.2.3.1 Balance FA/RA

Balance FA/RA is an abbreviation of a *balance* between *front axle grip* and *rear axle grip*. In practice, it stands for a *balance* between *transient understeer* and *transient oversteer* [40–43,45–47]. Through various handling tests, the worst (or maximum) levels of the understeer and oversteer are perceptually evaluated. Then, the balance FA/RA is assessed based on an overall impression on these levels.

As shown in Figures 37.19 and 37.20, the transient understeer and transient oversteer are subjectively assessed in a turn. Both their ideal targets are just *steady-state neutral steer* to exactly follow an ideal

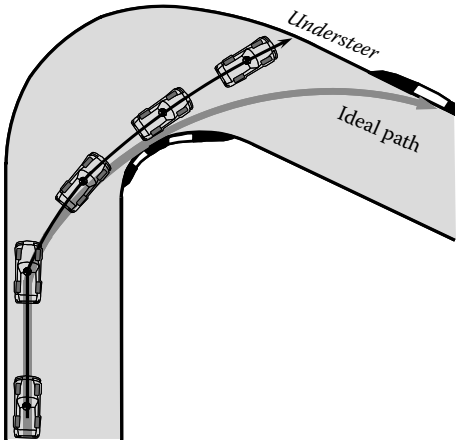

FIGURE 37.19 Transient understeer.

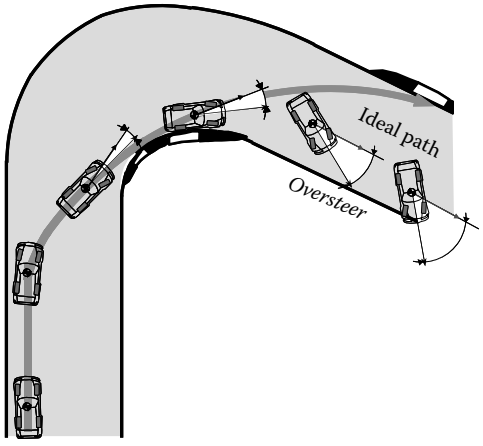

FIGURE 37.20 Transient oversteer.

vehicle path with desirable *vehicle attitude* relatively aligned along the vehicle path in a turn. In other words, the less understeer or oversteer closed to the neutral steer, the better. The vehicle path and attitude are exclusively dependent on the levels of front axle grip and rear axle grip relative to each other.

The transient understeer is a perceptual measurement of front axle grip in a turn. Bigger understeer indicates less front axle grip that provides less capability to precisely follow an ideal vehicle path. It is subjectively assessed as smaller or bigger understeer primarily depending on a smaller or bigger resultant turn, respectively. Each test engineer makes his or her own subjective rating by comparing his or her perceptual vehicle path against his or her own reference value, that is, the vehicle path of the neutral steer.

Similar to the transient understeer, the transient oversteer is a perceptual barometer of rear axle grip in a turn. Bigger oversteer stands for less rear axle grip that induces more slip at a rear axle. Then, it produces outward sway and then bigger vehicle attitude relatively away from vehicle moving direction in a turn. It is subjectively assessed bigger oversteer by estimating driver's perceptual vehicle nose-in attitude relative to his or her own reference value representing the neutral steer. Big oversteer is normally not desirable, because it is more difficult for a normal driver to control a vehicle having a big oversteer tendency.

For example [45], Figure 37.21 shows the transient steer characteristic of a racing car during cornering. It is featured transient understeer and transient oversteer in the zones of the entry and the exit, respectively. In the midcorner where a steady-state condition is usually attained, there exists a transition from the understeer to the oversteer. Since the racing car is equipped with a rear engine and rear driving wheels, it loses some cornering force at a rear axle when it fully accelerates in the exiting zone. That's why this car behaves transient oversteer while exiting in a corner, especially at low-friction surface.

37.2.3.2 Power-Off Reaction

Power-off reaction is a criterion of grip loss of a rear axle caused due to an instantaneous load transfer from the rear axle to a front axle while powering off immediately just after full powering on with fixed steering in a turn (refer to Figure 37.22). The sudden load shift results in an impulsive increase and a simultaneous decrease of cornering forces at the front and rear axles, respectively. The change of cornering forces does quickly increase a yaw moment momentarily producing more vehicle nose-in attitude.

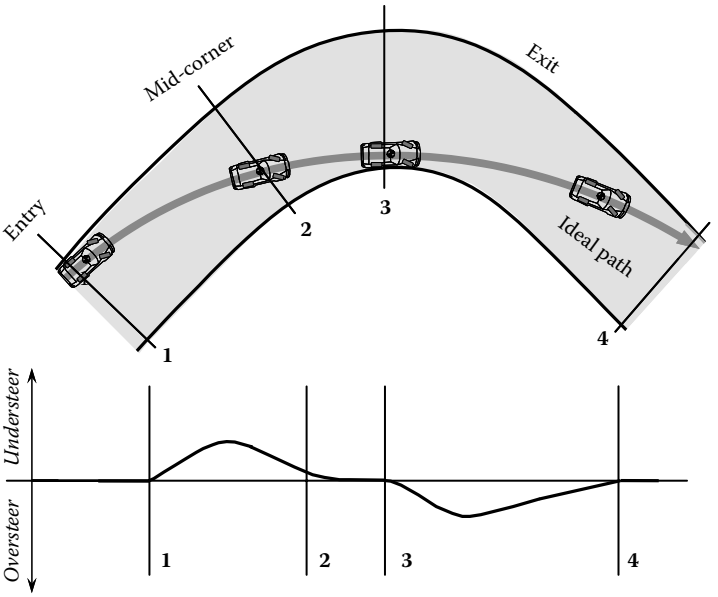

FIGURE 37.21 Transient understeer and oversteer.

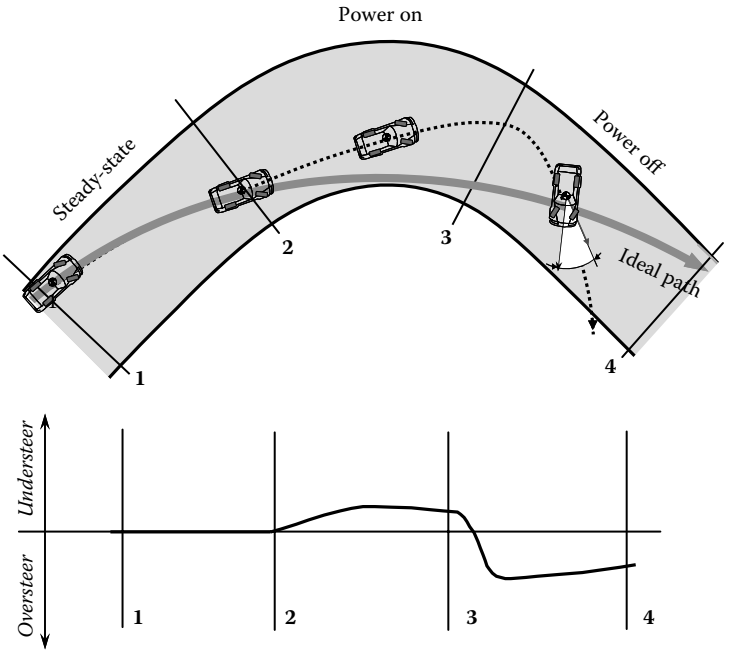

FIGURE 37.22 Power-off reaction steer.

The power-off reaction steer is defined to generally describe the quickness of steer variation from the transient understeer to the transient oversteer as shown in Figure 37.22 [45]. In practice, the power-off reaction steer is subjectively assessed with a driver's perceptual vehicle nose-in attitude change with respect to a time interval from full power on to instantaneous power off. The levels of the understeer and oversteer are additionally evaluated. For better power-off reaction, (a) a slow and smooth power-off reaction steer as well as (b) small transient understeer and (c) small transient oversteer is desirable. It is easy to control a vehicle conducting better power-off reaction behavior.

37.2.3.3 Grip Limit

Grip limit represents the attainable maximum speed in still controlling a vehicle in lane changing or cornering. It is assessed by the speed limit to be achievable at the worst situation. This grip limit is dependent on not only the *grip capabilities* (or cornering forces) of front and rear axles but also their *grip balance*. As shown in Figure 37.23, the cornering forces of the front and rear axles should be more progressive but without their sudden drops beyond the slip angle causing the grip limit for better *predictability*.

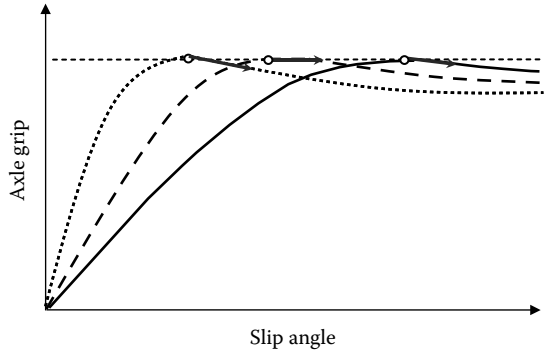

FIGURE 37.23 Different types of limit grip.

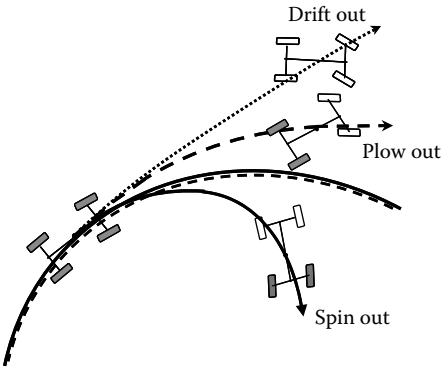

FIGURE 37.24 Limit-grip behavior.

Figure 37.24 presents three different cases of limit-grip behavior depending on the limits of cornering grip such as (a) *plow out*, (b) *spin out*, and (c) *drift out*. The plow out or spin out is caused due to the yaw moment of unbalanced cornering forces at front and rear axles. Specifically speaking, the plow out or spin out does wholly depend on the less grip of the front and rear axles relative to each other, respectively. In case the cornering forces are ideally well balanced, a vehicle does not get either plow out or spin out. It eventually gets drift out at a little higher grip limit that depends on the overall cornering grip of the vehicle.

37.2.3.4 Controllability at Limit

Controllability at limit is an overall impression on how easy to control a vehicle at grip limit. It is ideally preferable to have flat limit grip without its sudden drop so that in advance a driver can prepare for the next situation (refer to Figure 37.23). As slip angle increases, in practice, eventually the limit grip decreases. Some tires behave little oversteer at the grip limit, and it may be easy for a specially trained driver to control a vehicle with them.

37.2.3.5 Driving Power

Driving power is simply a traction ability to speed up while powering on in the exit zone of a corner. With good driving power, a vehicle can rhythmically follow the ideal line of the path in a handling circuit. It provides the perception of *agility* as well as a pleasure of sporty feeling.

37.2.4 Stability

During severe handling maneuver beyond grip limit, a vehicle may get into an unstable condition. With a driver's proper control, in this situation, some vehicles can recover (or converge) to a stable driving condition. Some others diverge to various accidents without recovery. Stability is an ability to make the vehicle come back to a next stable turn or lane change. It is represented by its six characteristics such as (a) *yaw stability*, (b) *rear axle stability*, (c) *roll stability*, (d) *braking stability*, (e) *rollover stability*, and (f) *bump steer.*

37.2.4.1 Yaw Stability

Yaw stability is an ability to keep down the yaw oscillation of a vehicle. The yaw oscillation is principally generated due to an unbalance of the lateral compliances between front and rear axles. In case the roll compliances of front and rear axles are unbalanced with their lateral compliances, the yaw oscillation may be also produced. For instance, if vehicle body roll motion has some phase lag behind vehicle path change, the yaw instability also occurred.

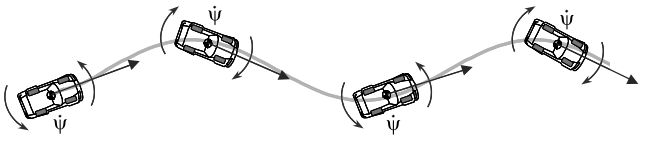

FIGURE 37.25 Yaw stability.

Depending on yaw damping, the cycle number of the yaw oscillation is determined. The fewer the cycles, the better. In practice, the yaw stability is assessed primarily using a perceptual measurement of the oscillation of vehicle path as shown in Figure 37.25.

37.2.4.2 Rear Axle Stability

Rear axle stability is an ability to restrict the sideslip oscillation of a vehicle. This oscillation has occurred due to the lack of rear axle grip relative to front axle grip. For good rear axle stability, the magnitude of the sideslip oscillation should be small enough. In addition, it should be easy to recover. As shown in Figure 37.26, the rear axle stability is evaluated mainly through perceptually measuring the oscillation of vehicle attitude.

37.2.4.3 Roll Stability

Roll stability is an ability to depress the roll oscillation of a vehicle. The excessive roll oscillation is mainly due to an improper balance of the roll compliance of the vehicle. Both the magnitudes of roll oscillation and roll damping are important for roll stability (refer to Figure 37.27). In practice, a driver's subjective rating on the roll stability is additionally influenced by vehicle pitch oscillation. The driver cannot completely separate the vehicle roll from the vehicle pitch only using one's perception without an objective measurement. The roll stability is assessed by using a perceptual measurement on the oscillation of vehicle body motion.

37.2.4.4 Braking Stability

Braking stability is an ability to stop a vehicle without any disturbance of vehicle attitude or path while full braking in a turn. With bad braking stability, a vehicle stops with the misalignment of vehicle heading direction along an intended path. The braking stability is assessed by perceptually evaluating the disturbance(s) of the vehicle attitude and/or path.

37.2.4.5 Rollover Stability

Rollover stability is an ability to restrain a vehicle from its rollover motion (refer to Figure 37.28). In general, the rollover gets into a fatal accident. Therefore, these days, it is a hot issue to automotive

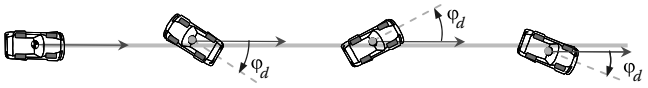

FIGURE 37.26 Rear axle stability.

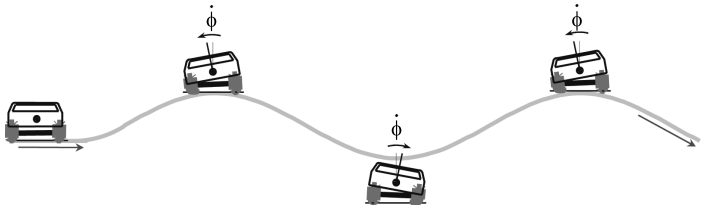

FIGURE 37.27 Roll stability.

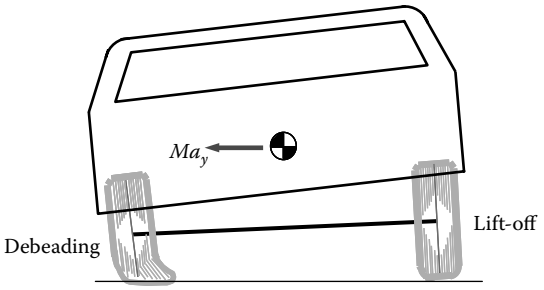

FIGURE 37.28 Rollover stability.

makers as well as tire makers. In order to assess the rollover stability, both the debead of a tire(s) from a rim(s) and the separation of a tire(s) from road surface are subjectively or objectively checked through a series of specially designed rollover tests.

37.2.4.6 Bump Steer

While a vehicle is running over bumps, its toe is constantly changed due to the jounce and rebound of each front suspension (refer to Figure 37.29). In this case, steer instability may occur. In that case, the vehicle cannot follow an indented path in a turn. Instead, the vehicle follows disturbed paths, and it requires continuous steering corrections to come back to the intended path. This steer instability is called bump steer.

37.2.5 Comfortability

Comfortability belonged to the areas of both vehicle dynamics and noise, vibrations, and harshness (NVH). The vehicle dynamics deals only the vibrations of sprung and unsprung masses. On the other hand, the NVH represents the vibrations of flexible components. In this handbook, the comfortability representing ride performance is limited only within the scope of the vehicle dynamics. The comfortability is composed of (a) *primary ride*, (b) *secondary ride*, and (c) *impact ride*.

37.2.5.1 Primary Ride

Primary ride is the vibratory characteristic of a sprung mass associated with the principal stiffnesses of tires occurred while driving on a wavy road. Its frequency ranges up to about 5 Hz, which includes some frequency band inducing motion sickness. The specific range is wholly dependent on the size of a vehicle. In general, the primary ride is principally represented by *body bounce*. But it may be specifically categorized into several zones of frequency ranges.

37.2.5.2 Secondary Ride

Similar to the primary ride, secondary ride is the vibratory characteristic of unsprung masses supported with the principal stiffnesses of tires generated while driving a rough road. Its frequency ranges from about 5 to 25 Hz. Its range is also dependent on the size of a vehicle. Similar to the

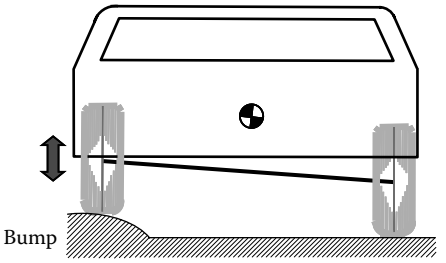

FIGURE 37.29 Bump stability.

primary ride, the secondary ride is generally represented by *wheel hop*. However, it can be specifically divided into several zones of frequency ranges.

37.2.5.3 Impact Ride

Impact ride is wholly determined by an impact shock(s) due to the enveloping characteristic(s) of a tire(s) while driving over various impact objects. In general, it is called *impact harshness*. Its frequency usually ranges from about 25 to 60 Hz (at most 100 Hz). The impact ride does not include the local vibratory characteristic of tire components, which produce higher-frequency vibrations belonging to an NVH scope. In reality, a driver's subjective assessment on the impact ride is also influenced by audible high frequencies in addition to tactical low frequencies.

The impact ride is generally characterized as (a) *impact magnitude*, (b) *impact sharpness*, and (c) *after-impact damping*. The impact magnitude is just the size of an impact shock. The impact sharpness is the level of sharpness (or acuteness) of the impact shock, which ranges from round to sharp. The after-impact damping is the amount of damping to kill the vibration of a tire itself after impacting. The smaller the magnitude, the less the sharpness, or the more the damping, the better.

37.3 SUBJECTIVE TEST

Dry handling and ride performances are assessed through five *maneuvers* such as (a) *straight ahead*, (b) *steering*, (c) *lane changing*, (d) *cornering*, and (e) *riding* as shown in Figure 37.30 [40–43]. Each maneuver is composed of several *tests*. For the purpose of evaluating wet handling, however, only some tests are usually selected dependent on each company. In Table 37.1, a cross-functional relationship between subjective assessment and subjective test is illustrated using a cross-functional matrix of capabilities and maneuvers. In Tables 37.2 through 37.6, these matrices are shown in details as cross functions of characteristics against tests.

For each test, both *curb weight with a driver* (or *unladen*) and *gross vehicle weight (GVW)* (or *fully laden*) conditions are in general used. However, it is wholly depending on each automaker or tire company. Each test condition and procedure is individually described as follows.

37.3.1 Straight-Ahead Maneuver

A straight-ahead maneuver is composed of four tests of straight-ahead driving with (a) *free steering*, (b) *fixed steering*, (c) *powering on/off*, and (d) *braking*. These tests are designed for the purpose of assessing straightability.

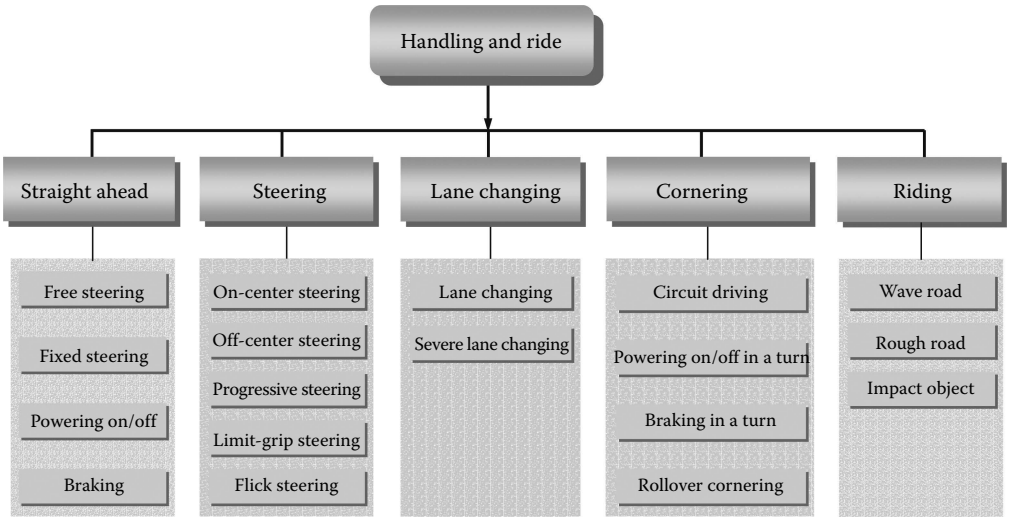

FIGURE 37.30 Subjective test for the assessment of dry handling and ride performances.

37.3.1.1 Free Steering in Straight Ahead

A free-steering-in-straight-ahead test is targeted to check whether or not a vehicle can run in straight ahead with free steering at constant speed. Its purpose is to examine the *residual pull* characteristic of the suspension system, steering system, and tires of a vehicle (refer to Figure 37.8). The summary of test condition and procedure is given as

Driving speed: Constant speed usually at 100 kph with a high gear.
Steering input: Free steering at the center steering.
Procedure: Start free steering from the exact center steering point after removing a static friction effect.

37.3.1.2 Fixed Steering in Straight Ahead

A fixed-steering-in-straight-ahead test is designed to find the *running straight* characteristic of a vehicle to run in straight ahead without any drift, wander, or sloppiness at constant speed (refer to Figure 37.9). This lateral deviation is caused due to suspension sensitiveness against road irregularity or wind change. For this test, fixed steering is employed as

Driving speed: Constant speed up to limit.
Steering input: Fixed steering at the center steering.
Procedure: Start fixed steering from the exact center steering point after removing a static friction effect.

37.3.1.3 Powering On/Off in Straight Ahead

The purpose of a powering-on/off-in-straight-ahead test is to evaluate the *torque steer* characteristic of a vehicle. The torque steer is subjectively determined by the degree of drifting motion of the vehicle with fixed steering (refer to Figure 37.10). In general, the vehicle drifts to an adjacent lane with full power on and returns to the original lane with instantaneous power off.

In order to find the defect of a power train system, second transmission gear is employed. On the other hand, a higher gear is used to examine the flaw of tires:

Driving speed: 40 kph with second gear and 80 kph with a higher gear.
Steering input: Fixed steering at the center steering.
Procedure: Apply full power on and then suddenly lift throttle off in straight ahead.

37.3.1.4 Braking in Straight Ahead

Through a braking-in-straight-ahead test with hands-on steering, the *braking straight* characteristic of a vehicle is subjectively measured after complete stop. The braking straight is usually represented

by the degree of deviation of vehicle attitude. Soft hands-on steering should be applied so that steering disturbance is also detected at the end of braking process:

Driving speed: 100 kph or normal driving speed.
Steering input: Soft hands-on steering at the center steering.
Procedure: Apply full braking in straight ahead until complete stop with VDC (also called ESP or ESC) turned off.

37.3.2 Steering Maneuver

In order to evaluate the steering behavior of a vehicle, steering maneuver is specially designed. In general, it consists of five steering tests such as (a) *on-center steering*, (b) *off-center steering*, (c) *progressive steering*, (d) *limit-grip steering*, and (e) *flick steering*. For these tests, basically both clockwise and counterclockwise directions of steering input are applied. These processes are repeated a few times until subjective assessment is complete.

In this handbook, "*perceptual*" is used to describe a ramp, step, impulse, or sinusoidal steering input, so that a perceptual one is distinguished from a mechanical one. For example, a perceptual ramp steering input is not a real ramp steering input, but only it is perceived like a ramp steering input.

37.3.2.1 On-Center Steering

Through an on-center steering test, *on-center feel* at and around the center of steering is subjectively assessed (refer to Figures 37.12 and 37.13). Since the on-center feel is a kind of microscopic property, it is very important that vehicle speed should be kept constant during the whole test process. In addition, the application of an on-center steering input must be very gentle and precise in order to feel the on-center steering behavior of a vehicle.

For this test, a slow perceptual ramp steering input with its miniature magnitude from the steering center to one direction is applied while driving in straight ahead. After releasing a steering handwheel in order to return to straight running again, the same amount of the steering input from the steering center to the other direction is employed. In case these steps are repeated for several cycles, the steering input looks like a weave steering input, which eventually produces the profile of steering torque:

Driving speed: Constant speed up to limit.
Steering input: Miniature *slow perceptual ramp* steering.
Procedure: Apply a steering input from the steering center in straight ahead.

37.3.2.2 Off-Center Steering

The purpose of an off-center steering test is to assess (a) *steering response* and (b) *steering effort* while driving both in straight ahead and in a turn (refer to Figures 37.14 and 37.17). This test contains two different test methods. The first method requires a small perceptual step steering input while driving in straight ahead. In addition, the second method employs the steering input in a turn. It is important that this test requires very clear steering stop just after the application of the perceptual step steering input in order to measure the time delay of vehicle turning reaction after the steering input:

Driving speed: Constant speed up to limit.
Steering input: Small *perceptual step* steering.
Procedure: Apply a steering input both in straight ahead and in a turn.

37.3.2.3 Progressive Steering

While slowly crossing double or triple lanes (the wider, the better), a progressive steering test is carried out. Its purpose is to evaluate the *linearity* characteristic of vehicle path reaction against a

gradually incremental steering input (refer to Figure 37.15). This test requires a big or middle perceptual ramp steering input while driving in straight ahead:

Driving speed: Constant speed up to limit.
Steering input: Big or middle *perceptual ramp* steering.
Procedure: Apply a steering input in straight ahead.

37.3.2.4 Limit-Grip Steering

A limit-grip steering test is designed to evaluate *steering addition* to find whether or not tires can produce an additional cornering force during limit-grip cornering in a handling circuit. Sometimes, a driver wants to have some more turn(s) in the middle of a corner in order to drive an understeer behaved vehicle back to an intended path or overcome any uncertainty of driving condition. For this test, a small perceptual ramp steering input is additionally applied at the limit grip in a corner. Thereafter, vehicle path change is observed:

Driving speed: Constant speed at limit.
Steering input: Small *perceptual ramp* steering.
Procedure: Apply a steering input at grip limit in a corner.

37.3.2.5 Flick Steering

When a vehicle is running in straight ahead, a flick steering input is applied with 90° of steering handwheel angle away from the steering center. Then, immediately, the vehicle gets imposed into an unstable situation with yaw oscillation. In case the yaw oscillation is damped out, the vehicle can get back to a stable driving condition. Otherwise, the yaw oscillation may be amplified to eventually spin out as shown in Figure 37.24. This recovery characteristic is dependent on the self-aligning moment, front–rear lateral compliance balance, roll compliance, and rear axle grip of tires including corresponding vehicle subsystems.

Through the flick steering test, the recovery characteristic is subjectively assessed in terms of (a) *returnability*, (b) *yaw stability*, and (c) *roll stability* (refer to Figures 37.18, 37.25, and 37.27). In the case of critically bad rear axle grip, (d) *rear axle stability* may be supplementarily evaluated (refer to Figure 37.26). Especially, the test is designed to mainly evaluate the yaw stability distinctively against the rear axle stability. For this test, a perceptual impulse (or flick) steering input is applied such that 90° of steering handwheel angle is turned from the steering center as quickly as possible while driving in straight ahead and then immediately the steering handwheel is released free. Afterward, observe the returning motion of the steering handwheel and vehicle reaction as well:

Driving speed: Constant speed up to limit.
Steering input: 90° of *perceptual impulse* steering.
Procedure: Apply a steering input from the steering center and then immediately release the steering handwheel in straight ahead.

37.3.3 Lane-Changing Maneuver

In practice, lane changing is most frequently operated as a handling maneuver in highways and public roads. Depending on its severity, the lane changing induces the modes of controllability and stability. This maneuver is usually composed of two tests of (a) *lane changing* and (b) *severe lane changing.*

37.3.3.1 Lane Changing

The purpose of a lane-changing test is in general to pass over a vehicle appeared in front at a highway as well as a freeway as shown in Figure 37.31. While lane changing, both controllability and stability are mainly evaluated by checking transient understeer and oversteer tendencies and stability characteristics. Through this test, (a) *balance FA/RA*, (b) *grip limit*, (c) *controllability at limit*,

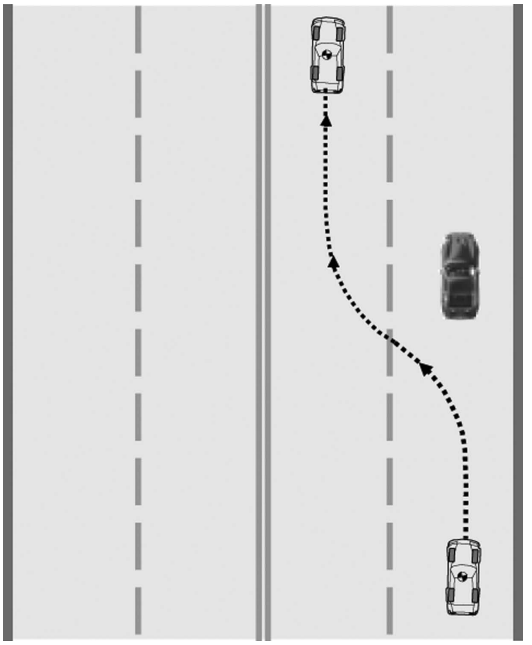

FIGURE 37.31 Lane changing.

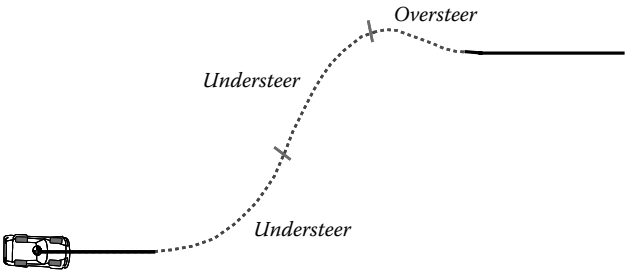

FIGURE 37.32 Steer characteristic during lane changing.

(d) *yaw stability*, (e) *rear axle stability*, and (f) *roll stability* are assessed (refer to Figures 37.19, 37.20, 37.23, 37.24 through 37.27).

The lane-changing test basically contains two consecutive turns in opposite directions in order to cross a single lane. For example, as shown in Figure 37.32, a vehicle is initially turning left and then is turning right in order to run straight in the next left lane. In general, a vehicle behaves *transient understeer* in the first and second turns. *Transient oversteer* is subjectively assessed at the end of the lane changing as shown in Figure 37.32. In order to achieve two consecutive turns, three phases of steering handwheel operations are needed such as (a) left-hand-side steering, (b) steering from the left-hand side to the right-hand side, and (c) left-hand-side steering to the center of steering.

For this test, the angle of a steering handwheel ranges between around ±45°. In addition to this constrained steering input, there exists another constraint that a test engineer should keep vehicle lateral movement within the next lane. Depending on the reaction of vehicle path change in response to each steering application, the speed of the next steering application should be properly adjusted. In case the vehicle has bad lane-change behavior, it requires an additional steering input to come back to the path:

Driving speed: Constant speed up to limit.
Steering input: 45° of *perceptual sinusoidal* steering.

Procedure: Apply three consecutive steering input with constant throttle ideally as

$$\text{center} \xrightarrow{\pm 45^\circ} \frac{R45^\circ}{L45^\circ} \xrightarrow{\mp 90^\circ} \frac{L45^\circ}{R45^\circ} \xrightarrow{\pm 45^\circ} \text{center}$$

37.3.3.2 Severe Lane Changing

For the purpose of avoiding a vehicle not to run over an object, such as a child or a ball, suddenly appeared in front, severe lane changing is required as shown in Figure 37.33. In this kind of an emergency situation, a driver normally tends to instantly lift throttle off. When only a single lane exists in each direction, once the vehicle moves to the next lane, then it should immediately return to the original lane. Since the vehicle totally crosses two lanes, more often, severe lane changing is called double-lane changing.

Through the severe lane-changing test, (a) *balance FA/RA*, (b) *grip limit*, (c) *controllability at limit*, (d) *rear axle stability*, and (e) *roll stability* are mainly assessed (refer to Figures 37.19, 37.20, 37.23, 37.24, 37.26, and 37.27). In case a front–rear lateral or roll compliance balance is very bad, (f) *yaw stability* is additionally evaluated (refer to Figure 37.25). Particularly, the rear axle stability is distinctively evaluated through this test, while the yaw stability is assessed through a flick steering test.

The severe lane changing test is basically composed of three consecutive turns. For example, as shown in Figure 37.34, it is assumed that a vehicle turns a left lane and then backs to the original lane. The severe lane-change process is done through (a) the first turn to about halfway to the left lane, (b) the second turn to the left lane and then continuously back to the original lane, and (c) the last turn to run straight in the original lane. The vehicle usually behaves *transient understeer* in the beginning of every turn, but it may behave *transient oversteer* in the first turn due to sudden power off even at 80 kph. In general, the *transient oversteer* is subjectively evaluated at the ends of the second and third turns.

In order to achieve these three turns, five phases of steering handwheel operations are needed such as (a) initially left-hand-side steering, (b) steering from the left-hand side to the right-hand side, (c) fixed steering with about 90° of steering handwheel angle for a steady-state turn, (d) left-hand-side steering to make vehicle path straight, and then (e) right-hand-side steering back to the center of steering. In addition, some more steering corrections may be needed depending on vehicle performance. The steering handwheel angle is supposed to range between about ±90°.

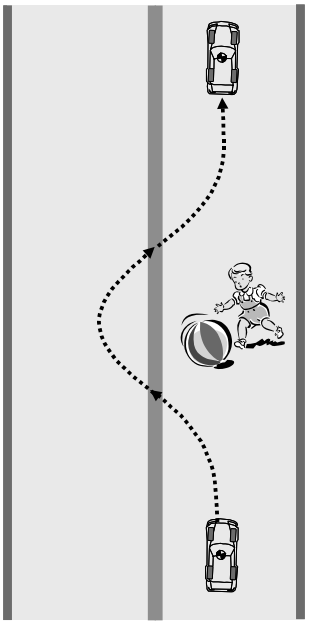

FIGURE 37.33 Severe lane changing.

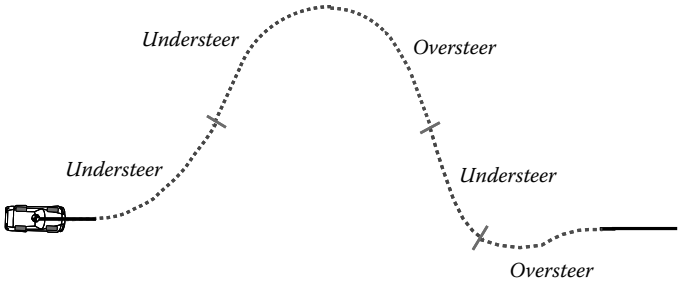

FIGURE 37.34 Steer characteristic during severe lane changing.

Similar to the lane changing, there exist two constraints of the steering handwheel angle and vehicle lateral movement restricted only within two adjacent lanes. The speed of each steering application and the duration of the fixed steering are appropriately determined based on vehicle path reaction in response to the previous steering application:

Driving speed: 80 kph.
Steering input: 90° of *perceptual sinusoidal* steering.
Procedure: Apply four consecutive steering inputs starting with instant power off ideally as

$$\text{center} \xrightarrow{\pm 90^\circ} \begin{matrix} R90^\circ \\ L90^\circ \end{matrix} \xrightarrow{\mp 180^\circ} \begin{matrix} L90^\circ \\ R90^\circ \end{matrix} \xrightarrow{\pm(90^\circ + \Delta\delta_{sw})} \begin{matrix} R\Delta\delta_{sw} \\ L\Delta\delta_{sw} \end{matrix} \xrightarrow{\pm \Delta\delta_{sw}} \text{center}$$

37.3.4 Cornering Maneuver

Cornering maneuver is just normally driving in corners such as an entrance to a highway, an exit from a highway, or an interchange between highways or public roads. Through this maneuver, (1) steerability, (2) controllability, and (3) stability are usually investigated. The maneuver consists of four tests of (a) *circuit driving*, (b) *powering on/off in a turn*, (c) *braking in a turn*, and (d) *rollover cornering*. During cornering maneuver, sometimes a vehicle plows out, spins out, or drifts out of a course. In this situation, it is required to control the vehicle to come back to the course in order to avoid any accident.

In order to control a vehicle while sliding at or beyond grip limit, at least the effective heading and moving directions of the vehicle itself, front tires, and rear tires must be perceived at any instant. In a transient turn, these two directions of each component are normally seldom coincided. The moving directions of the vehicle, front tires, and rear tires are dependent on each other. The effective heading direction of the rear tires is about along that of the vehicle in the case of a front-wheel-steering car. However, the effective heading direction of the front tires is completely controlled only by a steering input.

For the purpose of explaining the mechanism of how to control a vehicle while sliding, two cases are discussed here:

1. Sliding at or beyond grip limit
   When a vehicle plows out, spins out, or drifts out at or beyond grip limit as shown in Figure 37.35, steer a steering handwheel to align the effective heading direction of front tires along the moving direction of a vehicle so that slip angles at the front tires become about zero. For that purpose, continuously adjust a steering handwheel to make the self-aligning moment of a front axle be nearly zero. Once the vehicle is controlled from sliding, steer the steering handwheel appropriately to follow an intended path.

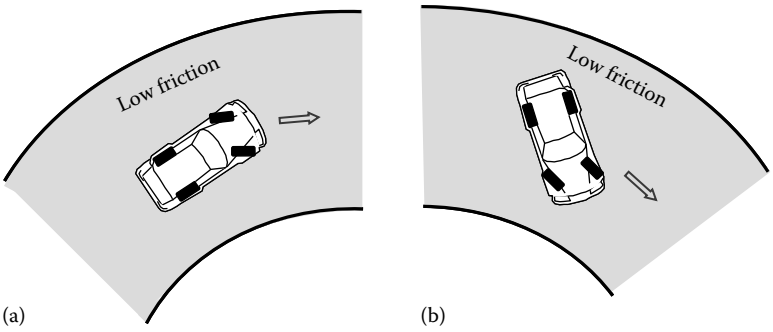

FIGURE 37.35 Control of a vehicle by aligning the heading direction of front tires along vehicle moving direction. (a) No sliding and (b) spin out.

2. Crossing from low friction to high friction
   Within low friction surface, follow exactly the same procedure of the previous case as shown in Figure 37.35. When front tires are crossing from low-friction surface to high-friction surface such as from wet surface to dry surface as shown in Figure 37.36a, hold a steering handwheel to keep the front tire heading direction along the vehicle moving direction. As soon as the front tires have entered the high-friction surface as shown in Figure 37.36b, immediately

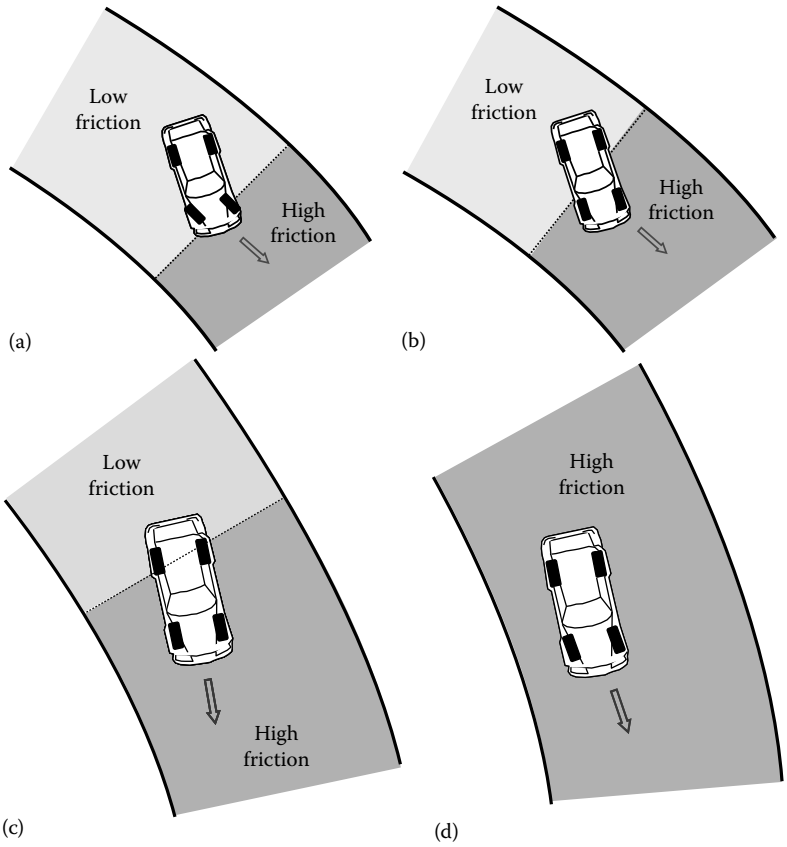

FIGURE 37.36 Control of a vehicle by aligning front tires while crossing from low-friction surface to high-friction surface. (a) Crossing of front tires, (b) just after crossing of front tires, (c) crossing of rear tires, and (d) following an intended path.

readjust the steering handwheel to align the front tire heading direction along the vehicle heading direction in order to make a turn.

As a result, the vehicle moving direction becomes aligned along about the vehicle heading direction as much as possible. In other words, the vehicle moving direction becomes along close to the effective heading direction of rear tires so that slip angles at the rear tires become as small as possible. When the rear tires are crossing from the low-friction surface to the high-friction surface as shown in Figure 37.36c, just keep the same steering handwheel angle so that slip angles at the rear tires become nearly zero. Immediately after the rear tires have entered the high-friction surface as shown in Figure 37.36d, follow an intended path using normal steering maneuver.

It is noted that at the low-friction surface, a longitudinal load shift has not much occurred due to power on/off or braking in a turn so that the load shift does not much induce the loss of cornering grip (refer to Figures 37.3b and 37.4b). Instead, the effect of a friction ellipse concept is much significant on the cornering grip loss (refer to Figure 37.5). At the high friction, however, the effect of the load transfer on the cornering grip loss is much bigger than that of the friction ellipse concept.

37.3.4.1 Circuit Driving

A circuit driving test is mainly targeted to make an overall assessment on path following characteristic that is also called *line trace*. This test in a handling circuit is also called a *road course test*. Through the test, (a) *steering precision*, (b) *steering angle*, (c) *steering effort*, (d) *returnability*, (e) *balance FA/RA*, (f) *grip limit*, (g) *controllability at limit*, and (h) *driving power* are subjectively evaluated (refer to Figures 37.16 through 37.20, 37.23, and 37.24). In order to do the circuit driving test successfully, the maneuvers of braking, gear changing, and steering must be properly done.

Figure 37.37 presents a standard cornering procedure in a handling circuit. An ideal path in a corner is always pursued based on the principle of "*creating the biggest turning radius*," so that the maximum exiting vehicle speed is achieved. For that purpose, a driver must directly target to drive ahead to three points: (1) an entering point in straight ahead or from the exiting point of the just previous corner, (2) an apex (or a clipping point) directly headed from the entering point, and (3) an exiting point directly forwarded from the apex. The cornering procedure contains four phases such as (a) approaching a corner, (b) turning in a corner, (c) holding in a steady-state turn, and (d) exiting in a corner.

While approaching a corner, entering vehicle speed should be appropriately adjusted through braking. During turning in a corner, a steering handwheel angle is progressively increased with constant throttle at limit speed. Afterward, steady-state cornering is carried out until reaching the apex. In order to exit in a corner from the apex to the exiting point, full power on is generally applied to get the maximum vehicle speed. During this exiting phase, the steering handwheel

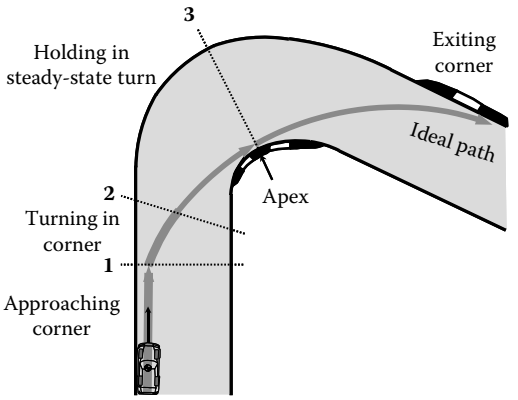

FIGURE 37.37 Circuit driving.

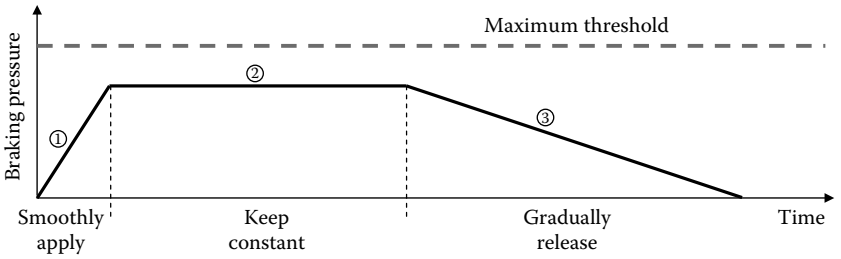

FIGURE 37.38 Braking process.

angle is gradually released by using self-aligning moment, which makes a steering handwheel naturally return to a steering center point.

Before entering a corner, a proper braking process is first carried out to reduce vehicle speed. As shown in Figure 37.38, the process is composed of three steps: (1) smoothly apply braking pressure, (2) keep constant braking pressure until getting intermediate desired speed, and (3) gradually release the braking pressure to get the final desired speed. The same level of constant braking pressure is targeted before entering all corners in a handling circuit. The application of braking just before running over any impact object should be avoided.

While braking, a gear downshift is complete. When the gear downshift is carried out from a higher gear to a lower gear, it is necessary to raise engine rpm so that there causes no shock to a drive line. A professional way to do the gear downshift is called *heel and toe* as shown in Figure 37.39. For that purpose, the right foot of a driver is on both a brake pedal and a throttle pedal, while the left foot is on a clutch pedal. Specifically speaking, while the toe of the right foot is still on the brake pedal, its heel is turned to the throttle pedal. Then, rotate the heel to flip the throttle pedal to increase the engine rpm while keeping braking with the toe. Afterward, the gear downshift can be smoothly done without any shock.

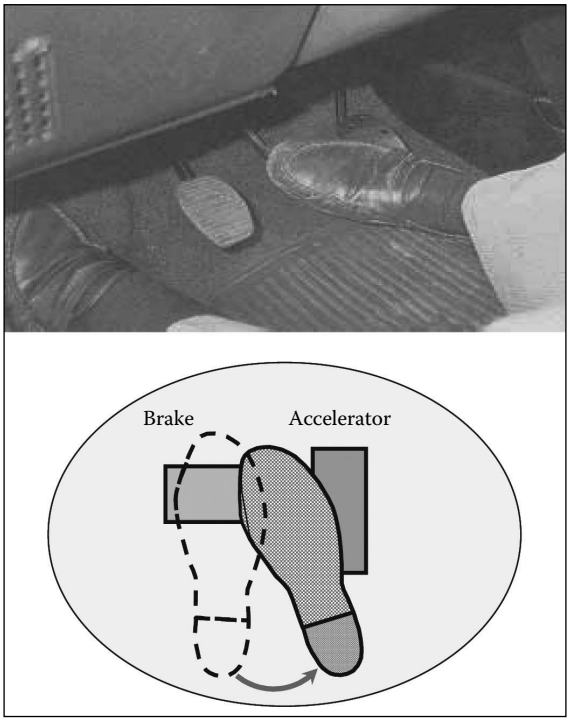

FIGURE 37.39 Heel and toe.

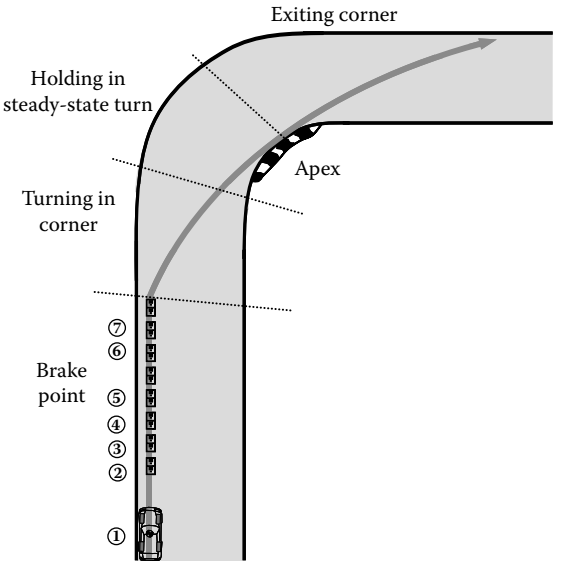

FIGURE 37.40 Gear downshift and other procedure during circuit driving.

As shown in Figure 37.40, the process of gear downshift before cornering is summarized as

1. Approach to a corner
2. Start to brake
3. Declutch and simultaneously gear shift down while keeping braking
4. Flip throttle on to match engine rpm while keeping braking, or keep throttle on until the rpm is adjusted
5. Immediately release clutch
6. Keep constant throttle on up to the entry point
7. Turn in while keeping constant throttle on

In case the engine rpm matching is not appropriate in Step 4, a vehicle shock is induced in Step 5. If a clutch is released too early, a forward shock is caused due to too high engine rpm. If it is delayed to release the clutch, on the other hand, a rearward shock occurred due to not enough engine rpm.

For the purpose of series of steering applications to follow an intended path in a handling circuit, the proper operation of a steering handwheel is necessary. The angle between two hands on a steering handwheel is desired to keep about 150° in any situation as shown in Figures 37.41 and 37.42. Each arm is supposed to keep bent about 120° of angle between its upper and lower parts. It is important to note that at every corner, a hands-on steering application is required in order to be gradually increased and be smoothly released during turning in and exiting in a corner, respectively.

In case of steering to the right-hand side shown in Figure 37.41, the left and right hands are turned from (a) and (b) of Phase 1 to (c) and (d) of Phase 2, respectively. Afterward, the left hand is relocated to (e) of Phase 3, and then the right hand is shifted to (f) of Phase 4. For the left-hand-side steering, the similar process to the right-hand-side steering is applicable as shown in Figure 37.42. The right hand is located from (b) of Phase 1 to (d) of Phase 2 and then to (e) of Phase 3. The left hand is moved from (a) of Phase 1 to (c) of Phase 2 and finally to (f) of Phase 4.

The condition and process of a circuit driving test are summarized as

Driving speed: Limit speed.
Steering input: Path following steering.

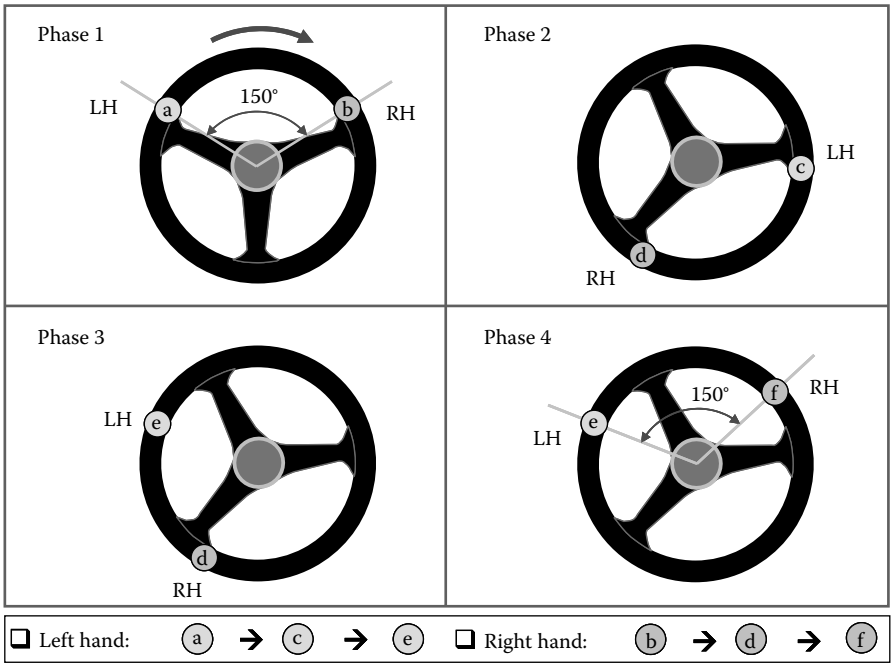

FIGURE 37.41 Steering to right-hand side.

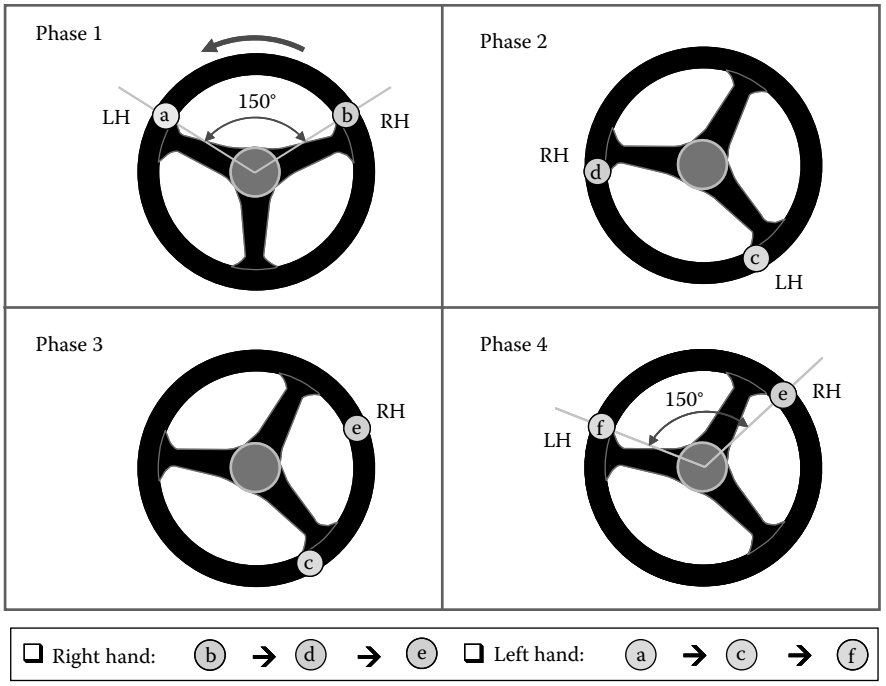

FIGURE 37.42 Steering to left-hand side.

Procedure: Make a corner turn as follows (refer to Figure 37.40):

1. Brake and downshift to a lower gear in straight ahead before entering a corner
2. Approach in a corner toward an outer curve line
3. Follow along the outer curve line with constant throttle
4. Turn toward an apex (or a clipping point) with constant throttle
5. Hold a steady-state turn with fixed steering and constant throttle
6. Exit in the corner toward an outer curve line with power on

37.3.4.2 Powering On/Off in a Turn

While we are entering in a corner from straight driving at high speed, from time to time, we realize that our entering vehicle speed is too high to make a safe turn. In that situation, in general, a normal driver immediately lifts throttle off in order to reduce the speed. Then, there exists an instantaneous load transfer from a rear axle to a front axle. This load transfer causes the loss of rear axle grip and instead adds more to front axle grip, which sometimes makes serious oversteer tendency due to a rear axle's swing out (refer to Figure 37.22).

The main purpose of a powering-on/off-in-a-turn test is to evaluate *controllability* to overcome a *load transfer effect* from a rear axle to a front axle when momentarily throttle changing in a turn. In addition, *stability* is also assessed in the worst case. For that purpose, (a) *balance FA/RA*, (b) *power-off reaction*, (c) *controllability at limit*, (d) *driving power*, and (e) *rear axle stability* are subjectively measured (refer to Figures 37.19, 37.20, 37.22, 37.24, and 37.26). In the case of a front-wheel-driving car, in general, full power on increases understeer tendency, but it reduces understeer tendency with a rear-wheel-driving car.

A sudden transition from full power on to power off causes an impulsive load shift, which results in an instantaneous decrease and an increase to the cornering forces of a rear axle and a front axle, respectively. The change of the cornering forces does quickly increase a yaw moment momentarily producing big oversteer. It should be considered that steering corrections are needed to bring the vehicle back on a course:

Driving speed: Limit speed.
Steering input: Fixed steering.
Procedure: Apply full power on before limit speed in a turn and momentarily power off at the limit speed.

37.3.4.3 Braking in a Turn

A braking-in-a-turn test is carried out in order to guarantee the *braking stability* of a vehicle under full braking in a turn. For that purpose, the deviation(s) of vehicle attitude or/and path is checked after complete stop. In the worst case, the vehicle gets out of a course. In consequence, it may get in an accident.

Since there usually exists a little time delay until full braking, a load transfer from a rear axle to a front axle due to braking is not as severe as powering on/off. The braking itself also reduces vehicle speed, and then it drops oversteer tendency. In addition, the unequal reductions of cornering forces at front and rear tires induced due to braking change steer characteristic. It should be considered that steering corrections are needed to bring the vehicle back on a course:

Driving speed: Limit speed.
Steering input: Fixed steering.
Procedure: Apply full braking in a turn until complete stop working or with VDC turned off.

37.3.4.4 Rollover Cornering

When a vehicle gets in an emergency situation, in general, a normal driver unconsciously applies a quick and big steering input in order to avoid an accident. In sequence, another rapid and big

countersteering input may be employed in the other direction. The inappropriate steering input makes the vehicle in a prompt turn, which causes a full load transfer from inner tires to outer tires. Depending on the rollover stability characteristic of the vehicle, roll vibration is either damped out or amplified to a rollover situation.

A rollover (cornering) test evaluates the *rollover stability* of a vehicle using specially designed test methods. For that purpose, a few test methods are so far used in practice. In this handbook, only the NHTSA rollover test method is introduced, because the others are for companies' own usages. It should be noted that this test is just an objective test operated by a steering (robot) machine to overcome its procedural difficulty. As the NHTSA's NCAP rollover rating system [48], this method consists of two processes: (1) a pretest to find a required steering input for the main test and (2) the main test to evaluate the rollover stability of a vehicle.

Using a steering (robot) machine, the pretest is carried out by gradually applying steering handwheel angle up to 270° with a ramp steering input of 13.5°/s with constant speed at 50 mph as shown in Figure 37.43. This maximum steering is kept for 2 s, and then the steering handwheel is completely released for a convenience to a driver. A certain value of steering handwheel angle causing 0.3 g of lateral acceleration is found. Then, the amplitude of a steering handwheel input to the main test is determined by multiplying the angle of 0.3 g normally by 6.5 times. 6.5 is a basic multiplier that is properly readjusted depending on a test result such as pass or failure.

For the main test, a vehicle is driven in straight ahead at a speed slightly higher than a desired entrance vehicle speed. The driver releases throttle off and simultaneously initiates a steering handwheel command described in Figure 37.44 using the steering (robot) machine. The entrance speed ranges from 35 to 45 mph and from 45 to 50 mph increased by 5 and 2.5 mph, respectively, until a termination condition is achieved. The termination is done based on either a two-wheel lift or the completion of the test through the maximum speed without the two-wheel lift. The two-wheel lift is defined as at least the 2 in. simultaneous lift of inside tires from the test surface.

For the main test shown in Figure 37.44, the first ramp steering handwheel input of 720°/s is applied up to the amplitude predetermined through the pretest. The maximum steering angle is kept until vehicle roll rate hits its band of ±1.5°/s. Afterward, the second ramp steering input of 720°/s is reversely steered up to the predetermined amplitude in the other direction. Then, the maximum steering input is kept for 3 s, and then the steering is fully released to steering center.

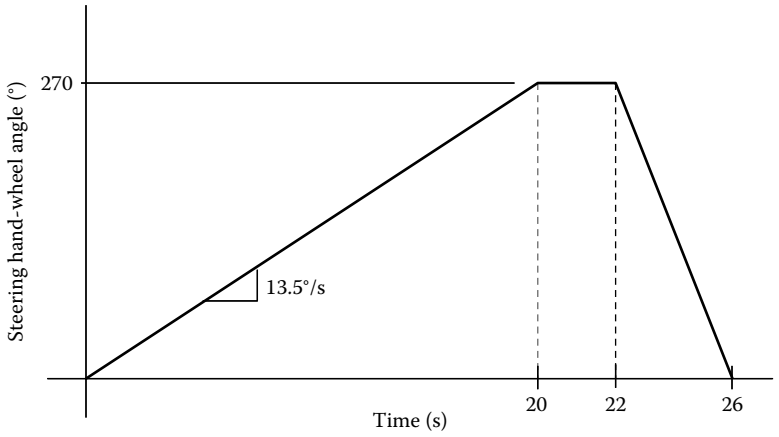

FIGURE 37.43 Steering handwheel input of a pretest of NHTSA's NCAP rollover rating system. (From Forkenbrock, G.J. et al., A demonstration of the dynamic tests developed for NHTSA's NCAP rollover rating system: Phase VIII of NHTSA's light vehicle rollover research program, NHTSA DOT HS 809 705, 2004.)

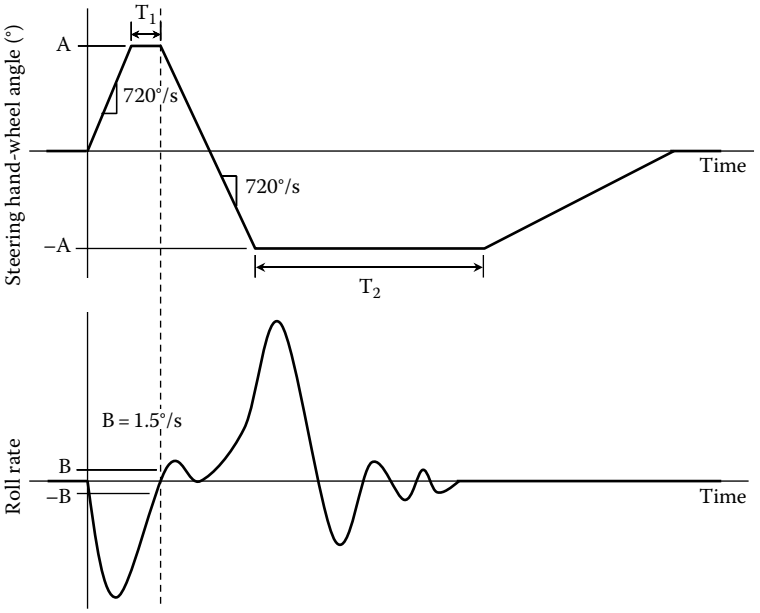

FIGURE 37.44 Steering handwheel input to and roll rate response of the main test of NHTSA's NCAP rollover rating system. (From Forkenbrock, G.J. et al., A demonstration of the dynamic tests developed for NHTSA's NCAP rollover rating system: Phase VIII of NHTSA's light vehicle rollover research program, NHTSA DOT HS 809 705, 2004.)

It should be considered that steering corrections are needed to bring the vehicle back on a course. The summary of the tests is as follows:

Driving speed: From 35 to 45 mph and from 45 to 50 mph increased by 5 and 2.5 mph, respectively.
Steering input: Series of *ramp* steerings.
Procedure: Lift throttle off and simultaneously initiate a steering handwheel command using a steering (robot) machine.

37.3.5 Riding Maneuver

For the purpose of evaluation of ride performance, a riding maneuver is generally used while driving on various public roads or highways. For a convenience, most automobile and tire makers also utilize specially designed ride roads. The ride road is just a collection of ride evaluation road segments in several tracks [40]. Sometimes, it contains some artificial segments.

In this handbook, wavy road, rough road, and impact object driving tests are introduced. Each test speed is just normal driving speed on a public road or a highway.

37.3.5.1 Wavy Road Driving

Driving on a wavy road produces the very low-frequency vibration of a sprung mass. The purpose of a wavy road driving test is to assess *primary ride* (or *body bounce*) as the vibratory characteristic of the sprung mass. Its frequency ranges up to about 5 Hz.

37.3.5.2 Rough Road Driving

When a vehicle is running on a rough road, the low-frequency vibrations of its unsprung masses are induced. A rough road driving test is generally used to evaluate *secondary ride* (or *wheel hop*) as the vibratory characteristic of the unsprung masses. Its frequency ranges from about 5 to 25 Hz.

37.3.5.3 Impact Object Driving

The purpose of an impact object driving test is to assess *impact ride* (or *impact harshness*) as the impact characteristic of a vehicle running over various impact objects. Its frequency in general ranges from about 25 to 60 Hz (at most 100 Hz). The impact objects are composed of a broken edge, a joint, a drain cover, and a cat's eye.

37.4 OBJECTIVE TEST

For various handling objective tests, ISO international standard defines the terminology of vehicle dynamics and road-holding ability [11]. In addition, it standardizes the open-loop test procedures for steady-state circular driving behavior and lateral transient response characteristics against step steering input, sinusoidal steering input, random steering input, and braking in a turn [12–16]. As a severe lane-change maneuver, the standardized test procedure of a double-lane-change test is also provided [17].

ISO international standard 2631-1 defines measurement methods for periodic, random, and transient whole-body vibration [18]. It provides the frequency-dependent weightings of sensitivity affecting health, comfort, and motion sickness due to the different axes of vibration. It plays a role to provide a basic guidance to evaluate ride quality. Jang and Griffin studied the effect of phase, frequency, magnitude, and posture on discomfort associated with differential vertical vibration at the seat and feet [49].

Since the final judgment to assess the handling and ride performances of a vehicle is carried out only through various subjective tests, the procedure and condition of an objective test should be the same as those of a specific subjective test. Any other objective test with different test procedures and conditions may provide some other useful information, but it hardly represents the subjective test performed for subjective assessment.

In this handbook, subjective and objective tests are recommended to be simultaneously carried out. Otherwise, at least the objective test must keep the same procedure and condition of the subjective test. For handling and ride objective tests, different sensors are used.

37.4.1 Handling Test

During a handling test, *steering* (*handwheel*) *angle*, *steering* (*handwheel*) *torque*, *longitudinal* and *lateral components of vehicle velocity*, *longitudinal* and *lateral components of vehicle acceleration*, *yaw rate*, *pitch rate*, and *roll rate* are generally measured [50]. For that purpose, (a) a steering wheel sensor, (b) a speed sensor, (c) an acceleration sensor, and (d) a Gyro sensor are utilized. Supplementarily, (e) a GPS can be employed to trace vehicle path.

For example, a lane changing test shown in Figure 37.32 was employed to illustrate objective measurement variables. All measurement signals were obtained with a 100 Hz sampling rate. For the purpose of filtering the sampled data, a phaseless (zero-phase-shift) digital filter was used with its passband ranging from 0 to 5 Hz. This filter is well documented in ISO international standard [12,13,16].

37.4.1.1 Steering Wheel Sensor

In order to measure steering handwheel angle, speed, and torque, a steering wheel sensor system is mounted after removing a steering handwheel as shown in Figure 37.45. Depending on resolution requirement, the steering wheel sensor should be properly chosen. For the measurement of on-center steering, a high-precision system is required (refer to Figure 37.45a). Otherwise, a standard precision system with wide ranges of measurement is used (refer to Figure 37.45b). Figure 37.46 shows the measured data of steering handwheel angle, speed, and torque obtained during lane changing.

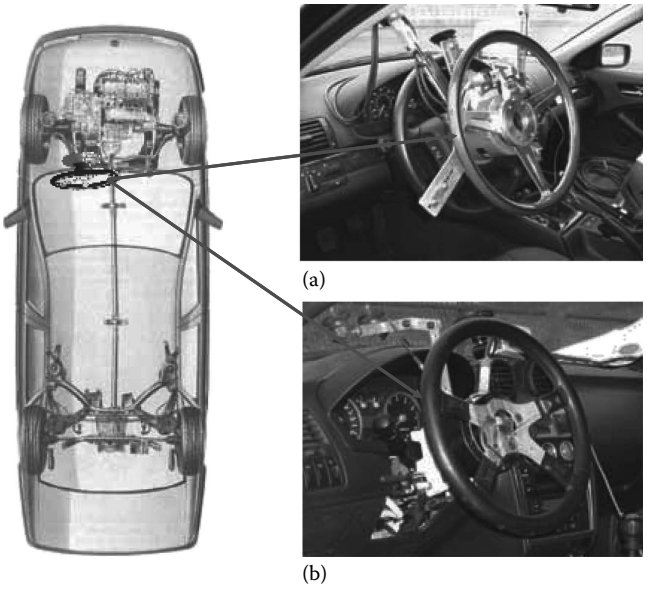

FIGURE 37.45 Steering wheel sensor. (a) High precision sensor and (b) standard precision sensor.

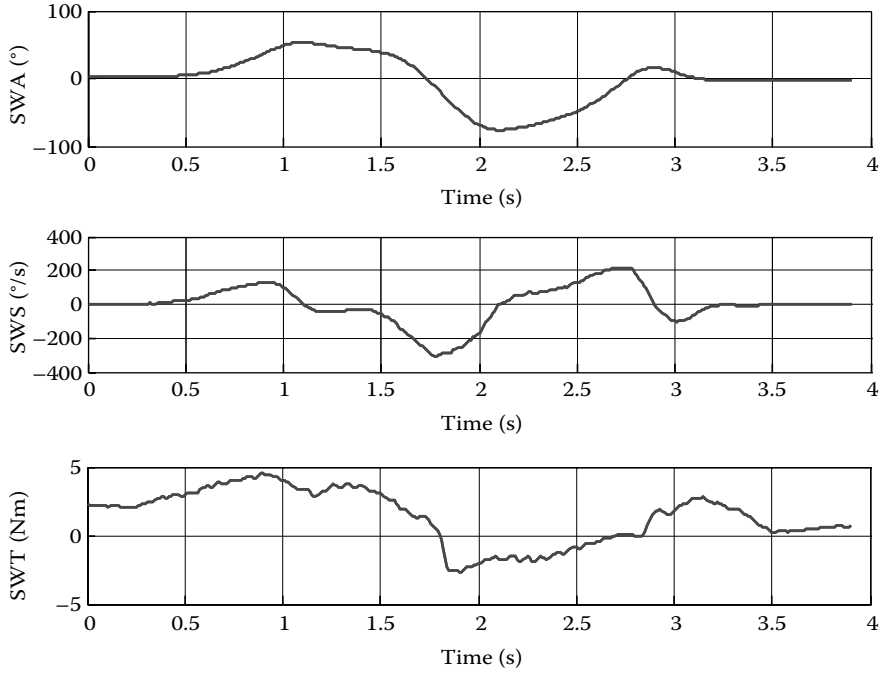

FIGURE 37.46 Steering handwheel angle, speed, and torque measured at a steering system during lane changing.

37.4.1.2 Speed Sensor

As shown in Figure 37.47, a 2-axis speed sensor is equipped at the rear position of a vehicle to gain the longitudinal and lateral components of vehicle velocity. Using this sensor, the components defined with respect to the body-fixed coordinates are measured. Figure 37.48 shows the longitudinal and lateral components measured during lane changing. While the longitudinal component is almost kept constant, the lateral component is shown various due to the directional change of the vehicle velocity.

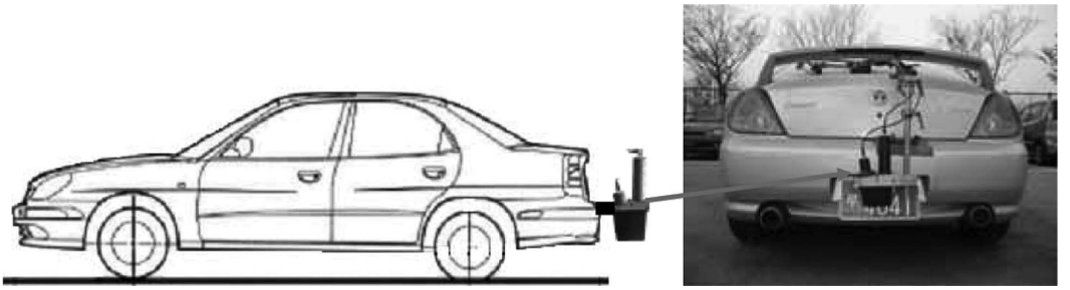

FIGURE 37.47 A speed sensor.

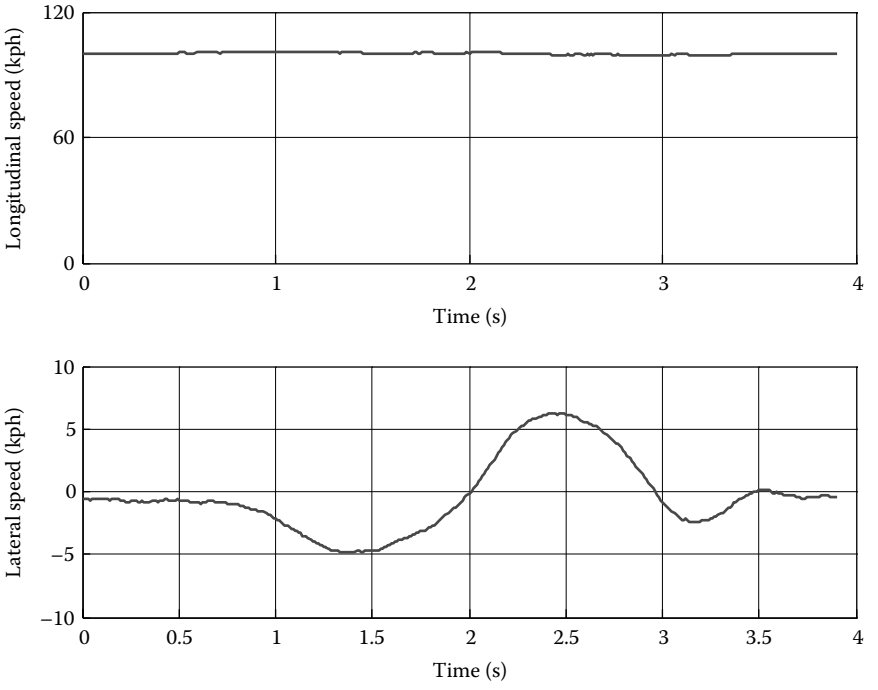

FIGURE 37.48 Longitudinal and lateral components of vehicle velocity measured at a rear position during lane changing.

Using the measured data, vehicle speed, its sideslip angle, and other vehicle motion variables are extracted. Before starting that process, the measured data should be transformed with respect to the coordinates parallel to the ground surface from the body-fixed coordinates in order to compensate roll and pitch effects. Nowadays, a speed sensor packaged together with a Gyro sensor and other sensors can be located inside of a vehicle as shown in Figure 37.49. Using this system, all the components defined with respect to both coordinates can be automatically obtained.

37.4.1.3 Acceleration Sensor

Figure 37.49 illustrates a 3-axis accelerometer installed at a rear location near a driver seat inside a vehicle. Three components of acceleration measured during lane changing are shown in Figure 37.50. Except the lateral component, the others are almost kept constant. In order to analyze the measured data regarding handling performance, in general, the lateral component is mostly utilized. In addition, the longitudinal component is used only for the purpose of analysis of power on/off or braking.

FIGURE 37.49 An accelerometer and a Gyro sensor without/with a speed sensor or/and a GPS.

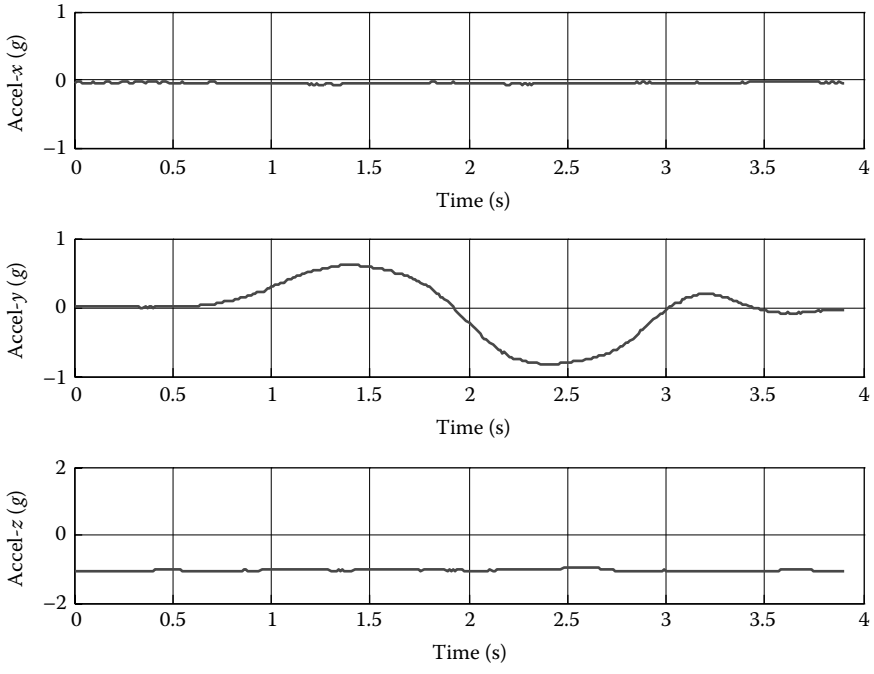

FIGURE 37.50 Longitudinal, lateral, and vertical components of acceleration measured at a rear location near a driver seat during lane changing.

Before utilizing the measured data for a vehicle dynamics analysis, the data should be transformed with respect to the coordinates parallel to the ground surface from the body-fixed coordinates to eliminate roll and pitch effects. Since these days the accelerometer is usually packaged together with a Gyro sensor, all the components defined with respect to both coordinates can be automatically gained.

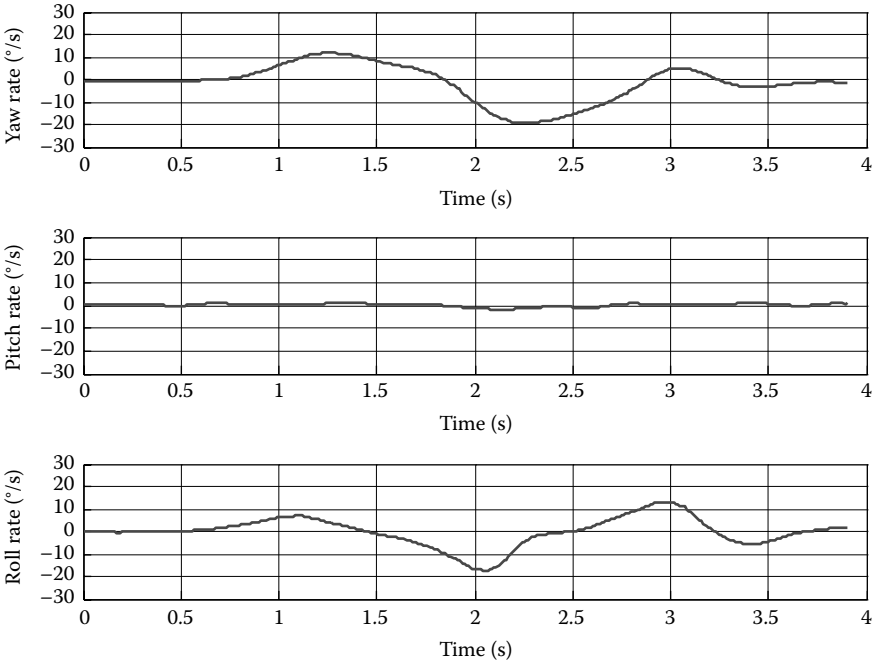

FIGURE 37.51 Yaw rate, pitch rate, and roll rate measured at a rear location near a driver seat during lane changing.

37.4.1.4 Gyro Sensor

A 3-axis Gyro sensor packaged together with an accelerometer is shown in Figure 37.49. Figure 37.51 shows three components of angular time rate measured during lane changing. Only yaw rate and roll rate are shown significant in this case. But, in general, all these data are utilized.

37.4.1.5 GPS

Sometimes a GPS is additionally used to measure vehicle path. Nowadays, the GPS packaged together with other sensors is generally employed (refer to Figure 37.49). The longitudinal and lateral coordinates of the vehicle path are given in Figure 37.52. The first and second ones present these coordinates against time, and the third one directly illustrates the vehicle path with representing its lateral coordinate against its longitudinal coordinate.

37.4.2 Ride Test

In order to analyze ride performance, six accelerometers attached to (a) a front wheel, (b) a rear wheel, (c) a vehicle floor, (d) a seat rail, (e) a seat cushion, and (f) a seat back may be needed as shown in Figure 37.53 [18]. A measurement at the seat back is more often not used because of its bad repeatability. A 3-axis accelerometer is usually used to measure the vibrations of three components of acceleration at each position. In general, the longitudinal and vertical components of the acceleration are utilized. Their frequencies range from about 0.5 to at most 100 Hz.

For example, a rectangular-shaped cleat bar on a concrete road shown in Figure 37.54 was chosen for an impact object driving test. Its height and width are 20 and 20 mm, and its length is long enough so that both left and right tires are simultaneously running over the cleat bar. For all test duration, test speed kept constant at 50 kph even while front and rear tires are passing over the cleat bar. All accelerations at six positions were measured to show the vibrations of all the positions. Their signals were measured with a 1000 Hz sampling rate and were filtered by a 100 Hz low-pass filter.

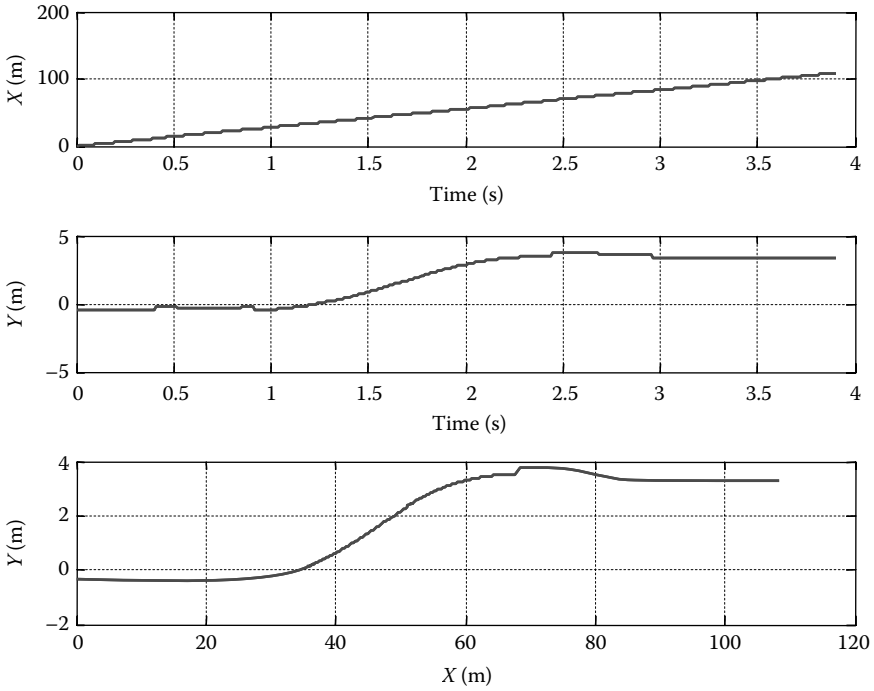

FIGURE 37.52 Longitudinal and lateral coordinates of vehicle path measured at a rear location near a driver seat during lane changing.

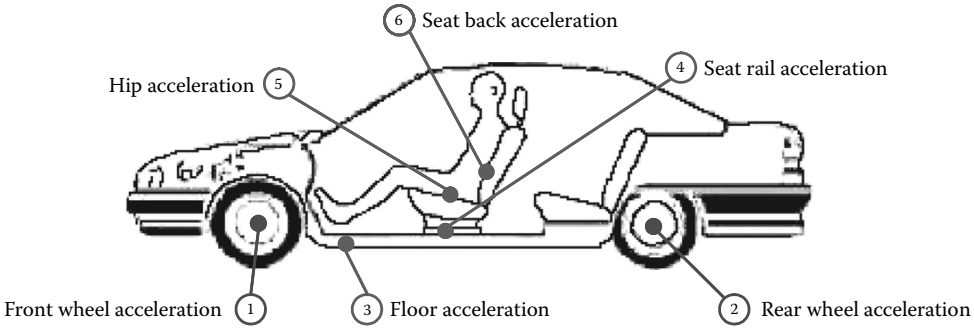

FIGURE 37.53 Measurements of accelerometers attached at five locations for ride tests.

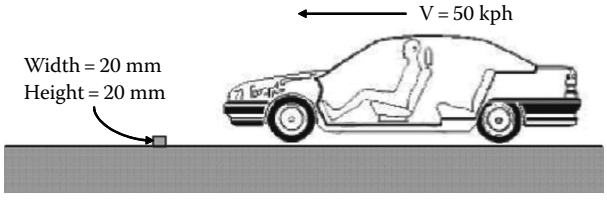

FIGURE 37.54 Driving over a rectangular-shaped cleat bar at the constant speed of 50 kph.

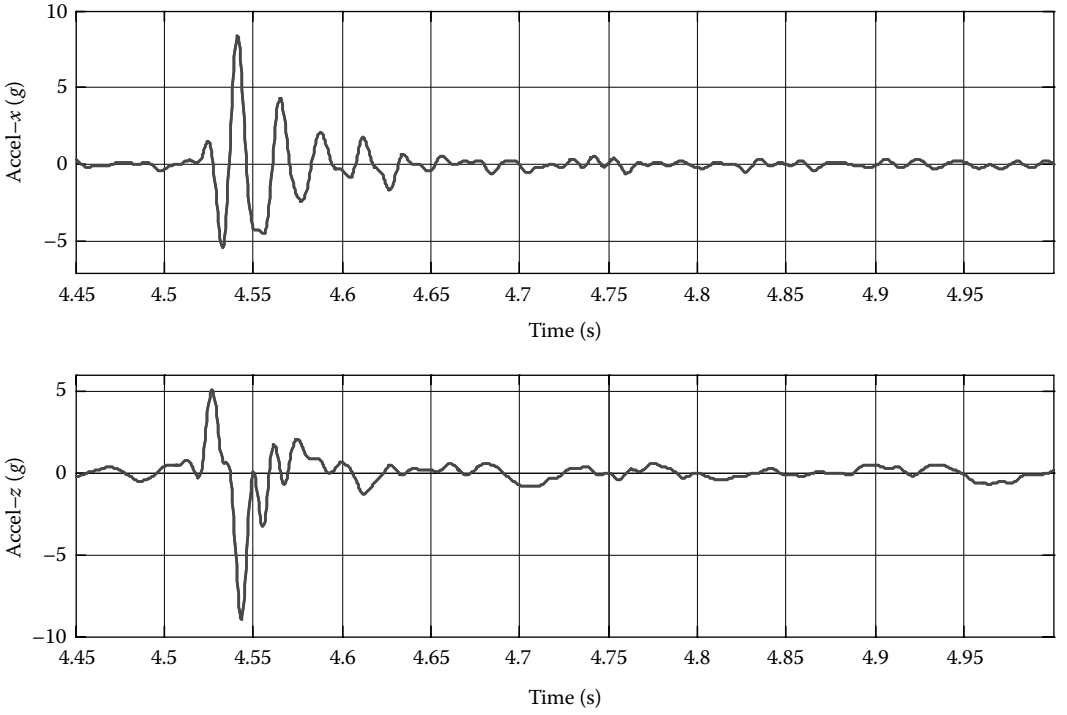

FIGURE 37.55 Longitudinal and vertical components of acceleration measured at a front knuckle during driving over a rectangular-shaped cleat bar.

37.4.2.1 Front Wheel

In order to illustrate front-wheel vibration, the longitudinal and vertical components of acceleration measured at a front knuckle during driving over the cleat bar are given in Figure 37.55. The peak value of the vertical component is bigger than that of the longitudinal component. The vertical component is damped out earlier than the longitudinal component.

37.4.2.2 Rear Wheel

Figure 37.56 shows the longitudinal and vertical components of acceleration measured at a rear knuckle to represent rear-wheel vibration. Contrary to the front-wheel vibration, the peak value of the longitudinal component is a little bigger than that of the vertical component. The longitudinal component is damped out earlier than the vertical component.

37.4.2.3 Vehicle Floor

An accelerometer is installed underneath a vehicle floor at a driver's foot position. In order to illustrate floor vibration perceived through a driver's foot, the longitudinal and vertical components of acceleration are given in Figure 37.57. While front tires are running over the cleat bar, the peak value of the vertical component is overall a little bigger in magnitude than the longitudinal component. The vertical component is damped out a little easier than the longitudinal component.

37.4.2.4 Seat Rail

Figure 37.58 shows seat-rail vibration with its longitudinal and vertical components of acceleration. The peak value of the longitudinal component is a little bigger than that of the vertical component only, while rear tires are passing over the cleat bar. After the impact of rear tires, the vertical component is not easily damped out.

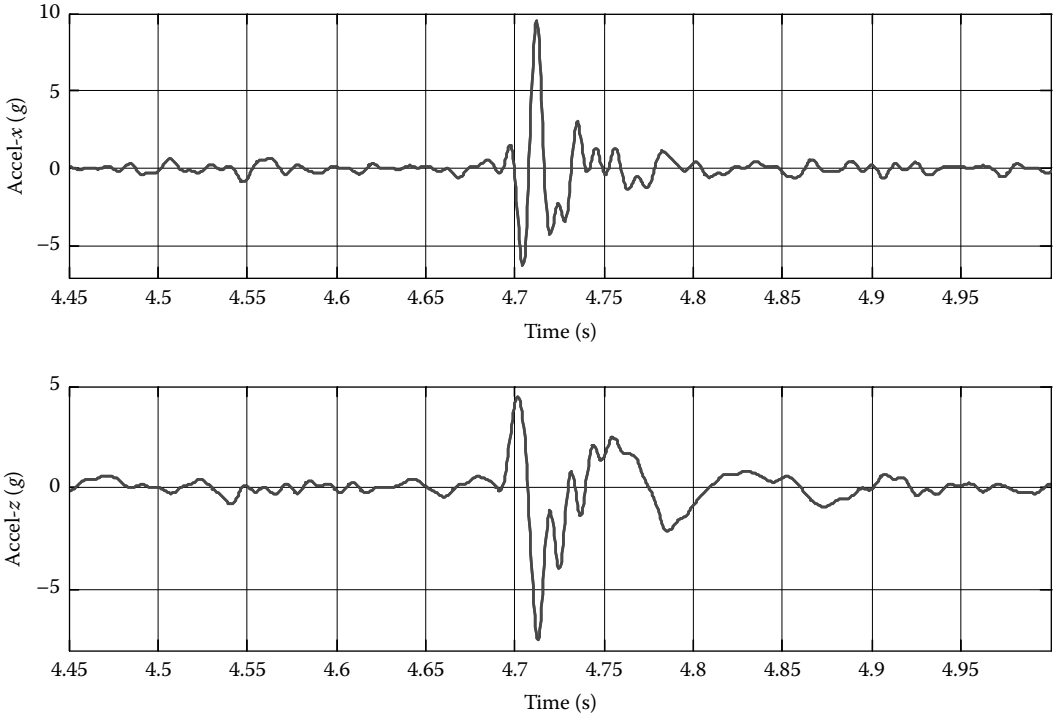

FIGURE 37.56 Longitudinal and vertical components of acceleration measured at a rear knuckle while driving over a rectangular-shaped cleat bar.

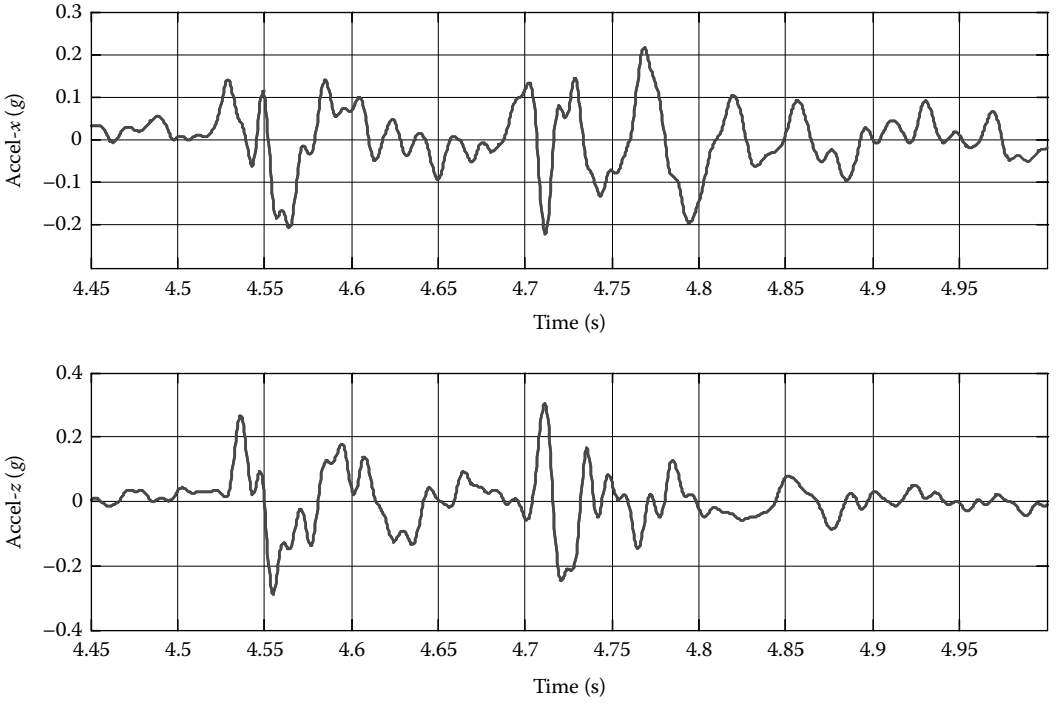

FIGURE 37.57 Longitudinal and vertical components of acceleration measured underneath vehicle floor at a driver's foot position while driving over a rectangular-shaped cleat bar.

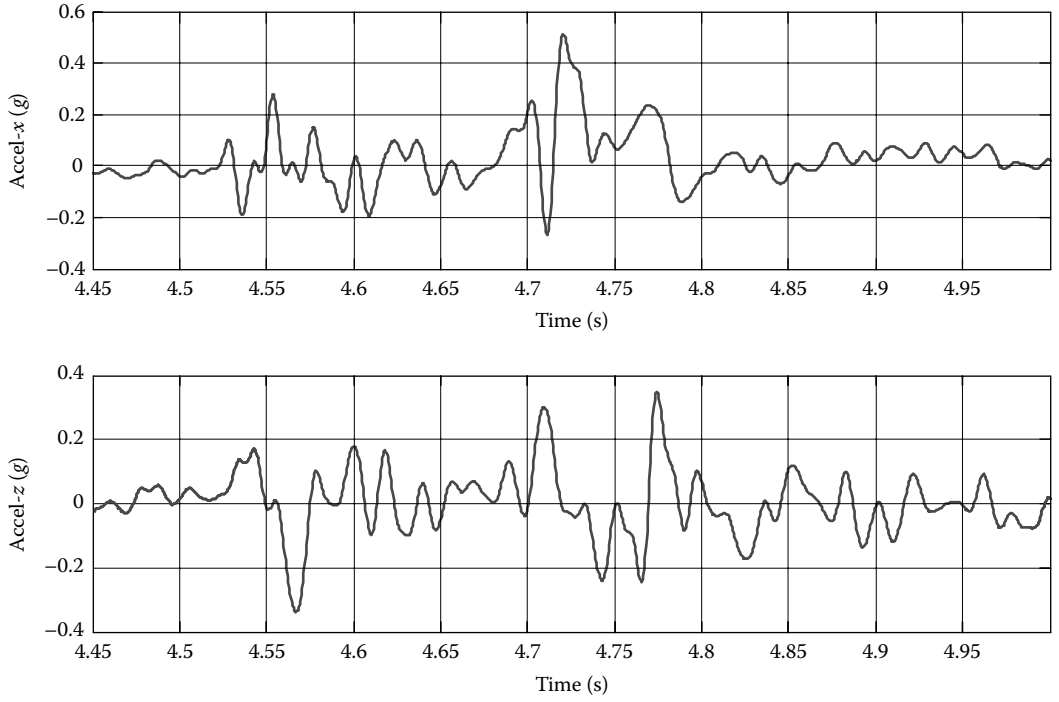

FIGURE 37.58 Longitudinal and vertical components of acceleration measured at a seat rail while driving over a rectangular-shaped cleat bar.

37.4.2.5 Seat Cushion

A seat cushion is a direct contact location, which a driver feels ride *comfortability* through. As shown in Figure 37.59, its vibration is represented by the longitudinal and vertical components of acceleration measured at the seat cushion. The peak value of the vertical component is much smaller than that of the longitudinal component during all impacts. After the impact of rear tires, both components are still vibrated for a moment.

The frequency of the vertical component is much lower than that of the longitudinal component. This phenomenon is on purpose induced due to the softness of the seat cushion.

37.4.2.6 Seat Back

A seat back is also one of the direct contact places with a driver body. Figure 37.60 illustrates the longitudinal and vertical components of acceleration measured at the seat back. The magnitude of the vertical component is much bigger than that of the longitudinal component in contrast to the seat cushion. That can be explained by the fact that the seat cushion and the seat back are designed to mostly absorb their vertical and longitudinal vibrations, respectively.

In Figures 37.58 and 37.60, the vertical component of the seat back vibration is shown bigger than that of the seat-rail vibration. This abnormal phenomenon is assumed due to the movement of a seat back sensor, which is tight to the seat back generally by fabric strings. The sensor naturally moves along the vertical direction with a driver. Therefore, the vertical component of the seat back vibration is measured dependent on a driver's leaning load on the seat back. In general, it is very difficult to get the good repeatability of the measurement of the vertical component.

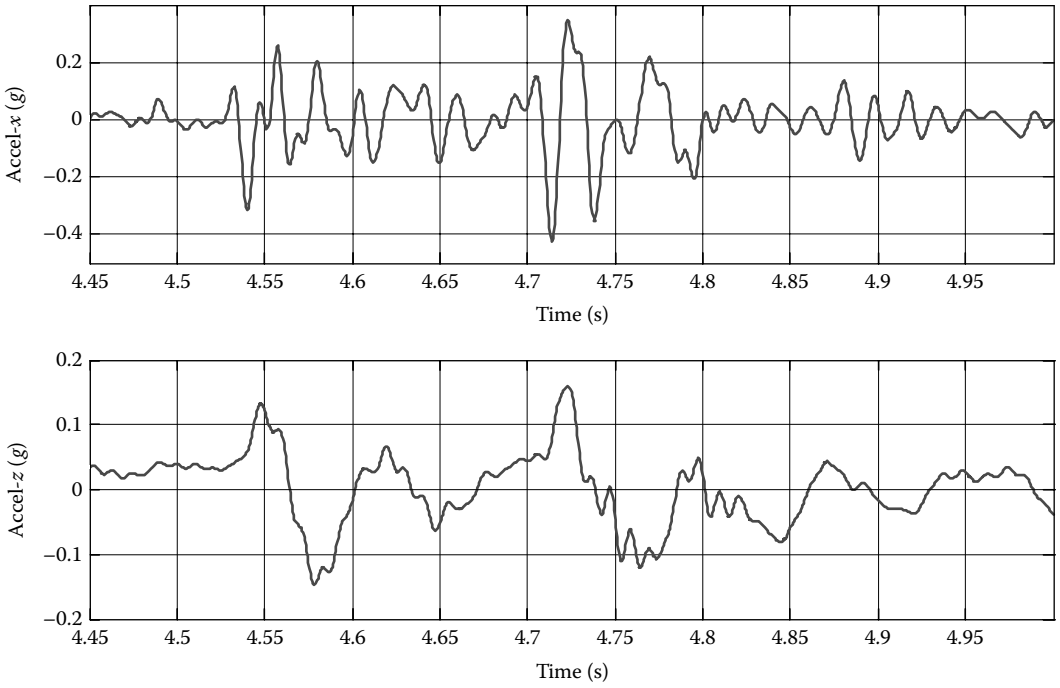

FIGURE 37.59 Longitudinal and vertical components of acceleration measured at a seat cushion while driving over a rectangular-shaped cleat bar.

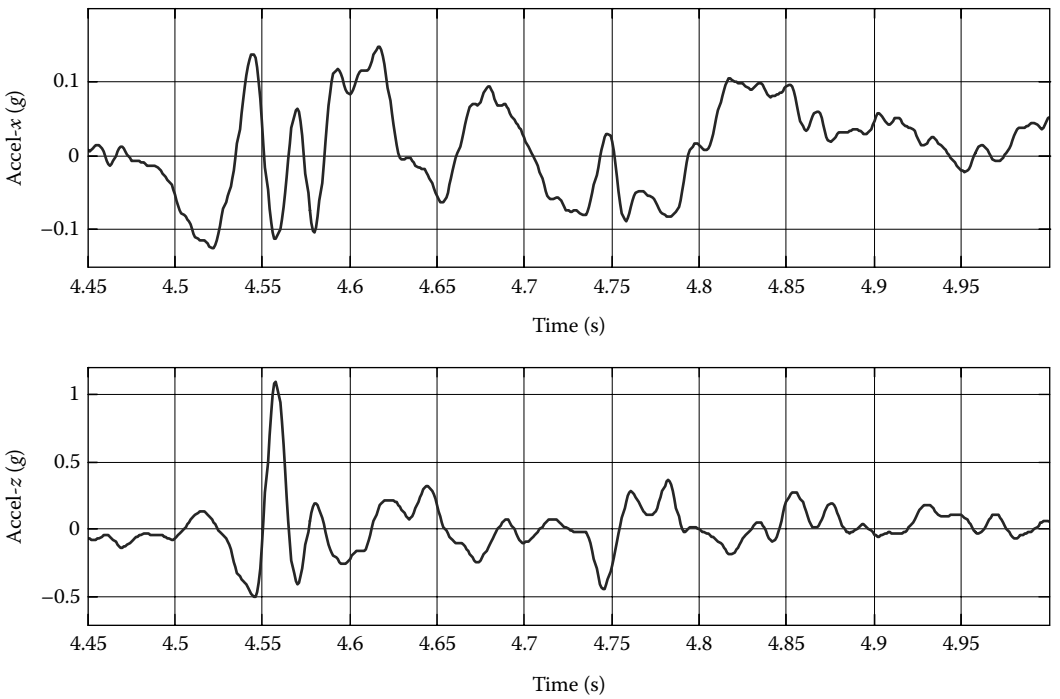

FIGURE 37.60 Longitudinal and vertical components of acceleration measured at a seat back while driving over a rectangular-shaped cleat bar.

37.5 VEHICLE DYNAMICS VARIABLES

During various subjective tests, a driver utilizes his own *subjective assessment variables* to make subjective assessment. At an instant, vehicle motion is described in terms of *vehicle motion variables*. During the tests, *objective measurement variables* are measured to illustrate the vehicle motion variables. In order to express the subjective assessment variables in mathematical formulations, *physical perception variables* are derived in terms of the vehicle motion variables. Eventually, they are extracted as functions of the objective measurement variables. In this handbook, only planar vehicle motion is presented for an example.

37.5.1 Vehicle Motion Variables

In order to describe planar vehicle motion, the center of mass, an effective front axle position, and an effective rear axle position are separately considered. As the main vehicle motion variables defined at the center of mass, *vehicle velocity V*, *turning velocity* ω, *yaw rate* $\dot{\psi}$, and *lateral acceleration* a_y are employed as shown in Figure 37.61. As the directional angle of vehicle traveling, *sideslip angle* β is defined, and *sideslip angle time rate* is denoted as $\dot{\beta}$.

For the purpose of illustrating local planar vehicle motion, *effective front steer angle* δ_{sf} and *effective rear steer angle* δ_{sr} in a steady-state turn are employed as shown in Figure 37.62. *Effective front and rear velocities* are denoted by V_f and V_r, respectively. Their directional angles are defined as *effective front slip angle* α_f and *effective rear slip angle* α_r. l, a, and b denote the distances between front and rear axles, between the center of mass and the front axle, and between the center of mass and the rear axle, respectively.

For a front axle, we have

$$V_f \sin(\delta_{sf} + \alpha_f) = V \sin\beta + a\dot{\psi}$$

Since in general $V_f \cong V$ at high speed, we get

$$\sin(\delta_{sf} + \alpha_f) \cong \sin\beta + \frac{a}{V}\dot{\psi} \tag{37.1}$$

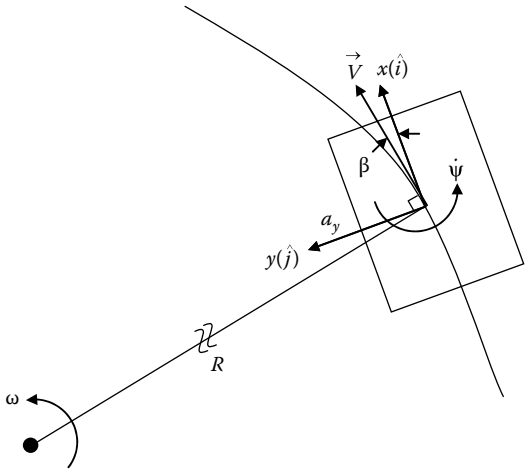

FIGURE 37.61 Vehicle motion parameters measured at the center of mass (in this situation $\beta > 0$).

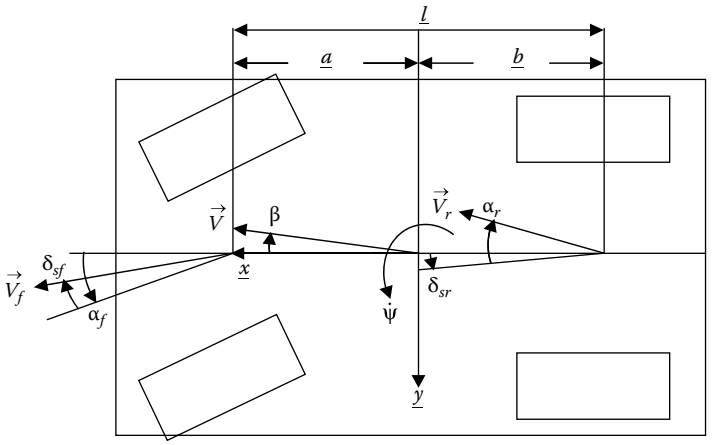

FIGURE 37.62 Effective steer and slip angles in a steady-state turn: $\delta_{sf} > 0$, $\delta_{sr} > 0$, $\beta < 0$, $\alpha_f < 0$, and $\alpha_r < 0$.

Similar to the front axle, for a rear axle, we also have

$$V_r \sin(\delta_{sr} + \alpha_r) = V \sin\beta - b\dot{\psi}$$

Since for most cases $V_r \cong V$ at high speed, we also get

$$\sin(\delta_{sr} + \alpha_r) \cong \sin\beta - \frac{b}{V}\dot{\psi} \tag{37.2}$$

Equations 37.1 and 37.2 yield

$$\sin(\delta_{sf} + \alpha_f) - \sin(\delta_{sr} + \alpha_r) = \frac{1}{V}\dot{\psi} \tag{37.3}$$

If R is defined as turning radius, for a steady-state turn, we have

$$V = R\dot{\psi} \tag{37.4}$$

Substitution of Equation 37.4 in Equation 37.3 becomes

$$\sin(\delta_{sf} + \alpha_f) - \sin(\delta_{sr} + \alpha_r) = \frac{l}{R} \tag{37.5}$$

Then,

$$\delta_{sf} = \sin^{-1}\left[\frac{l}{R} + \sin(\delta_{sr} + \alpha_r)\right] - \alpha_f \tag{37.6}$$

The partial derivative of Equation 37.5 yields

$$\frac{\partial \sin(\delta_{sf} + \alpha_f)}{\partial a_y} = \frac{\partial \sin(\delta_{sr} + \alpha_r)}{\partial a_y}$$

and

$$\cos(\delta_{sf}+\alpha_f)\frac{\partial(\delta_{sf}+\alpha_f)}{\partial a_y}=\cos(\delta_{sr}+\alpha_r)\frac{\partial(\delta_{sr}+\alpha_r)}{\partial a_y}$$

Then, we have

$$\frac{\partial\delta_{sf}}{\partial a_y}=\frac{\cos(\delta_{sr}+\alpha_r)}{\cos(\delta_{sf}+\alpha_f)}\frac{\partial(\delta_{sr}+\alpha_r)}{\partial a_y}-\frac{\partial\alpha_f}{\partial a_y}$$

For a small cornering activity, in case $\delta_{sr}\cong 0$, we get

$$\frac{\partial\delta_{sf}}{\partial a_y}\cong\frac{\partial(-\alpha_f+\alpha_r)}{\partial a_y} \tag{37.7}$$

For a steady-state turn as shown in Figure 37.63, from Equation 37.2, we have

$$\sin(\delta_{sr}+\alpha_r)=\sin\beta-\frac{b}{R} \tag{37.8}$$

The partial derivative of Equation 37.8 gives

$$\frac{\partial\sin(\delta_{sr}+\alpha_r)}{\partial a_y}=\frac{\partial\sin\beta}{\partial a_y}$$

and

$$\cos(\delta_{sr}+\alpha_r)\frac{\partial(\delta_{sr}+\alpha_r)}{\partial a_y}=\cos\beta\frac{\partial\beta}{\partial a_y}$$

Then, we get

$$\frac{\partial\beta}{\partial a_y}=\frac{\cos(\delta_{sr}+\alpha_r)}{\cos\beta}\frac{\partial(\delta_r+\alpha_r)}{\partial a_y} \tag{37.9}$$

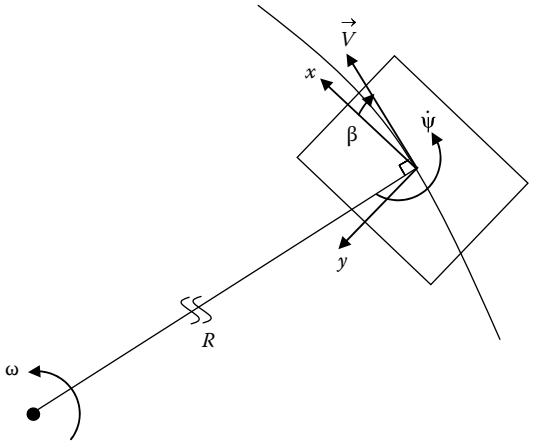

FIGURE 37.63 Steady-state turn (in this situation $\beta < 0$).

For a small cornering activity, in case $\delta_{sr} \cong 0$, we have

$$\frac{\partial \beta}{\partial a_y} = \frac{\partial \alpha_r}{\partial a_y} \tag{37.10}$$

Vehicle velocity at the center of mass is written as

$$\vec{V} = V_x \hat{i} + V_y \hat{j} \tag{37.11}$$

where

$\hat{i}$ and $\hat{j}$ are the longitudinal and lateral directional vectors fixed at the center of mass of a vehicle, respectively, as shown in Figure 37.61

V_x and V_y are the longitudinal and lateral components of V along $\hat{i}$ and $\hat{j}$, respectively

As the directional angle of vehicle moving, sideslip angle β is defined as

$$\beta \equiv \tan^{-1} \frac{V_y}{V_x} \tag{37.12}$$

Then, we get

$$V_x = V \cos\beta \tag{37.13a}$$

and

$$V_y = V \sin\beta \tag{37.13b}$$

The differentiation of Equation 37.11 yields

$$\frac{d\vec{V}}{dt} = \frac{dV_x}{dt}\hat{i} + V_x \frac{d\hat{i}}{dt} + \frac{dV_y}{dt}\hat{j} + V_y \frac{d\hat{j}}{dt} \tag{37.14}$$

The differentiations of Equations 37.13a and b also produce

$$\frac{dV_x}{dt} = \dot{V}\cos\beta - V\dot{\beta}\sin\beta \tag{37.15a}$$

and

$$\frac{dV_y}{dt} = \dot{V}\sin\beta + V\dot{\beta}\cos\beta \tag{37.15b}$$

If $\hat{k}$ denotes the directional vector perpendicular to both $\hat{i}$ and $\hat{j}$, we get

$$\frac{d\hat{i}}{dt} = \dot{\psi}\hat{k} \times \hat{i} = \dot{\psi}\hat{j} \tag{37.16a}$$

and

$$\frac{d\hat{j}}{dt} = \dot{\psi}\hat{k} \times \hat{j} = -\dot{\psi}\hat{i} \tag{37.16b}$$

Substitution of Equations 37.15a and 37.16b in Equation 37.14 yields

$$\frac{d\vec{V}}{dt} = (\dot{V}\cos\beta - V\dot{\beta}\sin\beta)\hat{i} + V\dot{\psi}\cos\beta\hat{j} + (\dot{V}\sin\beta - V\dot{\beta}\cos\beta)\hat{j} - V\dot{\psi}\sin\beta\hat{i}$$

Then, we get

$$\frac{d\vec{V}}{dt} = [\dot{V}\cos\beta - V(\dot{\psi}+\dot{\beta})\sin\beta]\hat{i} + [\dot{V}\sin\beta - V(\dot{\psi}+\dot{\beta})\cos\beta]\hat{j} \tag{37.17}$$

Now, we define $\dot{V}_x$ and $\dot{V}_y$ as

$$\dot{V}_x \equiv \dot{V}\cos\beta \tag{37.18a}$$

and

$$\dot{V}_y \equiv \dot{V}\sin\beta \tag{37.18b}$$

Using Equations 37.13a,b, 37.18a and b, Equation 37.17 is written as

$$\frac{d\vec{V}}{dt} = [\dot{V}_x - V_y(\dot{\psi}+\dot{\beta})]\hat{i} + [\dot{V}_y + V_x(\dot{\psi}+\dot{\beta})]\hat{j} \tag{37.19}$$

If a_x and a_y denote the longitudinal and lateral components of acceleration along $\hat{i}$ and $\hat{j}$, respectively, we get

$$a_x = \dot{V}_x - V_y(\dot{\psi}+\dot{\beta}) \tag{37.20a}$$

and

$$a_y = \dot{V}_y + V_x(\dot{\psi}+\dot{\beta}) \tag{37.20b}$$

Now, we get turning velocity as

$$\omega = \dot{\psi} + \dot{\beta} \tag{37.21}$$

In a steady-state turn shown in Figure 37.63, there exists sideslip outward, in which β becomes negative, that is, $\beta < 0$ in Equations 37.1 through 37.21.

37.5.2 Physical Perception Variables

A professional test engineer is observed to carry out his or her subjective assessment using his or her physical perception variables. For example, the physical perception variables only in planar vehicle motion are illustrated in this handbook. First of all, *steering handwheel angle* δ_{sw} and *steering handwheel torque* T_{sw} are perceived through a steering handwheel. A driver also senses *vehicle*

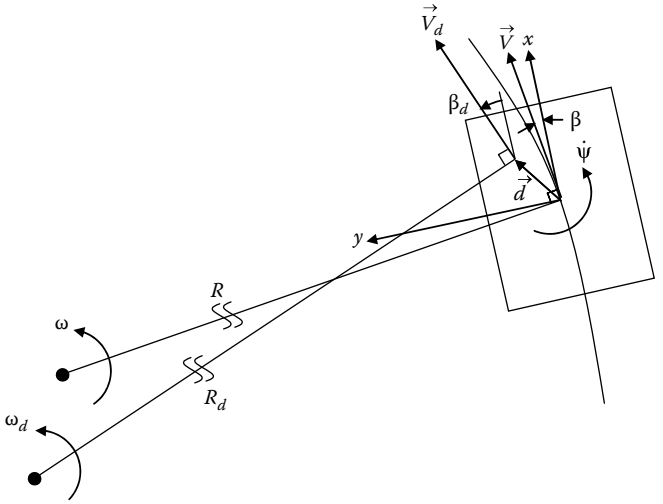

FIGURE 37.64 Driver perception parameters (in this situation $\beta > 0$ and $\beta_d > 0$).

speed V_{xd}, *turning curvature* κ_d, *turning velocity* ω_d, *nose angle* φ_d, and *nose angle time rate* $\dot{\varphi}_d$ through the reactions of vehicle path and attitude with respect to his or her seat [28,43].

As shown in Figure 37.64, vehicle velocity measured at a driver seat is symbolized by $\vec{V}_d$. A distance vector from the center of mass to a driver seat is denoted as $\vec{d}$. If the longitudinal and lateral components of $\vec{V}_d$ and $\vec{d}$ are defined along $\hat{i}$ and $\hat{j}$, they are denoted as V_{xd}, V_{yd}, d_x, and d_y, respectively. Now, we have

$$\vec{V}_d = V_x\hat{i} + V_y\hat{j} + \dot{\psi}\hat{k} \times (d_x\hat{i} + d_y\hat{j})$$

Subscript "*d*" stands for "*measured at a driver seat*" or "*with respect to a driver seat.*"

Then, we have

$$\vec{V}_d = (V_x - d_y\dot{\psi})\hat{i} + (V_y + d_x\dot{\psi})\hat{j} \tag{37.22}$$

It is also simplified as

$$\vec{V}_d = V_{xd}\,\hat{i} + V_{yd}\,\hat{j} \tag{37.23}$$

Then, Equations 37.22 and 37.23 yield

$$V_{xd} = V_x - d_y\dot{\psi} \tag{37.24a}$$

and

$$V_{yd} = V_y + d_x\dot{\psi} \tag{37.24b}$$

Substitution of Equations 37.13a and b in Equation 37.22 yields

$$\vec{V}_d = (V\cos\beta - d_y\dot{\psi})\hat{i} + (V\sin\beta - d_x\dot{\psi})\hat{j}$$

Its differentiation yields

$$\frac{d\vec{V}_d}{dt} = (\dot{V}\cos\beta - V\dot{\beta}\sin\beta - d_y\ddot{\psi})\hat{i} + (V\cos\beta - d_y\dot{\psi})\frac{d\hat{i}}{dt} + (\dot{V}\sin\beta - V\dot{\beta}\cos\beta - d_x\ddot{\psi})\hat{j} + (V\sin\beta - d_x\dot{\psi})\frac{d\hat{j}}{dt}$$

Using Equations 37.16a and b, we get

$$\frac{d\vec{V}_d}{dt} = (\dot{V}\cos\beta - V\dot{\beta}\sin\beta - d_y\ddot{\psi})\hat{i} + (V\cos\beta - d_y\dot{\psi})\dot{\psi}\hat{j} + (\dot{V}\sin\beta - V\dot{\beta}\cos\beta - d_x\ddot{\psi})\hat{j} + (V\sin\beta - d_x\dot{\psi})\dot{\psi}\hat{i}$$

Then, we have

$$\frac{d\vec{V}_d}{dt} = [\dot{V}\cos\beta - V(\dot{\psi}+\dot{\beta})\sin\beta - d_x\dot{\psi}^2 - d_y\ddot{\psi}]\hat{i} + [\dot{V}\sin\beta + V(\dot{\psi}+\dot{\beta})\cos\beta - d_y\dot{\psi}^2 + d_x\ddot{\psi}]\hat{j} \quad (37.25)$$

Substitution of Equations 37.13a,b, 37.18a and b in Equation 37.25 yields

$$\frac{d\vec{V}_d}{dt} = [\dot{V}_x - V_y(\dot{\psi}+\dot{\beta}) - d_x\dot{\psi}^2 - d_y\ddot{\psi}]\hat{i} + [\dot{V}_y + V_x(\dot{\psi}+\dot{\beta}) - d_y\dot{\psi}^2 + d_x\ddot{\psi}]\hat{j} \quad (37.26)$$

If a_{xd} and a_{xd} denote the longitudinal and lateral components of acceleration measured at a driver seat along $\hat{i}$ and $\hat{j}$, respectively, Equation 37.26 yields

$$a_{xd} = \dot{V}_x - V_y(\dot{\psi}+\dot{\beta}) - d_x\dot{\psi}^2 - d_y\ddot{\psi}$$

and

$$a_{yd} = \dot{V}_y - V_x(\dot{\psi}+\dot{\beta}) - d_y\dot{\psi}^2 - d_x\ddot{\psi}$$

Usage of Equations 37.20a and b gives

$$a_{xd} = a_x - d_x\dot{\psi}^2 - d_y\ddot{\psi} \tag{37.27a}$$

and

$$a_{yd} = a_y - d_y\dot{\psi}^2 + d_x\ddot{\psi} \tag{37.27b}$$

With known V_{xd} and V_{yd}, we get vehicle speed perceived at a driver seat as

$$V_d = \sqrt{V_{xd}^2 + V_{yd}^2} \tag{37.28}$$

If β_d is defined as the directional angle of vehicle moving measured at a driver seat, we get

$$\beta_d \equiv \tan^{-1}\frac{V_{yd}}{V_{xd}} \tag{37.29}$$

Then, we have

$$V_{xd} = V_d\cos\beta_d \tag{37.30a}$$

and

$$V_{yd} = V_d\sin\beta_d \tag{37.30b}$$

From Equation 37.23, we get

$$\frac{d\vec{V}_d}{dt} = \frac{dV_{xd}}{dt}\hat{i} + V_{xd}\frac{d\hat{i}}{dt} + \frac{dV_{yd}}{dt}\hat{j} + V_{yd}\frac{d\hat{j}}{dt} \tag{37.31}$$

From Equations 37.30a and b, we have

$$\frac{dV_{yd}}{dt} = \dot{V}_d\cos\beta_d + V_d\dot{\beta}_d\sin\beta_d \tag{37.32a}$$

and

$$\frac{dV_{xd}}{dt} = \dot{V}_d\sin\beta_d + V_d\dot{\beta}_d\cos\beta_d \tag{37.32b}$$

Substitution of Equations 37.16a,b, 37.32a and b in Equation 37.31 yields

$$\begin{aligned}\frac{d\vec{V}_d}{dt} &= (\dot{V}_d\cos\beta_d - V_d\dot{\beta}_d\cos\beta_d)\hat{i} + V_d\dot{\psi}\cos\beta_d\hat{j} \\ &\quad + (\dot{V}_d\sin\beta_d + V_d\dot{\beta}_d\cos\beta_d)\hat{j} - V_d\dot{\psi}\sin\beta_d\hat{i}\end{aligned}$$

Then,

$$\frac{d\vec{V}_d}{dt} = [\dot{V}_d \cos\beta_d - V_d(\dot{\psi} + \dot{\beta}_d)\sin\beta_d]\hat{i} + [\dot{V}_d \sin\beta_d + V_d(\dot{\psi} + \dot{\beta}_d)\cos\beta_d]\hat{j} \tag{37.33}$$

We define $\dot{V}_{xd}$ and $\dot{V}_{yd}$ as

$$\dot{V}_{xd} \equiv \dot{V}_d \cos\beta_d \tag{37.34a}$$

and

$$\dot{V}_{yd} \equiv \dot{V}_d \sin\beta_d \tag{37.34b}$$

Substitution of Equations 37.30a,b, 37.34a and b in Equation 37.33 yields

$$\frac{d\vec{V}_d}{dt} = [\dot{V}_{xd} - V_{yd}(\dot{\psi} + \dot{\beta}_d)]\hat{i} + [\dot{V}_{yd} - V_{xd}(\dot{\psi} + \dot{\beta}_d)]\hat{j} \tag{37.35}$$

Equation 37.35 gives

$$a_{xd} = \dot{V}_{xd} - V_{yd}(\dot{\psi} + \dot{\beta}_d) \tag{37.36a}$$

and

$$a_{yd} = \dot{V}_{yd} - V_{xd}(\dot{\psi} + \dot{\beta}_d) \tag{37.36b}$$

If turning velocity that a driver feels at his seat is denoted as ω_d, Equation 37.36b is expressed as

$$a_{yd} = \dot{V}_{yd} + V_{xd}\omega_d \tag{37.37}$$

Known a_{yd}, ω_d is computed as

$$\omega_d = \frac{a_{yd} - \dot{V}_{yd}}{V_{xd}} \tag{37.38}$$

Equations 37.36b and 37.37 also give

$$\omega_d = \dot{\psi} + \dot{\beta}_d \tag{37.39}$$

Now, turning curvature that a driver feels at his seat is determined as

$$\kappa_d = \frac{\omega_d}{V_{xd}} \tag{37.40}$$

where R_d is turning radius measured at the driver seat and $\kappa_d = 1/R_d$.

In order to describe vehicle attitude that a driver feels at his seat, nose angle measured at the driver seat is denoted as φ_d. Then, it is obtained as

$$\varphi_d = -\beta_d \tag{37.41}$$

Usage of Equations 37.41 and 37.29 yields

$$\varphi d = -\tan^{-1}\frac{V_{yd}}{V_{xd}} \tag{37.42}$$

Since for nose angle time rate we have $\dot{\varphi}_d = \dot{\beta}_d, \dot{\varphi}_d$ is determined using Equation 37.39 as

$$\dot{\varphi}_d = \dot{\psi} - \omega_d \tag{37.43}$$

It is noted that κ_d and ω_d represent vehicle path that a driver feels while driving in a turn. In addition, φ_d and $\dot{\varphi}_d$ represent vehicle attitude that a driver feels.

37.5.3 Objective Measurement Variables

While a steering wheel sensor is equipped at a steering system, a velocity sensor, a Gyro sensor, and an accelerometer are usually located away from the driver seat (refer to Figures 37.45, 37.47, and 37.49). Through the steering wheel sensor, *steering handwheel angle* δ_{sw} and *steering handwheel torque* T_{sw} are measured as shown in Figure 37.65. The velocity sensor measures *longitudinal velocity* V_{xm} and *lateral velocity* V_{ym}. Using the Gyro sensor and accelerometer, *yaw rate* $\dot{\psi}_m$ and *lateral acceleration* a_{ym} are measured, respectively.

Distance vectors from the velocity sensor and the Gyro sensor to the driver seat are denoted as $\vec{c}$ and $\vec{e}$, respectively. If their longitudinal and lateral components along $\hat{i}$ and $\hat{j}$ are also symbolized as c_x, c_y, e_x, and e_y, respectively, then we have

$$\vec{c} = c_x\hat{i} + c_y\hat{j} \quad \text{for a velocity sensor} \tag{37.44a}$$

$$\vec{e} = e_x\hat{i} + e_y\hat{j} \quad \text{for a Gyro sensor and an accelerometer} \tag{37.44b}$$

$\vec{V}_m$ denotes a measured velocity vector, and its longitudinal and lateral components along $\hat{i}$ and $\hat{j}$ are denoted as V_{xm} and V_{ym}, respectively. Then, $\vec{V}_m$ is written as

$$\vec{V}_m = V_{xm}\hat{i} + V_{ym}\hat{j} \tag{37.45}$$

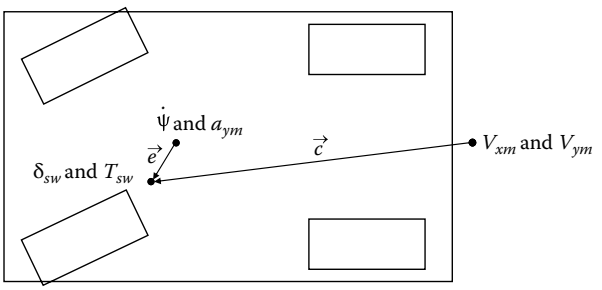

FIGURE 37.65 Objective measurement parameters.

Using Equations 37.24a and b, vehicle velocity felt by a driver can be computed as

$$V_{xd} = V_{xm} - c_y \dot{\psi}_m \tag{37.46a}$$

and

$$V_{yd} = V_{ym} - c_x \dot{\psi}_m \tag{37.46b}$$

Based on an assumption that a vehicle chassis behaves almost rigid against a low-frequency steering input, we have

$$\dot{\psi} = \dot{\psi}_m \tag{37.47}$$

If a_{ym} denotes measured lateral acceleration, usage of Equation 37.27b yields

$$a_{yd} = a_{ym} - e_y \dot{\psi}_m^2 + e_x \ddot{\psi}_m \tag{37.48}$$

where $\ddot{\psi}_m$ is electrically or numerically computed by differentiating $\dot{\psi}_m$.

As physical perception variables, *steering handwheel angle* δ_{sw} and *steering handwheel torque* T_{sw} are directly served. Using Equations 37.29, 37.34b, 37.38, 37.40, 37.42, and 37.43, other objective measurement variables are converted to additional physical perception variables such as *turning curvature* k_d, *turning velocity* ω_d, *nose* angle φ_d, and *nose angle time rate* $\dot{\varphi}_d$.

37.6 VEHICLE DYNAMICS ANALYSIS

As already explained, subjective assessment on handling performance is composed of more than twenty characteristics (refer to Figure 37.1, Tables 37.3 through 37.5). Among them, nowadays, only steady-state steer characteristic is written in forms of mathematical formulation based on a bicycle model of conventional vehicle dynamics [1–7]. The conventional vehicle dynamics cannot explain transient steer characteristics [26–28]. That's why all other characteristics still cannot be described in mathematical formulations. In this handbook, for transient steer characteristics, a new approach of vehicle dynamics analysis is introduced [28].

In order to evaluate the steer characteristic, (a) *steady-state steer*, (b) *transient understeer*, (c) *transient oversteer*, and (d) *power-off reaction steer* have been subjectively assessed so far. The steady-state steer represents a balance between front and rear axle grips during steady-state cornering [6–8]. It has been assessed for a long time through both dry and wet handling tests. However, these days, it is no longer used for a dry handling test; instead, it is still utilized for a wet handling test. The transient understeer, transient oversteer, and power-off reaction steer are mainly evaluated for a dry handling test [40–43].

The understeer or oversteer is perceptually defined in order to evaluate the grip capability of a front or a rear axle, respectively, against the required grip to get both righteous vehicle path and attitude in a transient turn. Power-off reaction steer subjectively measures the lack of rear axle grip relative to front axle grip caused due to a sudden load shift from the rear axle to the front axle while powering off immediately just after full powering on with fixed steering in a turn. All the steer characteristics are assessed through various subjective tests of (a) *lane changing*, (b) *severe lane changing*, (c) *circuit driving*, and (d) *powering on/off in a turn*.

37.6.1 FORMULATION

For the purpose of closely describing a driver's perception on steer characteristics, physical perception variables are employed. Furthermore, the steer characteristics are objectified using (a) *steer gradient* (*SG*), (b) *understeer coefficient* (*US*), (c) *oversteer coefficient* (*OS*), and (d) *power-off reaction steer coefficient*.

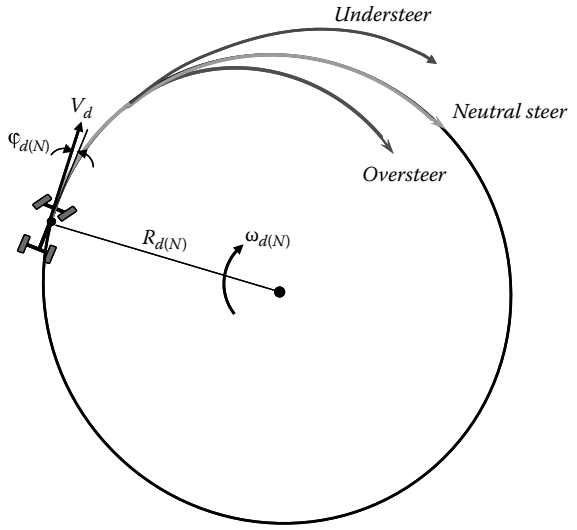

FIGURE 37.66 Steady-state neutral steer during steady-state cornering at a steering pad.

37.6.1.1 Steer Gradient

Figure 37.66 shows a steering pad test with fixed steering at constant speed for the evaluation of the traditional steady-state steer characteristic of a vehicle [6–8]. Here, (*steady-state*) *neutral steer* represents just steady-state turning characteristics with a constant turning radius and fixed steering. Once vehicle speed is very gently increased, the vehicle no longer keeps the constant radius turn due to the increase of a centrifugal force, that is, the neutral steer no longer lasts. In this situation, a balance between front and rear axle grips no longer remains. The lack of grip at one axle compared to the other produces more slip at its axle, which alters the turning radius.

In order to keep the same vehicle path, a steering handwheel should be properly adjusted. When a vehicle needs more steering angle, it is defined that the vehicle behaves *steady-state understeer*. If less steering angle is needed, on the other hand, it is defined for the vehicle to behave *steady-state oversteer*. As an objective index to evaluate the steady-state steer characteristic, *SG* is defined as a gradient of steering handwheel angle δ_{sw} with respect to lateral acceleration a_y. It is written by the SAEJ670e as [51]

$$SG \equiv \frac{\partial \delta_{sw}}{\partial a_y} \begin{cases} > 0 & \text{for steady-state understeer} \\ = 0 & \text{for steady-state neutral steer} \\ < 0 & \text{for steady-state oversteer} \end{cases} \tag{37.49}$$

37.6.1.2 Understeer Coefficient

Transient understeer characteristic is observed to be subjectively evaluated by vehicle path [28,43]. In order to represent the vehicle path as a function of *physical perception variables*, *turning curvature* κ_d and *turning velocity* ω_d are defined at a driver seat (refer to Figure 37.67). They quantitatively describe a driver's perceptual turning curvature and turning fastness, respectively. As shown in Figure 37.67, turning radius measured at the driver seat is denoted as R_d. The turning curvature is determined as a function of the turning radius, that is, $\kappa_d = 1/R_d$.

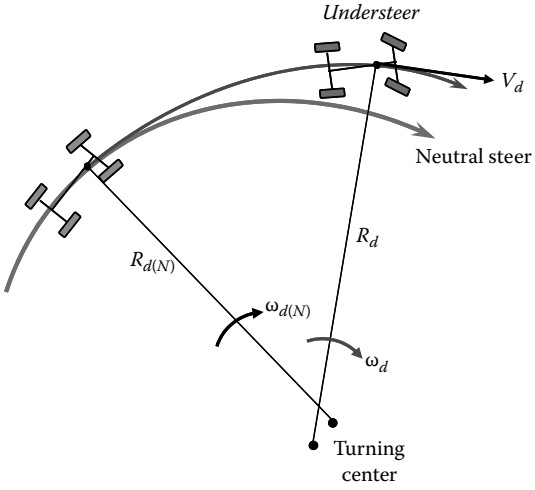

FIGURE 37.67 Turning radius and turning velocity representing transient understeer.

Using lateral acceleration a_{yd} and longitudinal velocity V_{xd} measured at the driver's seat, ω_d is computed using Equation 37.38 as

$$\omega_d = \frac{a_{yd} - \dot{V}_{yd}}{V_{xd}} \tag{37.38}$$

From Equation 37.40, we get

$$\kappa_d = \frac{\omega_d}{V_{xd}} \tag{37.40}$$

If $\kappa_{d(N)}$ and $\omega_{d(N)}$ are defined to represent κ_d and ω_d of steady-state neutral steer (refer to Figure 37.66), the transient understeer is formulated as

$$\Delta\kappa_d = sign(\Delta t_k)\left|\kappa_{d(N)} - \kappa_d\right| > 0 \quad \text{for transient understeer} \tag{37.50}$$

and

$$\Delta\omega_d = sign(\Delta t_\omega)\left|\omega_{d(N)} - \omega_d\right| > 0 \quad \text{for transient understeer} \tag{37.51}$$

where Δt_κ and Δt_ω are the time delays of κ_d and ω_d against $\kappa_{d(N)}$ and $\omega_{d(N)}$, respectively. In case κ_d and ω_d are following in behind $\kappa_{d(N)}$ and $\omega_{d(N)}$, respectively, Δt_κ and Δt_ω are positive. Therefore, the signs of $\Delta\kappa_d$ and $\Delta\omega_d$ just represent the time delays. Their magnitudes stand for the amounts of the transient understeer. Since the transient understeer is also dependent on driver's perceptual steering handwheel angle, κ_d and $\kappa_{d(N)}$ of Equation 37.50 should be measured at the same steering handwheel angle. Furthermore, the same rule is also applied to Equation 37.51.

In order to describe the transient understeer in a formulation, *US* is defined as

$$US \equiv w_{us1}\Delta\kappa_d + w_{us2}\Delta\omega_d > 0 \tag{37.52}$$

where w_{us1} and w_{us2} are understeer weighing factors, and they are dependent on each driver, vehicle, and test condition.

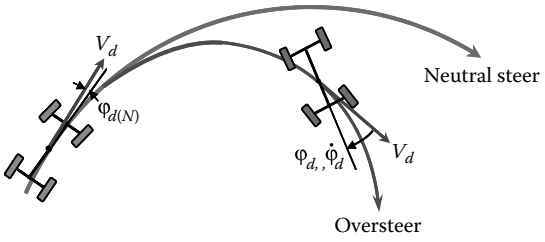

FIGURE 37.68 Nose angle and nose angle time rate representing transient oversteer.

37.6.1.3 Oversteer Coefficient

Contrary to the transient understeer, vehicle attitude is observed to subjectively determine *transient oversteer* characteristics [28,43]. For the purpose of designating the vehicle attitude, nose angle φ_d and its time rate $\dot{\varphi}_d$ defined at the driver seat are used as shown in Figure 37.68. They quantify driver's perceptual vehicle nose-in attitude and nose-in variational quickness. Then, it is determined as

$$\varphi_d = -\tan^{-1}\frac{V_{yd}}{V_{xd}}\begin{cases} > 0 & \text{for nose in} \\ = 0 & \text{for neutral nose} \\ < 0 & \text{for nose out} \end{cases} \tag{37.42}$$

where V_{xd} and V_{yd} are the longitudinal and lateral components of V_d. As the quickness of nose-in changes, the time rate of φ_d is obtained from Equation 37.43 as

$$\dot{\varphi}_d = \dot{\psi} - \omega_d \tag{37.43}$$

Similar to the transient understeer, the transient oversteer is determined as

$$\Delta\varphi_d = sign(\varphi_d)(\varphi_d - \varphi_{d(N)}) > 0 \quad \text{for transient oversteer} \tag{37.53}$$

where $\varphi_{d(N)}$ refers to φ_d of steady-state neutral steer (refer to Figure 37.66). Since $\dot{\varphi}_d$ representing the neutral steer is believed to be zero, we have

$$\Delta\dot{\varphi}_d = sign(\dot{\varphi}_d)\dot{\varphi}_d > 0 \quad \text{for transient oversteer} \tag{37.54}$$

For the purpose of formulation of the transient oversteer, OS is defined as

$$OS \equiv w_{os1}\Delta\omega_d + w_{os2}\Delta\dot{\varphi}_d > 0 \tag{37.55}$$

where w_{os1} and w_{os2} are oversteer weighing factors, and they also depend on each driver, vehicle, and test condition.

37.6.1.4 Power-Off Reaction Steer Coefficient

During powering off immediately just after full powering on with fixed steering, the reaction of a vehicle mostly affects the impulsive change of vehicle attitude [28,43]. A driver subjectively assesses power-off reaction steer characteristics based on his or her perception of instantaneous

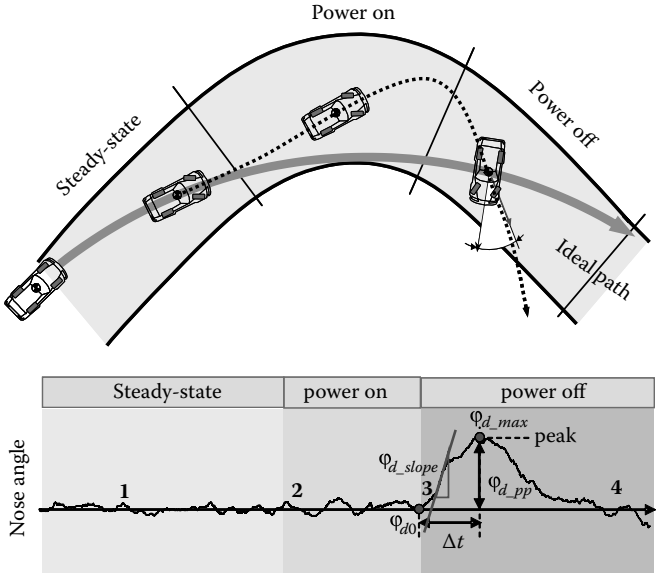

FIGURE 37.69 Nose angle characteristic parameters representing power-off reaction steer.

nose angle change. If φ_{d_0} and φ_{d_max} are the initial and maximum values of φ_d during powering off as shown in Figure 37.69, the peak-to-peak value of φ_d is written as

$$\varphi_{d_pp} = sign(\varphi_{d_max})(\varphi_{d_max} - \varphi_{d_0}) \tag{37.56}$$

As an incremental slope of φ_d, φ_{d_slope} is determined as

$$\varphi_{d_slope} = sign(\varphi_{d_max})\frac{\Delta\varphi_d}{\Delta t} \tag{37.57}$$

where $\Delta\varphi_d/\Delta t$ is the biggest representative slope of φ_d existing between φ_{d_0} and φ_{d_max}.

For the purpose of formulation of the power-off reaction steer, power-off reaction steer coefficient *PS* is defined as

$$PS \equiv w_{ps1}\varphi_{d_slope} + w_{ps2}\frac{\varphi_{d_pp}}{\Delta t_\varphi} + w_{ps3}\varphi_{d_pp} > 0 \tag{37.58}$$

where w_{ps1}, w_{ps2}, and w_{ps3} are the weighing factors of the power-off reaction steer coefficient, and they are also dependent on each driver, vehicle, and test condition. Δt_φ is a time interval between φ_{d_0} and φ_{d_max}.

37.6.2 Analysis

For example, one of the most popular European passenger cars with tires of 215/55R16V was selected to show the process of application of objective formulations representing subjective assessment. With GVW load condition, standard inflated front tire air pressure of 2.4 bar and underinflated rear tire air pressure of 1.4 bar are on purposely used to magnify test results. Through four different handling tests (refer to Figures 37.32, 37.34, 37.37, and 37.22), the subjective assessment and objective measurement were simultaneously carried out.

TABLE 37.7
Subjective Ratings Assessed during the Tests of Lane Changing, Severe Lane Changing, Circuit Driving and Power On/Off in a Turn

Transient Understeer	Transient Oversteer	Power-Off Reaction Steer
6.8	6.5	6.5

For each test, the overall subjective ratings of transient understeer, transient oversteer, and power-off reaction steer were made using a decimal digit rating as shown in Table 37.7. Their bigger values mean better performance with their smaller levels. In addition, δ_{sw}, V_x, V_y, $\dot{\psi}$, a_y, x, and y were measured. Then, κ_d, ω_d, φ_d, and $\dot{\varphi}_d$ of Equations 37.40, 37.38, 37.42, and 37.43 were computed. In order to obtain $\kappa_{d(N)}$, $\omega_{d(N)}$, and $\varphi_{d(N)}$ of Equations 37.50, 37.51, and 37.53, respectively, for simplicity, the objective measurements of quasi steady-state tests were carried out instead of steady-state tests.

In order to quantify the transient understeer, the maximum values of $\Delta\kappa_d$ and $\Delta\omega_d$ of Equations 37.50 and 37.51 are selected for each turn. In Table 37.8, the calculation results of $\kappa_{d(N)}$, κ_d, $\Delta\kappa_d$, $\omega_{d(N)}$, ω_d, and $\Delta\omega_d$ are given. For the purpose of objectification of the transient oversteer, Equations 37.53 and 37.54 are computed using the maximum values of φ_d, $\varphi_{d(N)}$, and $\dot{\varphi}_d$ regardless of steering handwheel angle. Table 37.9 shows the results of $\varphi_{d(N)}$, φ_d, and $\dot{\varphi}_d$ for $\Delta\varphi_d$ and $\Delta\dot{\varphi}_d$ for each peak. For power-off reaction steer, the computational results of φ_{d_0}, φ_{d_max}, φ_{d_slope}, $\varphi_{d_pp}/\Delta t_\varphi$, and φ_{d_pp} are summarized in Table 37.10.

A further correlation study between subjective assessment and objective measurement is referred to the reference [28]. It is recognized that still there exist some more issues to be resolved for the correlation.

37.6.2.1 Quasi Steady-State

For the purpose of replacing steady-state cornering tests by quasi steady-state tests, weave tests with very slow sweep rate were performed at six different vehicle speeds. For these tests, other driving conditions were kept the same as the main four tests. As shown in Figure 37.70, the measurements of turning curvature $\kappa_{d(N)}$, turning velocity $\omega_{d(N)}$, nose angle $\varphi_{d(N)}$, and nose angle time rate $\dot{\varphi}_{d(N)}$ were obtained as functions of steering handwheel angle δ_{sw} for each vehicle speed V_x. Since the width of the utilized proving ground is limited, the higher vehicle speed was obtained with the less steering handwheel angle.

Figure 37.70 illustrates that the turning curvature and nose angle are dependent on each vehicle speed. However, the turning velocity almost does not depend on the vehicle speed. Within about 90° of steering handwheel angle, they are about linear for 40 kph. For the higher vehicle speed, the narrower linear range of the steering handwheel angle can be achieved.

As shown in Figure 37.70, the nose angle time rate does not have any significant values for all vehicle speeds, instead almost zero. By curve fitting, $\kappa_{d(N)}$, $\omega_{d(N)}$, $\varphi_{d(N)}$, and $\dot{\varphi}_{d(N)}$ are determined as functions of δ_{sw} and V_x.

37.6.2.2 Lane Changing

Lane-changing maneuver contains two consecutive turns as explained in Figure 37.32. For that purpose, one cycle of steering handwheel angle δ_{sw} is applied such as half cycle each in opposite direction as shown in Figure 37.71. Afterward, some more steering correction is sometimes needed to compensate excessive transient oversteer behavior. By applying δ_{sw} in one direction, the first turn from the initial straight line is generated. After the vehicle is laterally displaced, it is necessary to reverse δ_{sw} to keep vehicle path straight in the second lane. By this reverse of δ_{sw}, the second turn is achieved.

For this lane-changing test, δ_{sw}, V_{xd}, V_{yd}, $\dot{\psi}$, and a_{yd} were obtained. Then, κ_d, ω_d, φ_d, and $\dot{\varphi}_d$ are computed using Equations 37.40, 37.38, 37.42, and 37.43. In addition, $\kappa_{d(N)}$, $\omega_{d(N)}$, and $\varphi_{d(N)}$ of Figures 37.72 and 37.73 are computed from the fitting equations of Figure 37.70 as functions of δ_{sw} of Figure 37.71 determined. As results, $\kappa_{d(N)}$, κ_d, $\omega_{d(N)}$, ω_d, $\varphi_{d(N)}$, φ_d, and $\dot{\varphi}_d$ have the same value of δ_{sw} at any instant shown in Figures 37.72 and 37.73.

In Figure 37.72, κ_d and ω_d are shown smaller in the absolute sense than $\kappa_{d(N)}$ and $\omega_{d(N)}$, respectively, in the first and second turns. Then, $\Delta\kappa_d$ and $\Delta\omega_d$ of Equations 37.50 and 37.51 become positive in both turns. Therefore, it is confirmed that there exist transient understeer behaviors in the first and second turns during lane changing as shown in Figure 37.32. The understeer tendency in the second turn is shown bigger than that in the first turn.

Figure 37.73 illustrates that each peak of φ_d or $\dot{\varphi}_d$ has occurred due to each reverse steering operation (refer to Figure 37.71). In general, the first peak of φ_d is relatively much smaller than the second peak. It is also located in the zone of the transient understeer (refer to Figure 37.72). In this zone, the transient understeer behavior is believed more dominant than transient oversteer behavior

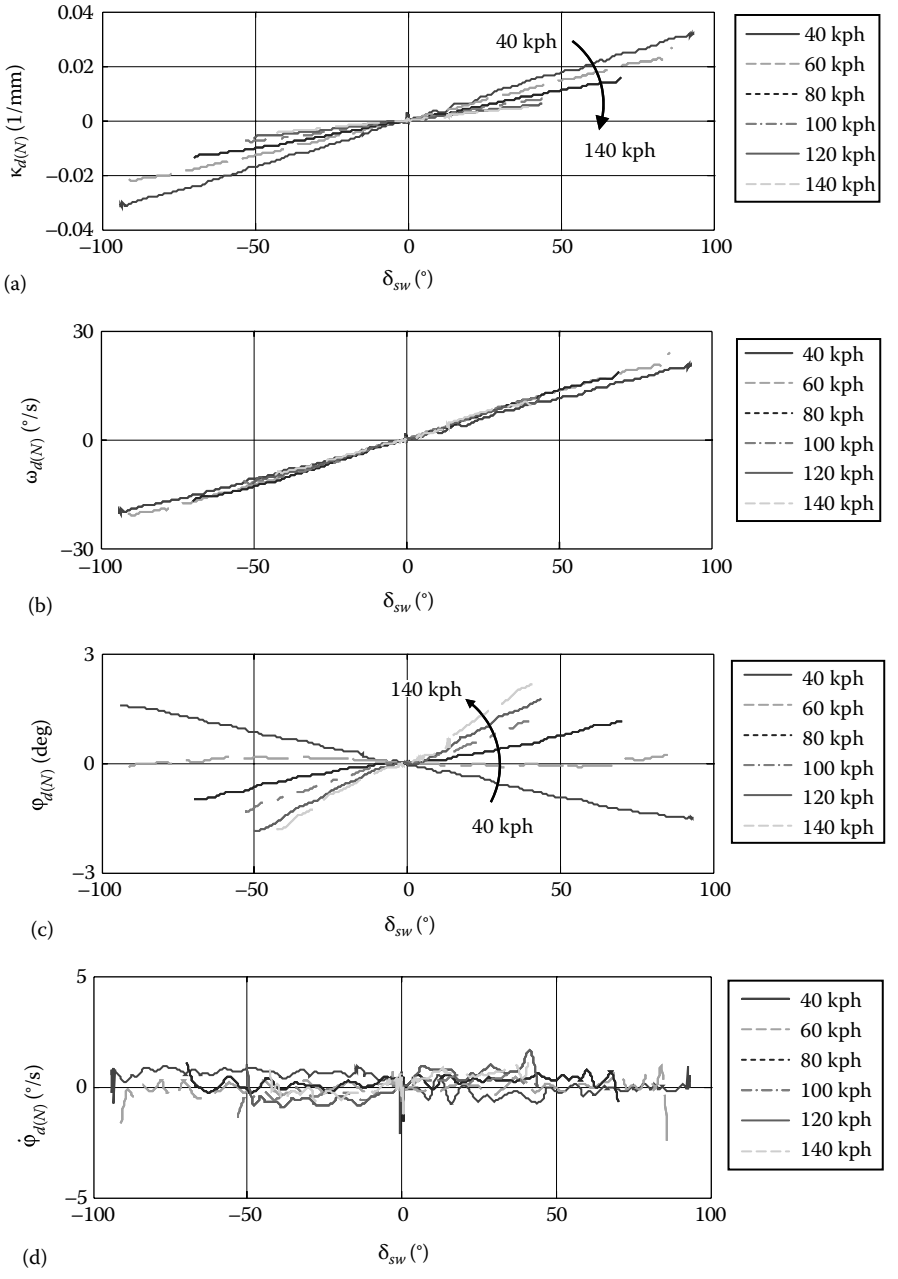

FIGURE 37.70 Quasi steady-state cornering data representing steady-state neutral steer with various vehicle speeds. (a) Turning curvature, (b) turning velocity, (c) nose angle, and (d) nose angle time rate.

so that the oversteer is not subjectively assessed. The second peak explains that the transient oversteer is assessed at the end of lane changing.

After applying the second reverse steer (refer to Figure 37.71), κ_d and ω_d are shown smaller in the absolute sense than $\kappa_{d(N)}$ and $\omega_{d(N)}$, respectively, in Figure 37.72. Even though that, the understeer is not subjectively assessed in this region (refer to Figure 37.32). As shown in Figures 37.32 and 37.73, in this region, the oversteer is believed much significant so that only the oversteer is subjectively assessed.

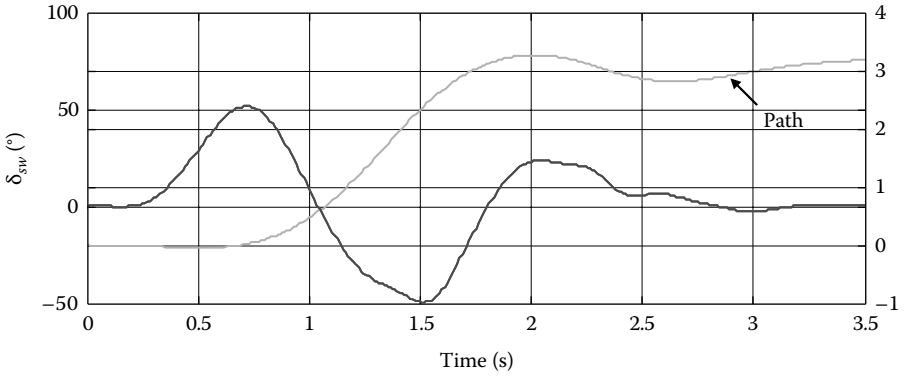

FIGURE 37.71 Steering handwheel angle and vehicle path measured during lane changing.

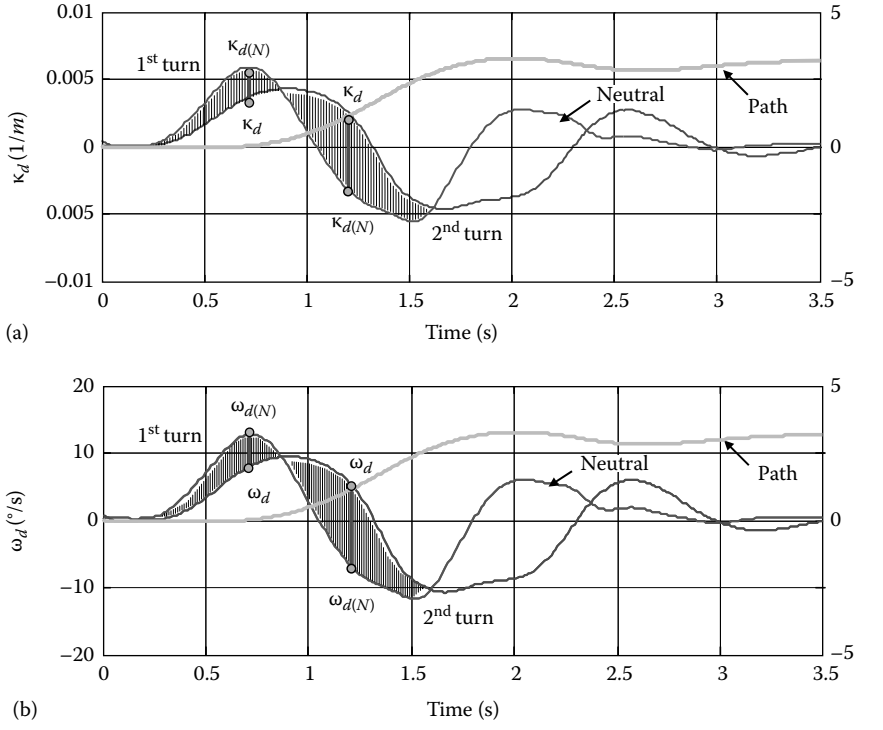

FIGURE 37.72 (a) Turning curvature and (b) turning velocity during lane changing.

37.6.2.3 Severe Lane Changing

In order to accomplish severe lane changing with three consecutive turns, one and half cycles of steering handwheel angle δ_{sw} are first applied (refer to Figure 37.34). Due to unwanted oversteer behavior, afterward, additional steering corrections are needed to correct vehicle path straight as shown in Figure 37.74. Similar to the lane changing, by applying δ_{sw} in one direction, a turn from the initial lane is made.

After a vehicle is laterally displaced closed to the second lane, it is necessary to reverse δ_{sw} and hold that for some moment in order that a vehicle moves back to the original lane again. From this reverse of δ_{sw}, the second turn is achieved. In order to return vehicle path straight in the original lane, afterward, the third turn is achieved by another reverse of δ_{sw} and some more corrections if needed.

Even for the severe lane changing, using the same way of the lane changing, $\kappa_{d(N)}$, κ_d, $\omega_{d(N)}$, ω_d, $\varphi_{d(N)}$, φ_d, and $\dot{\varphi}_d$ are computed as shown in Figures 37.75 and 37.76. Similar to the lane changing,

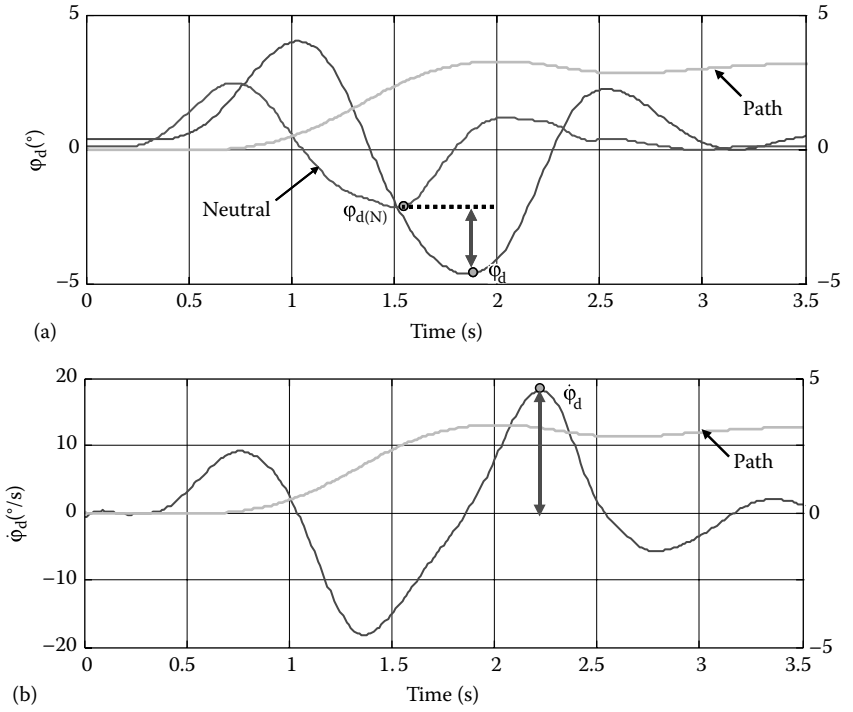

FIGURE 37.73 (a) Nose angle and (b) nose angle time rate during lane changing.

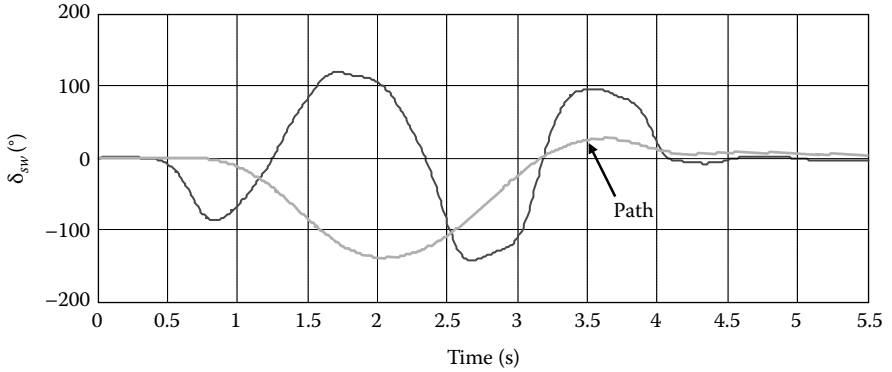

FIGURE 37.74 Steering handwheel angle and vehicle path measured during severe lane changing.

in the absolute sense, κ_d and ω_d are shown smaller than $\kappa_{d(N)}$ and $\omega_{d(N)}$, respectively, in each turn in Figure 37.75. Then, $\Delta\kappa_d$ and $\Delta\omega_d$ of Equations 37.50 and 37.51 become positive in all three turns. Therefore, it is also confirmed that there exist transient understeer behaviors in the three turns as shown in Figure 37.34. The understeer tendency in the third turn is the biggest among three turns.

In Figure 37.76, each peak of φ_d, $\varphi_{d(N)}$, or $\dot{\varphi}_d$ is observed after the application of each reverse steer (refer to Figure 37.74). Since the first peak is in general small enough to be ignored, it is believed not meaningful. Furthermore, Figure 37.76 demonstrates that there exist two significant peaks representing transient oversteer behaviors while severe lane changing (refer to Figure 37.34). After the third reverse steer, κ_d and ω_d are shown smaller in the absolute sense than $\kappa_{d(N)}$ and $\omega_{d(N)}$, respectively, in Figure 37.75. In this zone, the understeer is believed not perceptually interesting, since the oversteer is more important to be assessed.

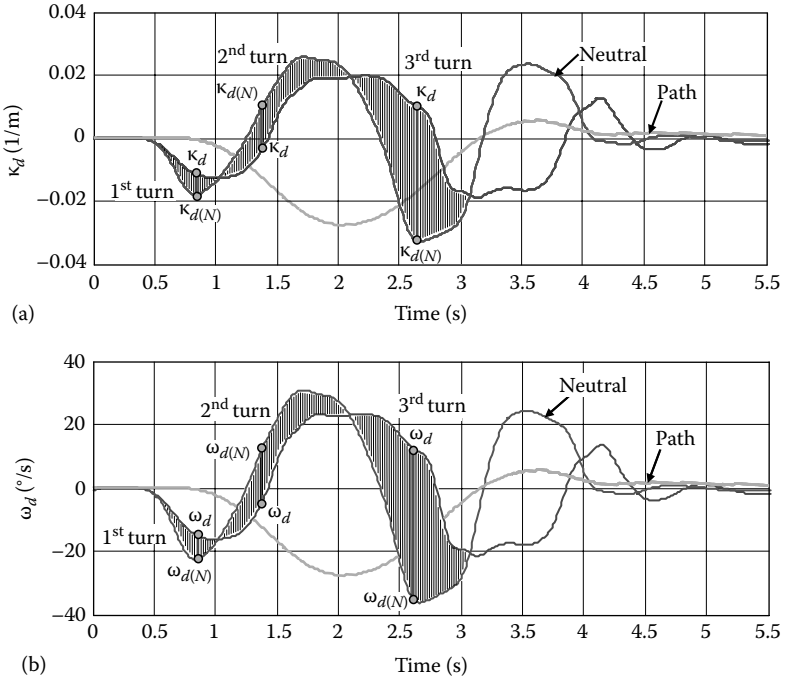

FIGURE 37.75 (a) Turning curvature and (b) turning velocity during severe lane changing.

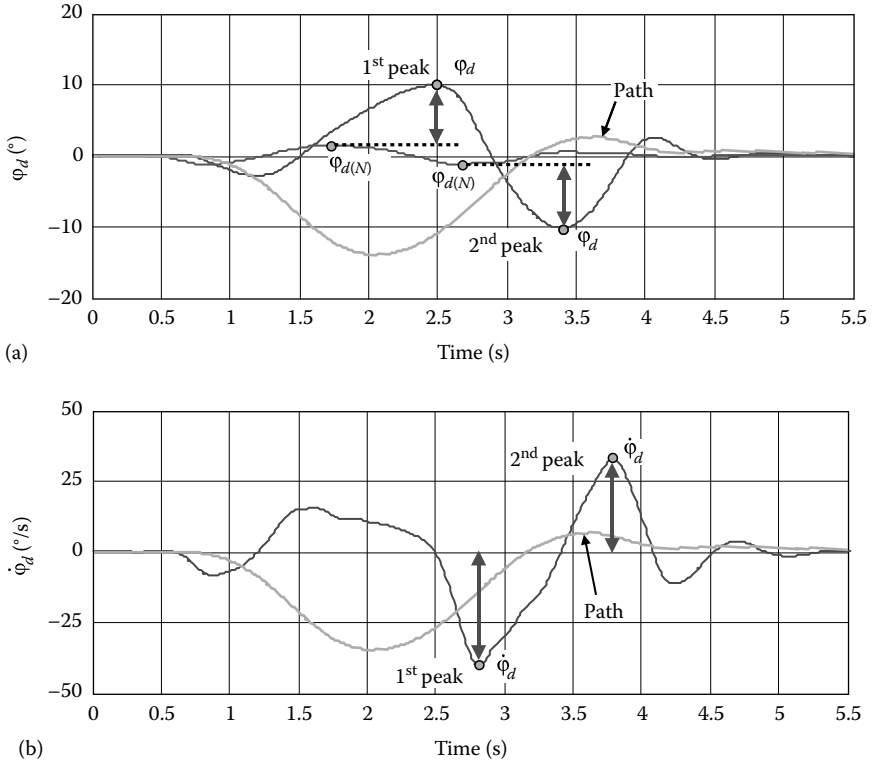

FIGURE 37.76 (a) Nose angle and (b) nose angle time rate during severe lane changing.

37.6.2.4 Circuit Driving

In general, a handling circuit contains many corners with various turning curvatures. By a driver's comment, one corner with the biggest severity was selected for this analysis. Figure 37.77 shows the objective measurement of δ_{sw} at this corner.

For circuit driving, Figures 37.78 and 37.79 are obtained using the same way of the lane changing. Since in Figure 37.78 positive values of $\Delta\kappa_d$ and $\Delta\omega_d$ are observed, transient understeer behavior is expected in this corner. In Figure 37.79, one significant peak of φ_d explains that there also exists transient oversteer tendency (refer to Figure 37.21).

37.6.2.5 Powering On/Off in a Turn

Figure 37.80 shows the objective measurements of steering handwheel angle and vehicle speed during powering on/off in a turn (refer to Figure 37.22). Steering handwheel angle δ_{sw} was maintained

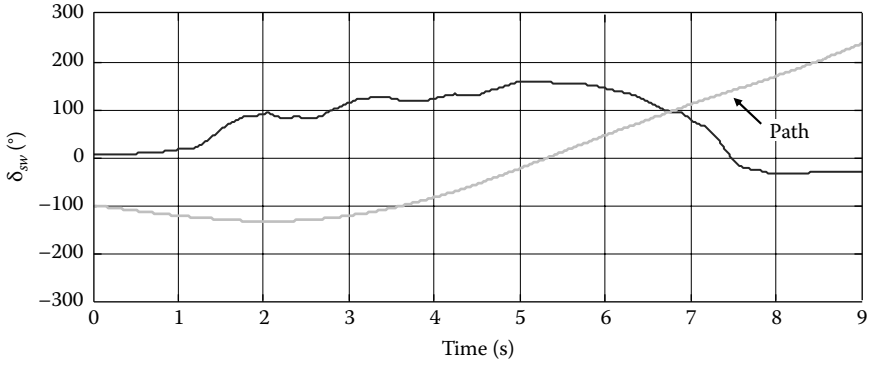

FIGURE 37.77 Steering handwheel angle and vehicle path measured during circuit driving.

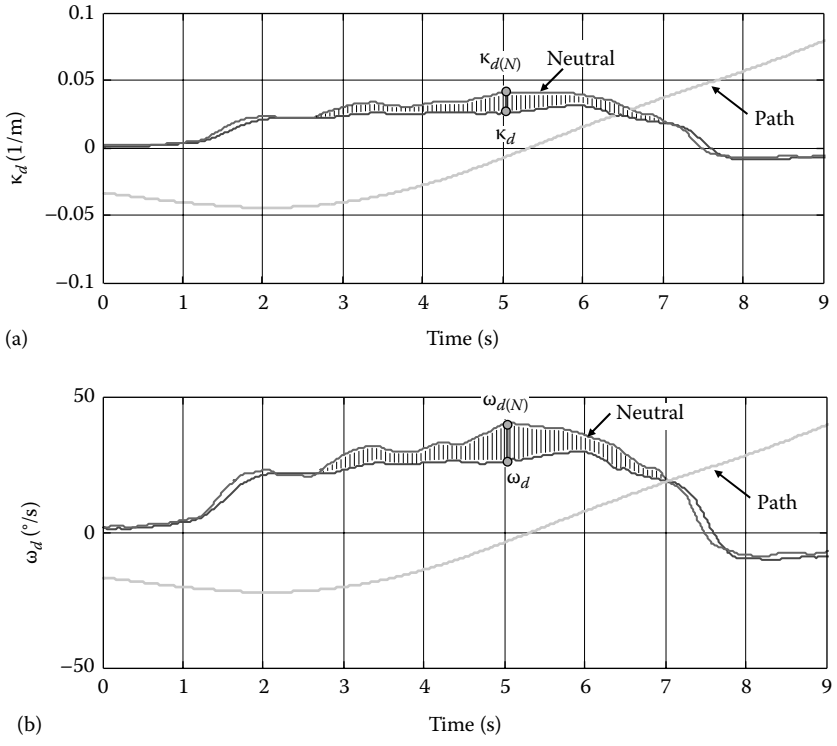

FIGURE 37.78 (a) Turning curvature and (b) turning velocity during circuit driving.

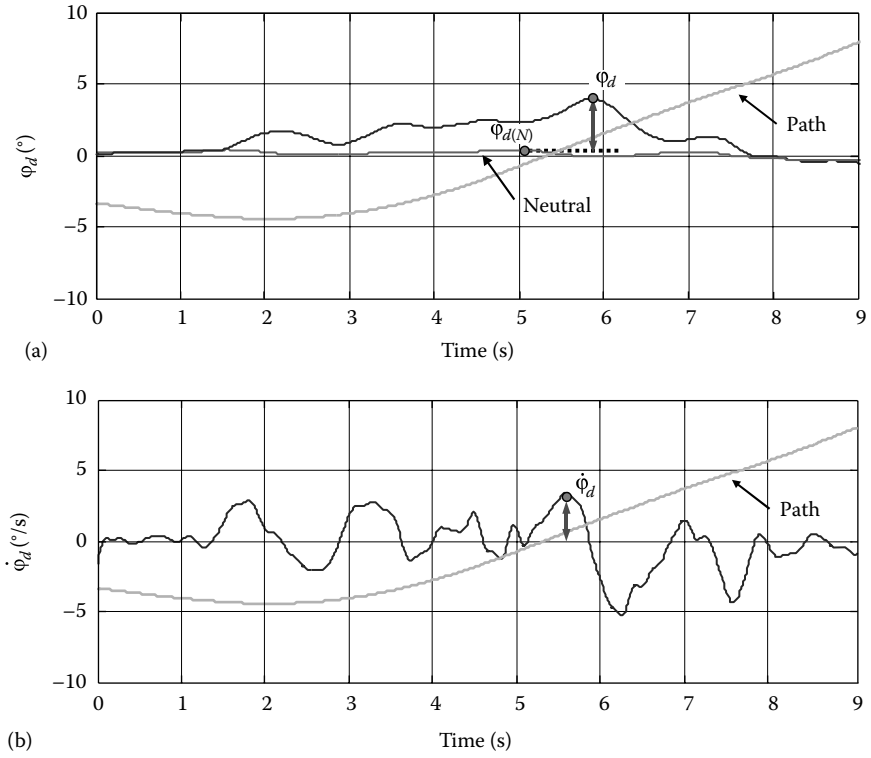

FIGURE 37.79 (a) Nose angle and (b) nose angle time rate during circuit driving.

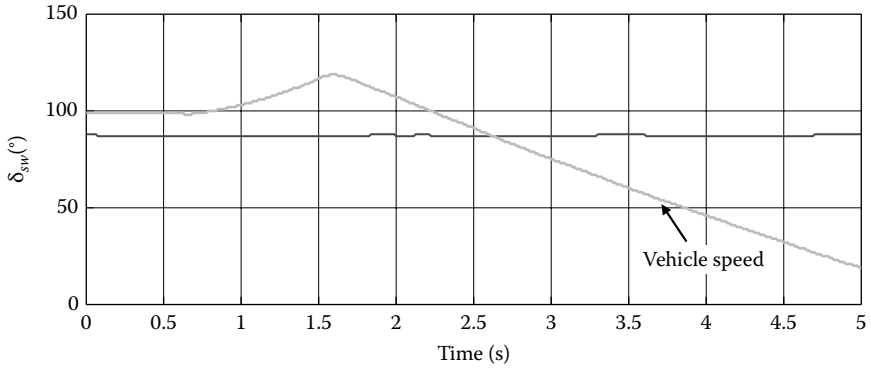

FIGURE 37.80 Steering handwheel angle and vehicle speed measured during powering on/off in a turn.

almost constant during the test. Using the same way of the lane changing, Figures 37.81 and 37.82 are determined for a powering on/off in a turn test.

Even though δ_{sw} is kept constant during the test, $\kappa_{d(N)}$ becomes constant only while steady-state cornering. It is due to vehicle speed change (refer to Figure 37.70). However, both κ_d and ω_d are decreased due to power on as shown in Figure 37.81. This means that a vehicle travels out from the steady-state path. This fact illustrates transient understeer behavior during powering on. Due to power off, in contrast to power on, κ_d and ω_d do not have any meaningful changes relative to $\kappa_{d(N)}$ and $\omega_{d(N)}$, respectively.

Due to constant δ_{sw}, $\varphi_{d(N)}$ also remains constant only while steady-state cornering as shown in Figure 37.82. By power on, only small meaningless disturbances of φ_d and $\dot{\varphi}_d$ from their steady-state values are shown. However, there are significant instantaneous changes of φ_d and $\dot{\varphi}_d$ due to power off.

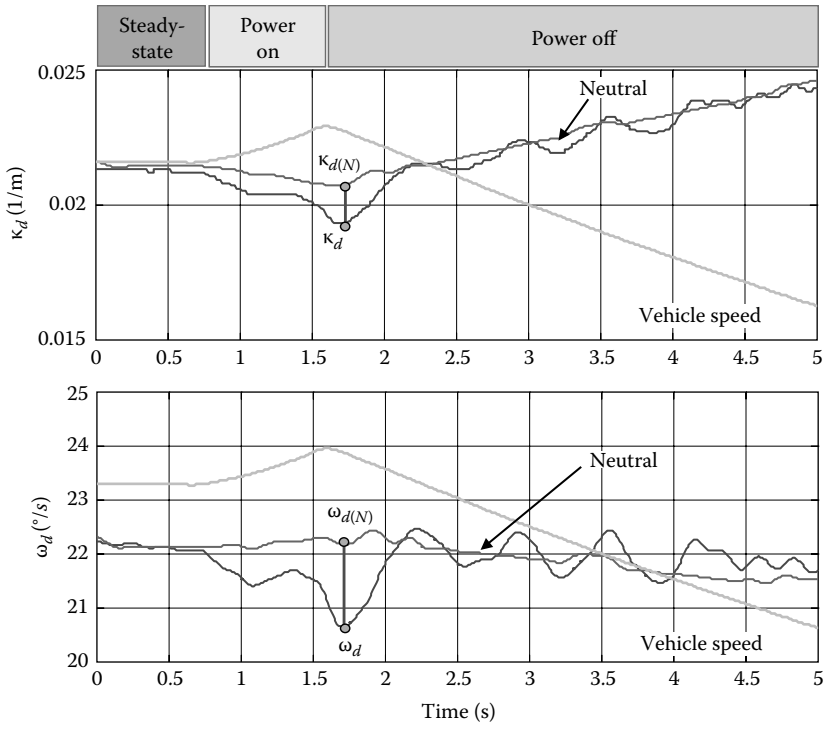

FIGURE 37.81 Turning curvature and turning velocity during powering on/off in a turn.

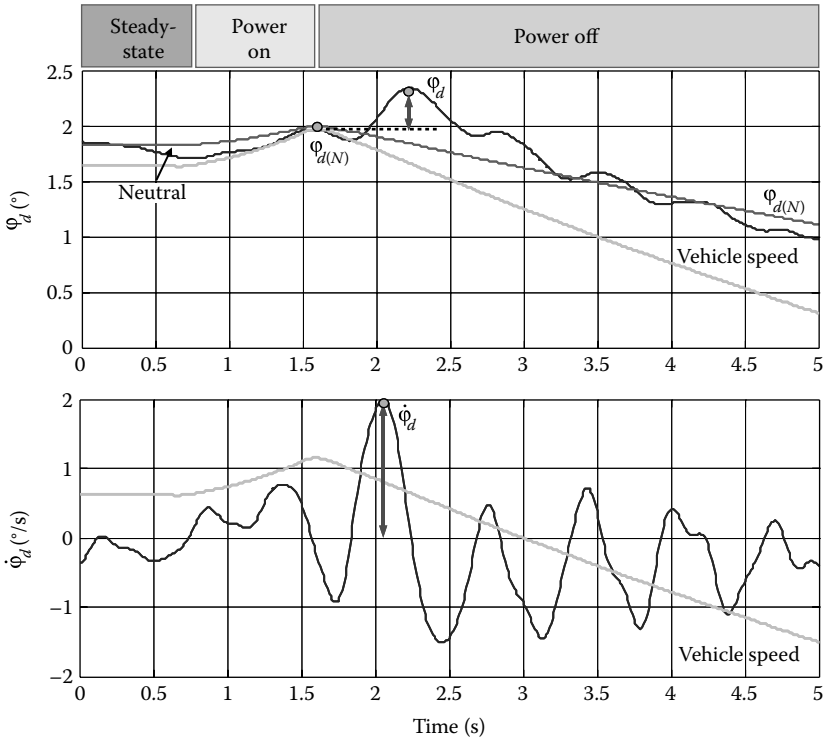

FIGURE 37.82 Nose angle and nose angle time rate during powering on/off in a turn.

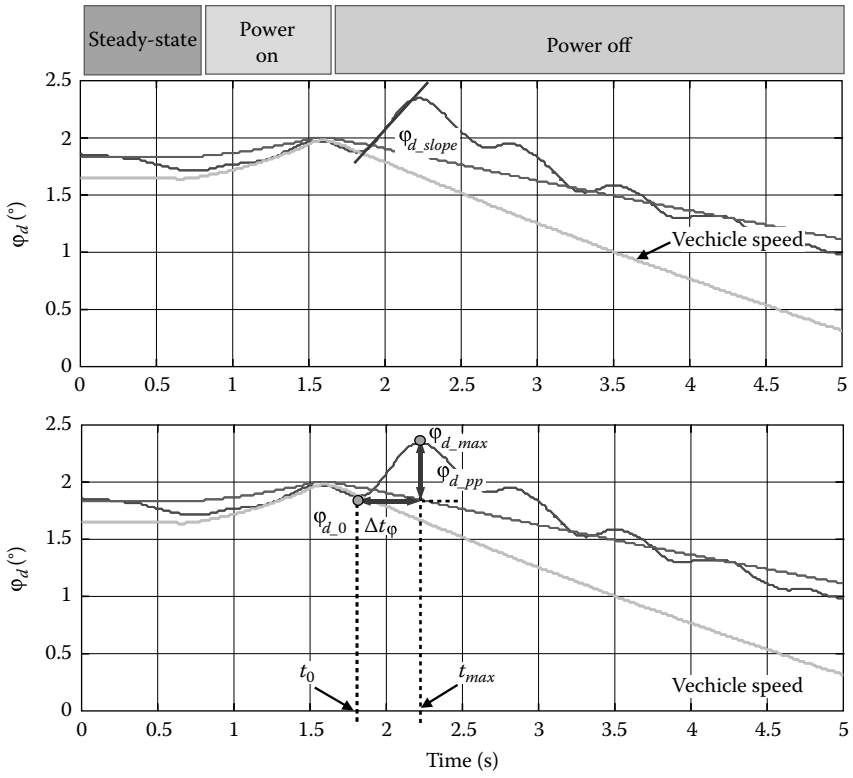

FIGURE 37.83 Characteristic parameters of power-off reaction steer.

These results show that the variation of vehicle nose-in attitude is more influenced by power off. This fact validates transient oversteer behavior during powering off (refer to Figure 37.22).

As the characteristic parameters of power-off reaction steer, φ_{d_slope} and φ_{d_pp} are shown in Figure 37.83. In addition, φ_{d_0}, φ_{d_max}, and Δt_φ are given for the computation of $\varphi_{d_pp}/\Delta t_\varphi$.

37.6.3 Conclusion

Instead of steady-state steer characteristic, nowadays, transient steer characteristic is subjectively assessed as one of handling performance. For that purpose, transient understeer is defined as a perceptual indicator of front axle grip necessary to get controllability in a turn. Transient oversteer and power-off reaction steer are also defined as perceptual measures of rear axle grip. The subjective assessment on the understeer or oversteer is significantly dependent on vehicle path or vehicle attitude, respectively. However, the understeer or oversteer does not much depend on the vehicle attitude and vehicle path, respectively. The power-off reaction steer is subjectively assessed based on a driver's perception on vehicle attitude impulsive change.

The transient understeer is formulated as a function of turning curvature and turning velocity, while the transient oversteer is written as a function of nose angle and nose angle time rate. The power-off reaction steer is expressed as a function of the incremental slope, (effective) durational change, and peak-to-peak value of the nose angle. These formulations are applied through four handling tests. The test results show the understeer, oversteer, and power-off reaction steer quantitatively described in figures.

In order to illustrate subjective tests necessary for each subjective assessment, for example, a cross-functional matrix between characteristics and tests regarding handling performance is given in Table 37.11. In Table 37.12, the summary of each subjective assessment is described. In the table,

TABLE 37.11
Cross-Functional Matrix between Characteristics and Tests Regarding Handling Performance

		Straight Ahead				Steering					Lane Changing		Cornering			
Performance	Maneuver	Free Steering	Fixed Steering	Powering On/Off	Braking	On-Center Steering	Off-Center Steering	Progressive Steering	Limit-Grip Steering	Flick Steering	Lane Changing	Severe Changing	Circuit Driving	Powering On/Off in a Turn	Braking in a Turn	Rollover Cornering

TABLE 37.12
Summary of Subjective Assessments Regarding Handling Performance

Performance		Description	What Is Evaluated	How to Test
Straightability	Residual pull	Lateral drift characteristic of a vehicle caused due to residual steering torque with free steering at constant speed	Lateral deviation	Free steering in straight ahead
	Running straight	Straight-running ability without any drift, wander, or sloppiness with fixed steering at constant speed	Drift, wander, and sloppiness	Fixed steering in straight ahead
	Torque steer	Lateral drift characteristic of a vehicle due to power on in straight ahead with fixed steering	Lateral deviation	Powering on/off in straight ahead
	Braking straight	Straight-braking ability without any disturbance of vehicle attitude or path when a vehicle instantaneously stops complete	Attitude or path deviation	Braking in straight ahead
Steerability	On-center	Steering torque and vehicle path change in response to a very slow steering input at and around the center of steering	Steering torque	On-center steering
	Steering response	Time-dependent vehicle path change against a transient steering input	Vehicle path change	Off-center steering
	Linearity	Linearity characteristic of trajectory of vehicle path against a gradually incremental steering input	Profile of vehicle path	Progressive steering
	Steering precision	Overall impression on how accurately a vehicle follows an intended path with a series of steering maneuvers	Path following Easiness to control	Circuit driving
	Steering angle	Output-to-input ratio of a steering input in getting the same path	Steering handwheel angle	Circuit driving
	Steering addition	Additional grip produced by an extra steering input at grip limit in a turn	Vehicle path change	Limit-grip steering
	Steering effort	Steering handwheel torque required to change the direction of vehicle path	Steering handwheel torque	Off-center steering, circuit driving
	Returnability	Quickness and precision of steering handwheel movement returning to its neutral position	Oscillation of steering handwheel angle	Flicking steering, circuit driving

TABLE 37.12 (continued)
Summary of Subjective Assessments Regarding Handling Performance

Performance		Description	What Is Evaluated	How to Test
Controllability	Balance FA/RA	Balance FA/RA	Vehicle path relative to that of NS Vehicle attitude relative to that of NS	Lane changing, severe lane changing circuit driving, powering on/off in a turn
	Power-off reaction	Steer characteristic due to an instantaneous load transfer from the rear axle to a front axle while powering off with fixed steering in a turn	Vehicle path relative to that of NS Vehicle attitude relative to that of NS Vehicle attitude impulsive change	Powering on/off in a turn
	Grip limit	Attainable maximum speed in still controlling a vehicle in lane changing or cornering	Speed limit, vehicle path Vehicle attitude	Lane changing, severe lane changing Circuit driving
	Controllability at limit	Overall impression on how easy to control a vehicle at grip limit	Vehicle path Vehicle attitude	Lane changing, severe lane changing Circuit driving, powering on/off in a turn
	Driving power	Traction ability to speed up while powering on in the exit zone of a corner	Vehicle speed increase	Circuit driving, powering on/off in a turn
Stability	Yaw stability	Ability to keep down the yaw oscillation of a vehicle	Oscillation of vehicle path	Flick steering, lane changing, severe lane changing
	Rear axle stability	Ability to restrict the sideslip oscillation of a vehicle	Oscillation of vehicle attitude	Flick steering, lane changing, severe lane changing, powering on/off in a turn
	Roll stability	Ability to depress the roll oscillation of a vehicle	Oscillation of vehicle body motion	Flick steering, lane changing, severe lane changing
	Braking stability	Ability to stop a vehicle without any disturbance of vehicle attitude or path while full braking in a turn	Disturbance of vehicle attitude or path	Braking in a turn
	Rollover stability	Ability to restrain a vehicle from its rollover motion.	Debeading Tire lift-off	Rollover cornering
	Bump steer	Steer instability caused due to the jounce and rebound of each front suspension	Vehicle path change	Circuit driving

TABLE 37.13
Conditions of Subjective Tests Regarding Handling Performance

	Test	Speed (kph)	Steering (deg)	Powering	Braking
Straight ahead	Free steering	100 (high gear)	Free	Constant	NA
	Fixed steering	Up to limit	Fixed	Constant	NA
	Powering on/off	40 (low gear) 80 (high gear)	Fixed	Full on and off	NA
Steering	Braking	Normal driving	Hands-on	NA	Full
	On-center steering	Up to limit	Miniature slow perceptual ramp	Constant	NA
	Off-center steering	Up to limit	$\pm(\delta_{sw0} + \Delta\delta_{sw})$ Perceptual step	Constant	NA
	Progressive steering	Up to limit	High and mid perceptual ramp	Constant	NA
	Limit-grip steering	Up to limit	$\pm(\delta_{sw0} + \Delta\delta_{sw})$ Perceptual ramp	Constant	NA

	Braking in a turn	Up to limit	Fixed	NA	Full
	Rollover cornering	Dependent on each test procedure			NA

what is evaluated and how to test are also briefly explained. Table 37.13 outlines the detailed conditions of speed, steering, powering on/off, and braking for each subjective test.

Figure 37.84 shows a hierarchical diagram from vehicle motion variables to performance through subjective assessment variables. Some of the vehicle motion variables are measured during numerous subjective tests. The objective measurement variables yield the physical perception variables defined with respect to a driver's point of view. The physical perception variables describe the subjective assessment variables in mathematical formulations.

The subjective assessment variables explain the driver's perceptual judgment on characteristics. The characteristics are the subgroups of capabilities. Finally, the capabilities are represented by performance. For an example, Table 37.14 illustrates the objective measurement variables, physical perception variables, and subjective assessment variables regarding transient understeer, transient oversteer, and power-off reaction steer.

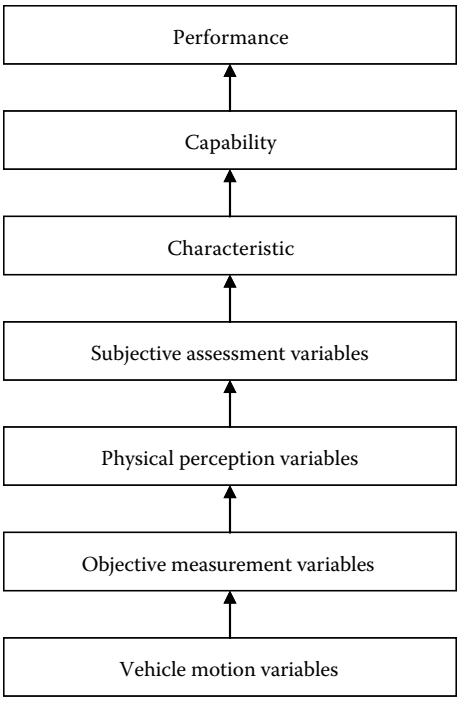

FIGURE 37.84 Hierarchical diagram from vehicle motion variables to performance through subjective assessment variables.

ACKNOWLEDGMENT

Special thank is owed to Dr. Hwi Joong Kim, the previous CTO of Hankook Tire, for his encouragement in the beginning and continuous support. I would like to thank Mr. Roger G. Becker, Lotus, for his open discussions; John P. Whitehead for a specially designed training program with MIRA; and to Mr. Franz-Jurgen Dressen, Ford, for his clear demonstration and discussion. Particular thanks are also due to Jung-Sik Kim for his successive help until the completion of this work.

Understanding the driver of an automobile has been attractive to researches from many different disciplines for more than half a century. On the basis of their acquirements, models of the (human) driver have been developed to better understand, analyze, and improve the combined couple of driver and automobile.

Due to distinctive demands on the models in accordance with different kinds of applications, a variety of various driver models are available. An overview of driver models is given with respect to their application and different methodical modeling approaches. The emphasis is put on the interest of engineers, who generally focus on the automobile (like design and optimization of vehicle components and the overall vehicle dynamics behavior) by applying their approved (mathematical) methods. Nonetheless, a brief look beyond is added to better complete the view on the involved task of driving and driver modeling for automobile dynamics application.

38.1 INTRODUCTION

In the early 40s of the last century, a systematic investigation of the dynamics of automobiles has been initiated [1]. The real automobile was mapped into a mathematical model, represented by differential equations, and a basic understanding of the vehicle system dynamics (VSD) was attained. It was not before the mid-1950s that the driver of the automobile was brought into view [2], in the 1960s e.g., [3–7]. Although it was already stated in the 1960s that automobile and driver form a closely coupled man–machine system and must consequently be treated as a whole [8], the main concern and focus—with the enormous amount of scientific publications in mind—remained on the vehicle ("without the driver"). And considering still the success of the development of automobiles, one may even see no deficit. With the introduction of systems controlling the dynamics and stability of the automobile, driver assistance

systems, and other systems taking over some control of the driver, all doubts should be resolved on the need of capable driver models, and many publications can be noted in this respect.

Further progress in understanding the human driving behavior was made since then, by putting engineers in touch with other disciplines like physiology and psychology (e.g., [9–11]), and a number of demands on models that aim to mimic the automobile driver have been addressed. Some of the key demands to be mapped in a driver model are listed briefly in the following:

- General human driver skills and characteristics (such as visual, vestibular, tactile, auditory), information reception, perception and processing, neuromuscular dynamics with thresholds, time delays and limitations, preview, prediction/anticipation, adaptation/learning, planning capabilities (path and speed adjustment)
- Specific types of drivers with respect to experience, age, willingness to take and accept risks, etc.
- Portraying features like concentration, tiredness, stress, emotions

Whether a model can be called a driver model of a human and reflects human driving behavior in a sufficient way or not will not be addressed here, but at least some of the aforementioned demands must be reflected in a model to distinguish from "automatic driving controllers", which are not covered here. Despite this restriction, a large number of articles with driver models have been published so far; a very extensive and thorough list of publications up to 1997 with many details on the human driver is given by Jürgensohn in [12]. More recent papers up to 2003 and a valuable insight into the understanding and modeling of the human driver are included in a state-of-the-art article on this topic by MacAdam [13].

Quite a lot of published driver models have basic ideas in common; they often differ in the way the previously listed demands are realized mathematically. But there are also more principal differences that usually result from differently emphasized demands dependent on the application. The applied methodical approach can be used to categorize driver models, for instance, into

- Mathematical methods, using control theory (transfer functions in frequency domain, optimal control, adaptive control, predictive control), identification theory, fuzzy logic control (FLC), neural networks (NNs), stochastic methods, and hybrid approaches, which generally result in (non)linear algebraic or differential equations
- Descriptive methods, resulting in classifications, schemes, descriptions, etc.

Another way of categorizing driver models is to have a look at their applications. Indeed, it is quite obvious, and this contribution has to prove that there is (can be) no unique driver model, but there are only driver models especially tailored to meet the specific demands of each application [14]. Although categorizing driver models by application seems to be reasonable, this intention is not as straightforward as it seems to be. On the one hand, a single driver model may be used for several different applications; on the other hand, applications themselves must be classified and cannot always be clearly separated from each other. To overcome this problem, the authors have chosen comprehensive categories of applications, which are refined at the beginning of each section. Within a category, models are combined to methodic bundles.

Although automobile and driver form a couple, the aim and reason of investigation are often focused either on the vehicle or on the driver, but still there are applications where the couple is not split. After defining driving task and environmental situation, which may include other automobiles with drivers (traffic), the main concern of analysis may be

- On the vehicle: Design and tuning of vehicle components, of the overall vehicle; vehicle dynamics; active safety matters with respect to onboard systems
- On the driver: Understanding driver and (individual) driving behavior in general, path and speed planning features, optimized driver behavior, subjective driving perception

- On the overall (combined) system: Reconstruction of accidents, accident analysis/prevention, learning tasks, evaluation of drivability and handling, driver support systems, active safety
- On the environment/traffic: Influence on/of other drivers in simulator or in traffic, traffic flow, general understanding of the "system" traffic

In this way, also the following sections are arranged. As comprehensive literature surveys are already available [12,13,15,16], often referred to papers are selected here to give a basic insight into "typical" driver models, considering the variety of different applications and mathematical approaches.

38.2 APPLICATIONS WITH FOCUS ON THE VEHICLE

38.2.1 General Remarks

A lot of vehicle dynamics application is done by engineers and they generally have their focus and interest on the vehicle itself. A model of the driver is mainly required to resolve given driving tasks that are the means for closed-loop tests and simulations. One may call this kind of driver a "virtual test driver" [17], as the main demand for this kind of applications on the driver model is to be able to follow a prescribed route at a given or self-imposed speed by operating a virtual prototype of the vehicle. Output quantities of the driver model are steering wheel angle/torque, accelerator or brake pedal position, and gear.

Typical interests of investigation are

- Vehicle component design
- Vehicle dynamics analysis, such as (closed-loop) handling behavior
- Overall vehicle stability analysis
- Design of onboard controls that influence vehicle dynamics and stability

For vehicle component design, load spectra are required, in particular to estimate life of fatigue. When measurements are not (yet) available, simulation is a tool to quantify them. Often the driver model is here more like a "driver robot" than a "test driver" when its task is simply kept to tracking at given speed profiles. But one has to keep in mind that the input from a technical driver and a human driver may be quite dissimilar even if this becomes not obvious from the motion of the vehicle as a result of the integrating behavior of the vehicle [17].

The "test driver" model needs enough complexity to represent both learnt patterns, which are considerably important in car driving, and correction elements. Driver models that include some level of anticipation or prediction or an internal model [13] and some level of compensation capability may well fit for this purpose.

Closely related to vehicle component design is simulating and optimizing (closed-loop) handling behavior—a typical task of vehicle dynamics analysis. In particular, effects of specific design parameters, for example, of the suspension, the steering system, or the tires, on handling and stability behavior are analyzed. However, when it comes to (subjective) evaluation of driveability and handling, the human test driver can still hardly be replaced (see Section 38.4 [12]).

Stability of the vehicle has long been studied without the driver (in open-loop tests) although the driver can appear to be a destabilizing part of the system. The introduction of control systems, that influence vehicle dynamics additionally to the driver, stimulated closed-loop stability analysis that consequently includes a driver model. For the design of this kind of controllers, the driver must be considered, either in outdoor or in simulator tests and in simulations, to account for a possible interference and coordination of both "controllers".

Certain types of virtual test driver models are used quite collectively for all these kinds of applications, mostly with control (theory) strategies, but also other methodical approaches can be noticed. Individual properties of the driver are often disregarded; nonetheless, models representing classes of particular types of drivers (with respect to experience, age, skills, etc.) are favorable.

Models of the automobile tend to be more complex and better validated than driver models and are nowadays often assembled with multibody system (MBS) or VSD software (ADAMS, CarSim, LMS, SIMPACK, veDYNA, and others). This may be the reason why driver models are offered from some MBS software packages as well, as closed-loop simulation will become quite easy from the user point of view. The basic idea of three of these driver models is reviewed here, and another in [18].

Some typical representatives of their class are presented in the following taking into account different mathematical approaches.

38.2.2 Virtual Test Driver Models

One may consider "driving an automobile" intuitively as a control task, and this may be a reason why control theory–based driver models have been successful since the first driver models have been introduced. Most of these models have been developed to control the lateral vehicle dynamics (for previous reviews, see [12,13,15,19]). Longitudinal dynamics is often simply kept to following a given or optimized speed profile, rather independent from the steering task of the driver, considering more the capabilities of the vehicle than those of the driver.

A look back to 1953, when Kondo [2,20] started with driver modeling in Japan, may be helpful to illustrate some of the roots that many following models up to now are (although not directly) obliged to [21]. Based on the two-wheel vehicle model on a straight line, running at constant speed with side wind disturbances, Kondo's driver steers in a way that a point, a certain distance along the vehicle centerline ahead, is going to coincide with the sight point, which is the preview distance L ahead on the reference course (see Figure 38.1).

From a control theory point of view, the steering strategy can be understood as the attempt of the driver to diminish Δy_p a distance L ahead of the vehicle. In terms of transfer functions, this can be illustrated in a more general form by the control loop of Figure 38.2, where $P(s)$ represents the preview strategy of the driver for the desired path y_d with path input y_0, $H(s)$ the control characteristics of the driver, $G(s)$ the transfer function(s) of the vehicle, and $B(s)$

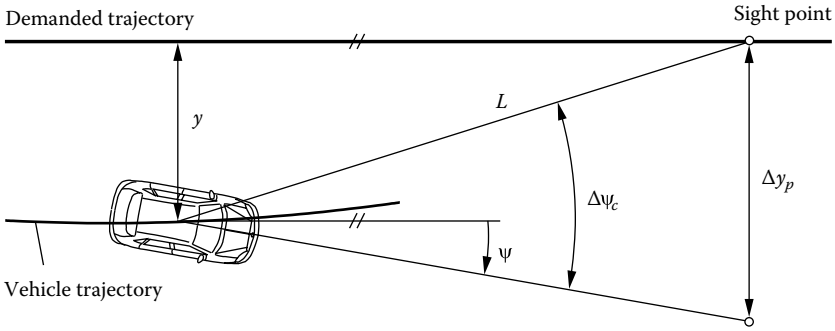

FIGURE 38.1 Kondo's "shaft" driver model.

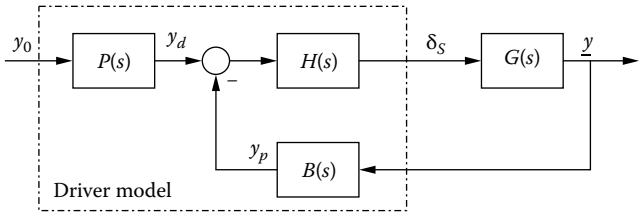

FIGURE 38.2 Basic control loop of preview tracking models.

the feedback function respectively, which is the prediction function of the vehicle motion. According to Figure 38.1, Δy_p can be seen as

$$\Delta y_p(t) \approx y(t) + L\psi(t) = y(t) + T_p v\psi(t) \approx y(t + T_p) \tag{38.1}$$

with the preview time $T_p = L/v$ following Kondo's suggestion in [20], vehicle speed v, yaw angle $\psi(t)$, and deviation $y(t)$. Consequently, Δy_p can indeed be interpreted as predicted lateral deviation $y(t + T_p)$ determining the prediction function $B(s) = e^{T_p s}$ in Figure 38.2 with $y_p = \Delta y_p$. With $P(s) = e^{T_p s}$ and $H(s) = K$, a simple proportional control is composed, and with respect to Kondo's "shaft" driver model in Figure 38.1, the steering angle follows from $\delta_s(s) = Ke^{T_p s} y(s)$ for desired $y_0 = 0$.

The term $v\psi(t)$ in (38.1) was replaced by $\dot{y}(t)$ for small $\psi(t)$ and low frequencies ($s \to 0$); thus, $B(s) = 1 + T_p s$ [22–24], and more often, by applying a Taylor series expansion for $y(t + T_p)$, a second-order prediction function is used (e.g., [19,25–28]):

$$B(s) = 1 + T_p s + \frac{1}{2} T_p^2 s^2 \tag{38.2}$$

Descending from the interest in human tracking and pilot/aircraft control, many contributions between 1959 and 1980 came from McRuer, Krendel, Weir, and others (e.g., [29–33]) and influenced human driver modeling strongly up to now. In [29],

$$H(s) = \frac{K(T_L s + 1)}{(T_I s + 1)(T_N s + 1)} e^{-\tau_r s} \tag{38.3}$$

was proposed for the human tracking behavior (without $B(s)$ and $P(s)$ in Figure 38.2). While the reaction time τ_r and T_N (neuromuscular delay time) are considered as human properties independent of the task, K, T_L, T_I are associated with the controlled system. Later, this approach was further modified to the "precision model" [32] and adopted, for instance, in [16,26] (see also later Equation 38.7).

Already in [2], Kondo introduced a second driver model, which represents a linear feedback of the deviation of yaw angle, course angle, and lateral position, and many following models can be seen as modifications and enhancements of this basic idea.

In [33,34], for instance, a driver model is proposed, which is, in short, a compensatory feedback of the deviation of the lateral position Δy with respect to a reference position and the yaw angle error $\Delta\psi$

$$\delta_s = Y_y Y_\psi \Delta y + Y_\psi \Delta\psi + \frac{K_c}{K_\psi} Y_\psi r_c + n \tag{38.4}$$

but also makes use of the local roadway curvature ρ_r^* (at the car's center of gravity (CG) position) and the vehicle forward speed u in $r_c = \rho_r^* u$; n is usually a filtered noise and represents a driver's remnant. The driver's transfer functions in (38.4) are specified by

$$Y_\psi = K_\psi (T_L s + 1) e^{-\tau_r s}, \quad Y_y = K_y \tag{38.5}$$

In literature [16], this model is often referred to as "STI pursuit driver model" or "STI compensatory driver model" when the roadway is straight or gently curving and ρ_r^* not taken into account and $\Delta\psi = \psi$ in (38.4) [34].

Reid et al. refined the model by integrating preview [16,35]. The control law reads

$$\delta_c = K_c\rho^* + K_\psi \Delta\psi_e + K_y \Delta y_e \tag{38.6}$$

where

- ρ^* is the road curvature previewed at the point on the road ahead of the car that it will reach after the preview time T_p
- $\Delta\psi_e$ is the difference between the vehicle heading angle and the roadway heading angle at a point where a line drawn from the driver's eye meets the lane centerline at a right angle
- Δy_e is the distance from the vehicle's centerline at a point adjacent to the driver's eye to the point where the above line meets the lane centerline

The applied steering angle δ_s to the vehicle follows then from a first-order lead–lag element with time delay τ_r, $\delta_s = H(s)\delta_c(s)$ with (here $K_M = 1$)

$$H(s) = K_M \frac{T_L s + 1}{T_I s + 1} e^{-\tau_r s} \tag{38.7}$$

that is a simplified form of the "precision model" [30,31].

Likewise, Allen et al. [36] consider the more illustrative visual angle between the vehicle's longitudinal axis and the aim (or sight) point, corresponding to $\Delta\psi_c$ in Figure 38.1. The difference ψ_f between $\Delta\psi_c$ and the visual angle ψ_v, that is, the angle between the vehicle's longitudinal axis and the point on the predicted vehicle path (along the current curvature ρ_v^*) close to the aim point

$$\psi_f = \Delta\psi_c - \psi_v, \quad \psi_v \approx \frac{L}{2}\rho_v^* \tag{38.8}$$

respectively the curvature error, $\rho_e^* = 2\psi_f / L$, is then to be eliminated by the driver. An additional feedback is included that accumulates the lateral deviation error Δy_e whenever the vehicle is not correctly positioned laterally on the lane. This visual feedback concept is meant to model the driver's steering control law, without implying that the driver visually focuses on any particular point in the driving scene, but scans actively the whole scene. Finally, the feedback of the yaw rate is intended as a motion feedback cue providing a high-frequency lead that the driver can use to compensate for vehicle lag.

For a recent adaptation and application of this model, see [37–39].

The well-known "crossover model" [30,31,33,40] provides a very effective way for the description of human regulation control tasks and is consequently often used for the parametrization of human driver models. The open-loop transfer function $H(s)G(s)$, which represents the combined system of driver $H(s)$ and vehicle $G(s)$, is described by the experimentally observed closed-loop behavior with

$$H(s)G(s) = \frac{\omega_c}{s} e^{-\tau_r s} \tag{38.9}$$

that means with integral behavior (–20 dB/decade) and adapted phase shift due to the dead time element ($\leq 90°$), in the immediate vicinity of the crossover frequency ω_c. The parameter τ_r is the effective system dead time.

The capability of the human driver for adaptation is achieved on the basis of the invariant overall system behavior; as a consequence the driver is able to compensate tracking errors despite changing

vehicle characteristics. Although the model looks very generally applicable, it faces limitations and the parameter may depend on the kind of input signal. In particular, in [13], it is pointed out that on the basis of driver–vehicle measurements [41], an increased gain (toward −60 dB/decade) and phase shift at low frequencies need to be taken into account for this modeling approach; at mid-range frequencies, the "crossover model" behavior is appropriate just in the immediate vicinity of the crossover frequency. For more recent (simulator) tests and values for crossover frequencies and phase margins at different driving maneuvers, see [27].

Many models are obliged to the aforementioned STI driver model idea; they may also show some modifications (e.g., [23,42]) or lead to rather own models [43]; others are simplifications of the aforementioned ideas (e.g., [44]); nevertheless, these kinds of models are often used as substitutes of the driver up to now.

A driver model that was followed up by others as well (e.g., [26,27,45–48]) is the two-level model from Donges [49]. In Figure 38.3, the two levels (or layers) can be identified, an anticipatory open-loop and a compensatory closed-loop control.

The open-loop control represents the guidance level of steering activity and simulates the anticipatory response to the deterministic run of the desired path curvature. The required parameters of this level are estimated by making use of the measurements of the desired path curvature and the driver's steering wheel angle and optimizing a quadratic criterion; thus, the anticipatory control is formulated in the discrete-time form of an nth-order scalar difference equation with discrete-time points $t_k (k = 1, 2, \ldots)$:

$$\delta_a(t_k) + a_n\delta_a(t_{k-1}) + \cdots + a_1\delta_a(t_{k-n}) = b_n\kappa_r(t_{k-1} + T_A) + \cdots + b_1\kappa_r(t_{k-n} + T_A) \tag{38.10}$$

where

T_A is the anticipation time
κ_r the desired path curvature
a_i, $b_i (i = 1 \ldots n)$ are time-invariant constants

As the differences in order n are small, a first-order approximation with two parameters is suggested, while in [26,50],

$$T_{2s}^2\ddot{\delta}_a(t) + T_{1s}\dot{\delta}_a(t) + \delta_a(t) = V_a\kappa(t + T_a) \tag{38.11}$$

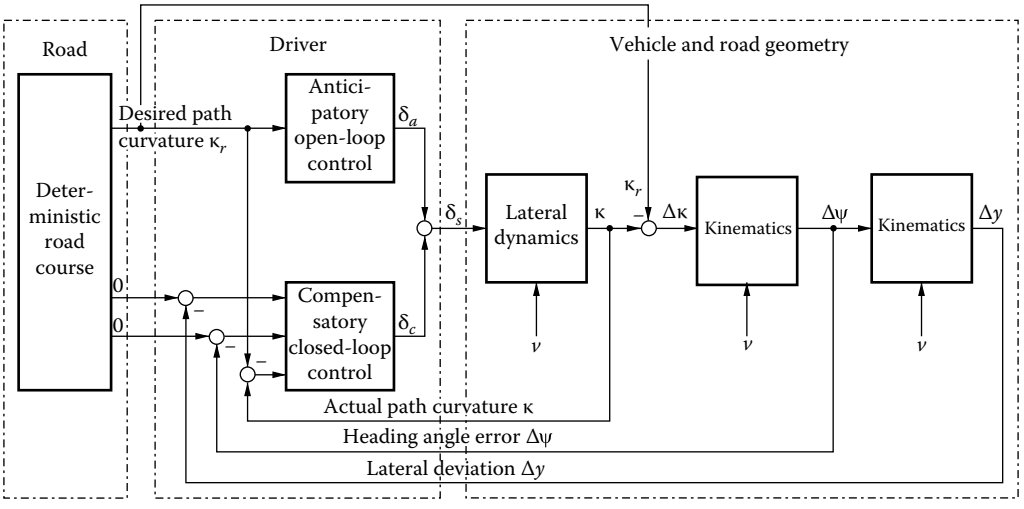

FIGURE 38.3 Two-level model from Donges. (From Donges, E., *Hum. Factors*, 20(6), 691, 1978.)

is proposed for the determination of the open-loop steering angle. The determination of the required steering angle for a two-wheel vehicle model to perfectly follow a given trajectory is used to set the parameters V_a, T_{1s}, T_{2s}, which then just depend on vehicle parameters and vehicle speed. It is thus assumed that the main contribution to the steering angle derives from the experience of the driver on the steering behavior of the vehicle and the steering wheel angle follows a given previewed path curvature at a single point ahead.

The success of the feedforward level has to be controlled in the stabilization level of the driver's steering activity (compensatory closed-loop control). Donges' driver in [49] compares actual and desired path curvature, that is, path curvature error $\Delta\kappa$, and observes heading angle error $\Delta\psi$ and lateral deviation Δy. The mathematical formulation of this compensatory closed-loop control is

$$\delta_c(t) = -\left[h_\kappa \Delta\kappa(t-\tau_r) + h_\psi \Delta\psi(t-\tau_r) + h_y \Delta y(t-\tau_r)\right] \tag{38.12}$$

where

τ_r is the human time delay

h_κ, h_ψ, h_y are gain factors, which are again computed from the difference between the measurements and the feedforward contribution and minimizing a quadratic criterion

They can be chosen to meet the features of the crossover model as well. This is the case in the model of Mitschke [26,27]. In the compensatory control, the predicted deviation $y(t+T_p)$ is the only feedback quantity, which is estimated by applying the transfer function $B(s)$ in (38.2) to $y(s)$. The simplified precision model (38.7) is suggested as a transfer function for the driver.

Because both control levels will not completely reproduce the driver's steering wheel angle, a remnant quantity is a third integral part of the model. The remnant comprises driver-induced signals that are not related to the steering task as well as shortcomings of the special structure and features of the model [49].

In [46], the two-level driver model following Mitschke is extended by a third level that takes also local deviations into account. The local control level is activated in critical situations when the other two levels fail and replaces them for a short period to reduce local deviations directly; a sliding controller is used considering physical limits of the driver. Another enhancement is published in [47]. The driver's internal vehicle model is refined by locally linearizing essential nonlinearities characterizing vehicle handling behavior. In this way, the driver model is enabled to perform good tracking behavior also at higher lateral accelerations. Tracking accuracy is further increased by incorporating information on the change of curvature in clothoids and the local curvature of vehicle motion in the prediction of the anticipated vehicle position. Longitudinal control is added on a corresponding two-level modeling approach in [51].

The multilevel driver model in [52], where all levels contribute to the steering angle, includes besides the three previous (but differently modeled) task levels "steering due to experience" as a fourth level. Adaptation of the driver (and his or her model parameters) to vehicle handling properties is characteristic for the anticipatory level but would be required, in particular at difficult but recurring driving situations, for the second and third level as well. Alternatively, the author suggests to incorporate the perceived mismatch of the expected lateral acceleration and steering moment with the actual values, $a_y(t)$, $M_s(t)$,

$$\delta_e(t) = k_1\left[k_y v^2 \delta_s(t) - a_y(t)\right] + k_2\left[k_M v^2 \delta_s(t) - M_s(t)\right] \tag{38.13}$$

with appropriate (vehicle) constants k_y, k_M and (driver) gains k_1, k_2.

As drivers are looking at a finite interval of the future path ahead, it is assumed for a major class of driver models that the driver is aiming to minimize tracking errors within this interval. Tracking errors can be composed of different kinds of variables, like lateral deviation and

heading angle and usually result from the difference between the previewed and desired path and the predicted vehicle motion.

An often referenced preview/prediction driver model, which is based on optimal control theory, has been presented by MacAdam [53]; it is the basis of the CarSim/TruckSim software package. The linear vehicle model is described in state-space representation by

$$\dot{\underline{x}} = \mathbf{A}\underline{x} + \underline{b}\delta_s \tag{38.14}$$

$$y = \underline{c}^T \underline{x} \tag{38.15}$$

with the state vector $\underline{x} = [y, v_y, \psi, \dot{\psi}]^T$, the input steering angle $\delta_s(t)$, and the output lateral displacement of the vehicle mass center $y(t)$. Implying a constant input $\delta_s(t+\tau), \forall \tau \in [0, T_p]$ over the preview interval $[t, t+T_p]$, the output $y(t+\tau)$ of the system (38.14), (38.15) is composed of the zero input and zero-state response by

$$y(t+\tau) = \underline{c}^T \mathrm{e}^{\mathbf{A}\tau}\underline{x}(t) + \underline{c}^T \left(\int_0^\tau \mathrm{e}^{\mathbf{A}\eta} \mathrm{d}\eta \right) b\delta_s(t) \equiv \underline{f}^T(\tau)\underline{x}(t) + g(\tau)\delta_s(t) \tag{38.16}$$

The optimal control $\delta_{s,opt}$, which minimizes the performance function

$$J = \frac{1}{T_p} \int_t^{t+T_p} [y_d(\eta) - y(\eta)]^2 \delta(T_p) \mathrm{d}\eta \tag{38.17}$$

where

$y_d(t)$ is the desired lateral displacement

$y(t)$ is the actual lateral displacement

$\delta(T_p)$ is the Dirac delta function for $[0,T_p]$ and thus utilizes single-point preview, can be derived by substituting (38.16) into (38.17) and setting the partial derivative of J with respect to δ_s zero:

$$\delta_{s,opt}(t) = \frac{y_d(t+T_p) - \underline{f}^T(T_p)\underline{x}(t)}{g(T_p)} \tag{38.18}$$

For a nonoptimal $\delta_s(t)$, the corresponding error $\epsilon(t+T_p) = y_d(t+T_p) - y(t+T_p)$ follows from (38.16) to

$$\epsilon(t+T_p) = y_d(t+T_p) - \underline{f}^T(T_p)\underline{x}(t) - g(T_p)\delta_s(t) \tag{38.19}$$

Substituting now (38.18) in (38.19) yields another expression for the optimal steering angle:

$$\delta_{s,opt}(t) = \delta_s(t) + \frac{\epsilon(t+T_p)}{g(T_p)} \tag{38.20}$$

that is used to take delay limitations of the human driver into account by introducing a transfer function $H(s)$ between $\delta_{s,opt}$ and the actual input δ_s to the vehicle. For $H(s) = \mathrm{e}^{-\tau_r s}$, with the effective transport lag τ_r, and the vector transfer function $\mathbf{G}(s) = [\mathbf{I}s - \mathbf{A}]^{-1}\underline{b}$ for the controlled element, the resulting driver model is displayed in Figure 38.4. The parameters T_p and τ_r can be used for adaptation to measurements and/or crossover model behavior.

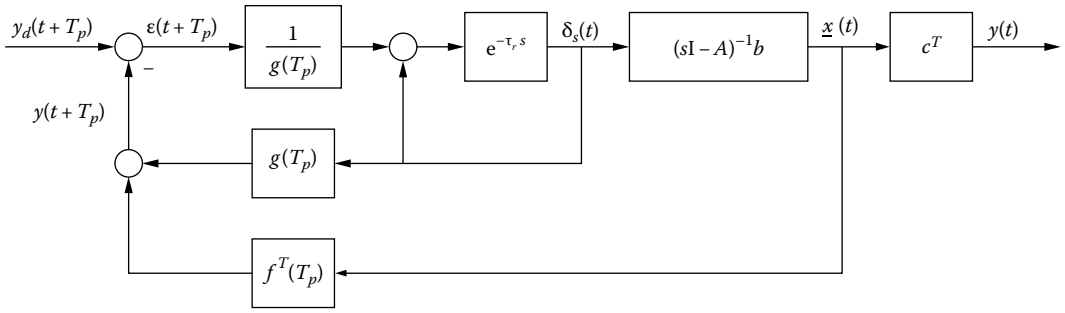

FIGURE 38.4 Optimal (single-point) preview control model. (From MacAdam, C.C., *IEEE Trans. Syst., Man, Cybern.*, SMC-11(6), 393, 1981.)

A recent extension of the previous model is proposed in [54,55]. The performance function to be minimized for the optimal steering angle is changed to

$$J = \int_{t}^{t+T_p} [s(\eta)]^2 d\eta \tag{38.21}$$

where $s(\eta)$ is defined by

$$s(\eta) = \left(k w_{\dot{y}}(\eta) \frac{d}{dt} + w_y(\eta) \right)^{n-1} \Delta y(\eta), \quad \Delta y(\eta) = y(\eta) - y_d(\eta) \tag{38.22}$$

with the weighting parameters $k, 0 \le w_{\dot{y}} \le 1, 0 \le w_y \le 1$. For $n = 2$ in (38.22), $\Delta\dot{y}(t) = \dot{y}(t) - \dot{y}_d(t)$ is considered and can also be interpreted as

$$\Delta\dot{y}(t) = \dot{y}(t) - \dot{y}_d(t) = v_y + v_x(\psi - \theta_d) \tag{38.23}$$

where

v_y is the lateral

v_x is the longitudinal speed and the term $(\psi - \theta_d)$ the vehicle yaw angle error

The gain k in (22) penalizes $\Delta\dot{y}(t)$; that means that drivers with a high gain pay more attention to the vehicle's yaw motion.

In [53], the desired trajectory is specified in the inertial coordinate system but is transformed here to the local (vehicle body) coordinate system to reflect the driver's viewpoint, similar as later shown in Figure 38.5. The derived steering angle may change once at half of the preview time; without this functionality and $k = 0$, the model reduces to MacAdam's driver model.

Another modification is the prediction of the vehicle motion. The driver learns to adapt to a vehicle gradually by learning to "invert the vehicle model" [54]. The learning process is approximated by a least square optimization of a fourth-order auto-regressive integrated moving average with external inputs (ARIMAX) model

$$A(q^{-1})y(k) = B(q^{-1})q^{-d}u(k-1) + \frac{e(k)}{1-q^{-1}} \tag{38.24}$$

with $d = 0$ and the z-domain operator q. $A(q^{-1})$ and $B(q^{-1})$ are recursively identified from rich steering excitations $u(k)$ of a nonlinear vehicle model and the resulting lateral displacement response $y(k)$ by minimizing the sum of squares of the residual error $e(k)$.

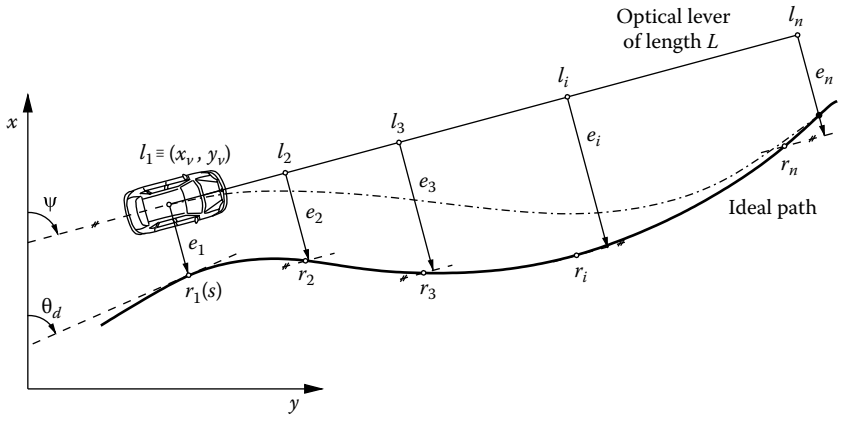

FIGURE 38.5 Preview schema (From Sharp, R.S. et al., *Vehicle Syst. Dyn*., 33, 289, 2000); the line-dotted trajectory refers to. (From Frezza, R. et al., *Proc. 2003 IEEE/ASME Int. Conf. Adv. Intell. Mechatron*., 1, 36, 2003.)

In [19], it is assumed that drivers get their basic experience from quasi-static driving, where the lateral acceleration of the vehicle (respectively the curvature of the vehicle trajectory) is about proportional to the steering angle input. That is why a performance criterion similar to (38.17) is minimized with respect to the lateral acceleration, which is then further processed by a transfer function according to (38.7) to derive the driver's steering angle. Single-point preview is applied, the lateral motion of the vehicle predicted using (38.2). Further, it is suggested to compose the transfer function of the driver/vehicle closed loop of a preview transfer function $P(s)$, describing the driver's preview ability, and a follower transfer function $F(s)$, which reflects the driver's following process. The authors propose $y(s)/y_d(s) = P(s) \cdot F(s) \approx 1$ for low frequencies as a control design rule, with the lateral position y and its desired value y_d. Longitudinal control is added in [56]. The method is further generalized in [57] for lateral control and also extended by longitudinal control in [58].

The concept of multipoint preview is clearly presented by Sharp et al. [59] (see Figure 38.5); a similar idea has been introduced in [60].

At position s along the trajectory, the driver experiences the right-angled deviations e_i between a set of n points $l_1, l_2, \ldots, l_n$ on an optical lever and corresponding points $r_1, r_2, \ldots, r_n$ on the desired path. The length of the optical lever is $L = T_p v_x$ (with longitudinal velocity v_x); the points can be equally spaced or more concentrated toward the CG of the vehicle, as realized in [59] with eight points. The distance $\overline{l_i l_{i+1}}$ is the same as distance $\overline{r_i r_{i+1}}$, and thus, the points $r_1, r_2, \ldots, r_n$ do not lie exactly on the direction perpendicular to the optical lever through the $l_1, l_2, \ldots, l_n$ points depending on the complexity of the trajectory geometry. It is reported that these errors seem not to have any significant influence on the robustness of the driver. The first point l_1 coincides with the CG of the vehicle and e_1 represents the vehicle lateral offset from the current intended position on the path. Besides the state feedback e_1, the difference $(\psi - \theta_d)$ between the vehicle yaw angle and the tangent angle of the intended path at r_1 is another state feedback used for the driver's steering control. The steering angle is then a linear combination of the control inputs

$$\delta_s = K_\psi(\psi - \theta_d) + K_1 e_1 + \sum_{i=2}^{n} K_i e_i \tag{38.25}$$

with the control gains $K_\psi, K_1, \ldots, K_n$. Although no systematic determination of these parameters is done, some general rules are given, for example, that the driver model preview gain sequence should be exponentially convergent to zero toward distant preview samples. Further, for extreme

driving conditions, saturation functions are applied on the weighted inputs in (38.25) to account for unreasonable high steering angles resulting in tire forces far beyond saturation.

This driver model also controls the longitudinal vehicle motion, even though completely uncoupled from the lateral control, and no human driver specifications are included—typical for many applied velocity tracking controllers. An ideal velocity profile needs to be provided, and with actual and target velocity a short distance ahead, a required constant acceleration a is evaluated. The longitudinal force F to maintain the desired forward motion is then

$$F = ma + I_f \frac{a}{r_f^2} + (I_r + I_e i_g^2)\frac{a}{r_r^2} + \frac{1}{2}\rho A c_x v_x^2 \tag{38.26}$$

with vehicle mass m and the moments of inertia I_f, I_r, I_e of front and rear axle rotating masses and inertia due to engine, which depends on the gear ratio i_g and the aerodynamic drag (aerodynamic drag coefficient c_x, longitudinal velocity v_x); drag by the steering wheels at cornering is neglected. When F is positive, a driving torque $T = Fr_r$ (rear wheel radius r_r); otherwise, an engine braking torque is applied, and a further residual braking torque is split to the front and rear axle according to a fixed braking ratio.

The (lateral) model was developed further by Sharp et al. in [61,62] by introducing the linear-quadratic regulator (LQR) method for the determination of the preview control parameters. The state-space representation ((38.14), (38.15)) of the two-wheel vehicle model is transferred to a time-discrete formulation, that is, the first row in (38.27):

$$\underline{z}(k+1) = \begin{bmatrix} \underline{x}(k+1) \\ \underline{y}_r(k+1) \end{bmatrix} = \begin{bmatrix} \mathbf{A}_v & 0 \\ 0 & \mathbf{D} \end{bmatrix} \begin{bmatrix} \underline{x}(k) \\ \underline{y}_r(k) \end{bmatrix} + \begin{bmatrix} \underline{0} \\ \underline{e} \end{bmatrix} y_{ri}(k) + \begin{bmatrix} \underline{b}_v \\ \underline{0} \end{bmatrix} \delta_s(k) \tag{38.27}$$

$$\underline{z}(k+1) = \mathbf{A}_c \underline{z}(k) + \underline{e}_c y_{ri}(k) + \underline{b}_c \delta_s(k) \tag{38.28}$$

The previewed road is described by the absolute lateral displacements in $y_r(k) = [y_{r0}, y_{r1}, \ldots, y_{rn}]^T$; thus, the second row of (38.27) is a shift process with respective $\mathbf{D}$ and $\underline{e}$ and the road input y_{ri} that becomes y_{rn} at the next step. The preview horizon is again n and $\underline{z} = [y, \dot{y}, \psi, \dot{\psi}, y_{r0}, y_{r1}, \ldots, y_{rn}]^T$.

The time-invariant LQR control is found from minimizing the quadratic cost function under white noise excitation:

$$J = \lim_{j\to\infty} \sum_{k=0}^{j} \left[\underline{z}^T(k) \mathbf{R}_1 \underline{z}(k) + \delta_s(k) r_2 \delta_s(k) \right] \tag{38.29}$$

with the weights $\mathbf{Q}$ in $\mathbf{R}_1 = \mathbf{C}^{\mathrm{T}}\mathbf{Q}\mathbf{C}$ and r_2. With sampling time T, respectively, sampling distance vT and by defining

$$\mathbf{C} = \begin{bmatrix} 1 & 0 & 0 & 0 & -1 & 0 & 0 & 0 & 0 & \ldots & 0 \\ 0 & 0 & 1 & 0 & 1/(vT) & -1/(vT) & 0 & 0 & 0 & \ldots & 0 \end{bmatrix} \tag{38.30}$$

not only the squares of the differences between the y-coordinate of the car's predicted reference point and the corresponding value y_{rj} for the lateral displacement of the road are minimized but also the squares of yaw angle differences $\{\psi(k) - [y_{r1}(k) - y_{r0}(k)]/(vT)\}$. After solving the algebraic Riccati equation

$$\mathbf{P}_\infty = \mathbf{A}_c^T \mathbf{P}_\infty \mathbf{A}_c - \mathbf{A}_c^T \mathbf{P}_\infty \underline{b}_c \left(\underline{b}_c^T \mathbf{P}_\infty \underline{b}_c + r_2 \right)^{-1} \underline{b}_c^T \mathbf{P}_\infty \mathbf{A}_c + \mathbf{C}^T \mathbf{Q} \mathbf{C} \tag{38.31}$$

the optimal steering angle results in

$$\delta_{s,opt}(k) = -\mathbf{K}_\infty \underline{z}(k) \quad \text{with } \mathbf{K}_\infty = \left(\underline{b}_c^T \mathbf{P}_\infty \underline{b}_c + r_2 \right)^{-1} \underline{b}_c \mathbf{P}_\infty \mathbf{A}_c \tag{38.32}$$

This preview control is based on a fixed reference system, as the preview driver model of MacAdam in [53], while in reality, all path observations are made by the driver from his or her moving position, and consequently, the authors in [61] transform the gain with respect to a relative system, similar to Figure 38.5.

Although the three driver models in [53,54] and [61,62] are very similar and rely all on optimal control theory (predictive control and LQR), they differ in some aspects: the applied performance criterion, use of absolute and relative lateral path and/or yaw angle information, preview horizon, and for how long the steering angle can change within the preview horizon. A thorough comparison and analysis of the differences of the aforementioned three approaches is done in [63].

The driver model in the commercial MBS software Adams/Car is based on [64]. The driver is organized in three hierarchical levels. The task planner sets the goal of the controller; the output is an optimal trajectory based on a criterion that mathematically codes the given task. The tactical planner is explained in more detail (see also [65]). This level computes an optimal trajectory based on the current state of the vehicle relative to the ideal trajectory. Trajectories are optimal in the sense that they fit at best the road in the interval $[t, t + T_c]$, where T_c is called the control horizon, equivalent to L in Figure 38.5, where an optimal trajectory (dash-dotted line) is illustrated; the ideal trajectory is also measured at n look ahead distances, although here exactly on the direction perpendicular to the longitudinal vehicle axis through the points $l_1, l_2, \ldots, l_n$.

For each time step t, the desired path is described by a function $y = p(x) = \sum_{j=0}^{r} a_j x^j$ in the vehicle body frame coordinates. For the order of the polynomial, which has to meet the initial conditions $p(0) = 0$, $\mathrm{d}p/\mathrm{d}x = 0$, $r = 4$ is suggested. The coefficients are then computed with minimum square fit taking into account weights on the preview distances l_i and may depend on speed v and curvature κ constraints (bounded steering angles). A "kinematic vehicle model" with wheelbase $l_a + l_b$ is applied:

$$\dot{x} = v\cos\psi, \quad \dot{y} = v\sin\psi, \quad \dot{\psi} = \frac{\tan\delta_s}{l_a + l_b} v = \kappa v \tag{38.33}$$

and no dynamics and no slip are considered in this level. From (38.33), there follows $\dot{\psi} = \kappa v$ and thus the desired yaw rate

$$\dot{\psi}_d = \left.\frac{d^2 p(x)}{\mathrm{d}x^2}\right|_{x=0} v = 2a_2 v \tag{38.34}$$

which is to be set in the third level. The motion controller acts on the throttle, brake, and clutch to track a given velocity profile as well as on the steering wheel. By applying the two-wheel vehicle model (with moment of inertia I_z), assuming that the front lateral tire force F_{yf} can be controlled directly and by setting

$$\ddot{\psi} = \frac{1}{I_z}(l_a F_{yf}\cos\delta_s - l_b F_{yr}) \equiv \tilde{u} \tag{38.35}$$

where the rear lateral tire force F_{yr} is determined kinematically, the control $\tilde{u}$ is derived to achieve $\dot{\psi} = \dot{\psi}_d$ by simply designing a tracking controller for a plant whose transfer function is an integrator. With known $F_{yf} = F_{yf}(\alpha_f)$, the steering angle results finally from the estimated front sideslip angle α_f.

An example for using nonlinear control to represent a driver is [66–68], and the idea behind is applied in the driver model of the commercial software veDYNA [69]. A guidance level sets the desired trajectory and velocity profile (see also Section 3.2 [68,70]), in particular position and velocity of a "target point". In the stabilization level, a position controller tries to match a "target aim point" with the current "target point"; the "target aim point" is fixed on the vehicle's longitudinal

axis a specified preview distance ahead, although the CG of the vehicle with position x, y is chosen in [66,67] and in the following. The output of the position controller is a suitable steering wheel angle and brake/accelerator pedal positions to minimize the deviations from the target path and given or calculated speed profile.

On the basis of a nonlinear extended two-wheel vehicle model in state-space representation,

$$\underline{\dot{x}} = \underline{a}(\underline{x}) + \mathbf{B}\underline{u} \tag{38.36}$$

$$\underline{y} = \underline{c}(\underline{x}) \tag{38.37}$$

$$\underline{x} = [\beta, \psi, \dot{\psi}, v, x, y]^T, \quad \underline{y} = [x, y]^T, \quad \underline{u} = [F_{yf}, F_x]^T \tag{38.38}$$

the position x, y is controlled by deriving appropriate front lateral tire forces F_{yf} and longitudinal tire forces F_x; in this way, a combined control of longitudinal and lateral dynamics by the driver is achieved instead of a separated view. The nonlinearities in $\underline{a}(\underline{x})$ are mainly due to $\dot{x}$, $\dot{y}$, which depend nonlinearly on velocity v, yaw angle ψ, and sideslip angle β of the vehicle, details in [66,67]. Following the nonlinear decoupling method, the output equations in (38.37) have to be differentiated as often as at least one input that appears explicitly, in this case each of them two times. The second derivatives of the output vector $\underline{y}^*(t) = [\ddot{y}_1(t), \ddot{y}_2(t)]^T$ can now be expressed by

$$\underline{y}^*(t) = \underline{c}^*(\underline{x}(t)) + \mathbf{D}^*(\underline{x}(t))\underline{u}(t) \tag{38.39}$$

and respective matrices $\underline{c}^*$, $\mathbf{D}^*$ easily derived with (38.36) through (38.38). Considering (38.39) and presupposing that $\mathbf{D}^{*-1}(\underline{x}(t))$ exists, the control law reads

$$\underline{u}(t) = \mathbf{D}^{*-1}(\underline{x}(t))(-\underline{c}^*(\underline{x}(t)) + \Lambda\underline{w}(t) - \underline{q}^*(\underline{y}(t))) \tag{38.40}$$

where $\Lambda = \text{diag}\,(\lambda_i)$ is a weighting matrix for the desired position in $\underline{w}(t)$ ("target point"). By choosing

$$q_i^*(\underline{y}(t)) = \alpha_{1i} y_i(t) + \alpha_{2i}\dot{y}_i(t), \quad i = 1, 2 \tag{38.41}$$

and substituting (38.40) in (38.39), the dynamics of the system

$$\ddot{y}_1(t) + \alpha_{21}\dot{y}_1(t) + \alpha_{11} y_1(t) = \lambda_1 w_1(t) \tag{38.42}$$

$$\ddot{y}_2(t) + \alpha_{22}\dot{y}_2(t) + \alpha_{12} y_2(t) = \lambda_2 w_2(t), \tag{38.43}$$

can be adjusted with the constants λ_i and α_{1i},α_{2i} ($i = 1, 2$) to guarantee $\underline{y}(t) \to \underline{w}(t)$ in a linear characteristic of second order. With the resulting $u(t)$ and front lateral tire force $F_{yf} = F_{yf}(\alpha_f)$, the sideslip angle α_f and consequently the steering angle are determined; the control F_x is transferred to adequate brake/accelerator pedal positions.

Another type of nonlinear controller used for representing the driver is FLC. Fuzzy logic interfaces are said to resemble human thinking and the process of compromise in making a decision [71] and are in particular useful when mathematical models are very complicated. FLC offers the ability to develop rules that make intuitive sense and can be expressed in linguistic terms [72]. Nevertheless, there are fewer driver models with FLC to be found in literature than with previous classical control theory approaches, at least when models for virtual test drivers are considered. Two driver models are presented here as representatives in more detail ([72] and [73]); others are listed thereafter or in subsequent sections.

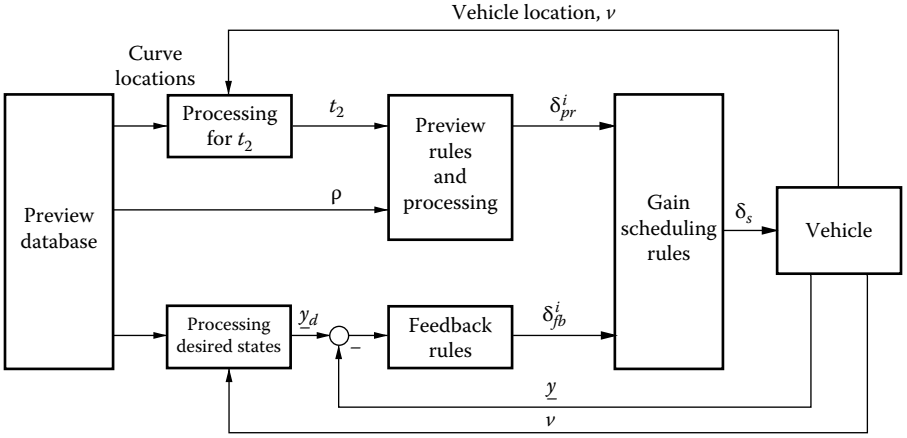

FIGURE 38.6 Driver model with FLC. (From Hessburg, T. and Tomizuka, M., *Contr. Syst. Mag.*, 14, 55, 1994.)

The block diagram of the feedback control in [72] is plotted in Figure 38.6. It is assumed that preview information regarding location, direction, and radius of curvature for each curved section on the reference track can be supplied. The controller is modularized in feedback, preview, and gain scheduling rules.

The input vector for the feedback rules is $\underline{y} = [y, \dot{y}, (\dot{\psi} - \dot{\psi}_d)]^T$, where y denotes the lateral error with respect to the road centerline and $(\dot{\psi} - \dot{\psi}_d)$ the rate of the heading angle error (see Figure 38.7a). The interference rules with linguistic variables *LE* (corr. to y), *CLE* (corr. to $\dot{y}$), *YWR* (corr. to $(\dot{\psi} - \dot{\psi}_d)$), and *DFB* (corr. to δ_{fb}) take the form

$$\text{IF } LE \text{ IS } A_{LE} \text{ AND } CLE \text{ IS } A_{CLE} \text{ AND } YWR \text{ IS } A_{YWR} \text{ THEN } DFB \text{ IS } A_{DFB} \tag{38.44}$$

with 5 different subsets each ("neg. big", "neg. small", "nil", "pos. small", "pos. big") corresponding to A_{LE}, A_{CLE}, and A_{YWR}; typical triangular membership functions are used [72], and common min–max method is applied. Consequently, for defuzzification, singletons (for now 9 different subsets, "neg. huge"…"nil"…"pos. huge", corresponding to A_{DFB}) are introduced and a resulting crisp steering angle δ_{fb} is obtained.

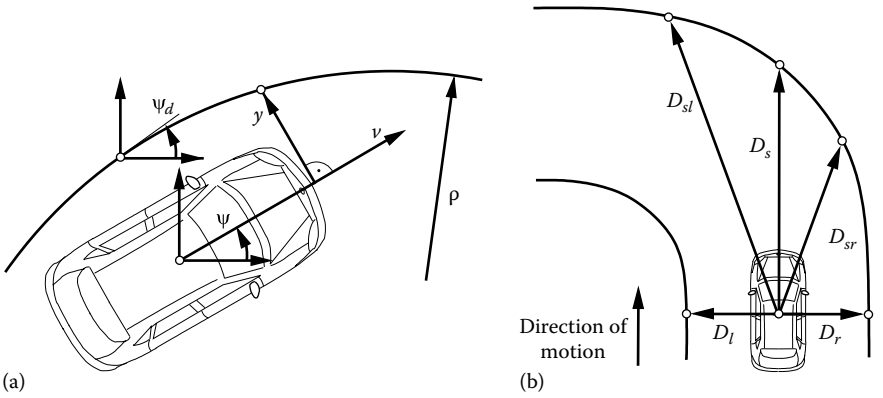

FIGURE 38.7 Sensing information for FLC driver model, (a) (From Hessburg, T. and Tomizuka, M., *Control Syst. Mag.*, 14, 55, 1994) and (b) (From Zeyada, Y. et al., Driver modeling using fuzzy logic controls for human-in-the-loop vehicle simulations, in: *Current Advances in Mechanical Design and Production VII*, Hassan, M.F., Megahed, S.M., Eds., Elsevier Science Ltd., Oxford, U.K., 2000).

The steering angle δ_{pr} follows the previewed road geometry ahead of the vehicle. The right amount of steering action for "look ahead" control depends on the predicted response characteristics of the vehicle, therefore on parameters p_c and p_n in

$$\delta_{pr} = \frac{p_c}{\rho_c} + \frac{p_n}{\rho_n} \tag{38.45}$$

which describes the preview term for the front wheel steering angle; ρ_c and ρ_n are current and next radii of curvature, respectively. p_c and p_n depend on $\min(t_2,t_w)$, where t_2 is the estimated time for the vehicle to reach the next curve transition and $t_w = 1$ s. With the preview database and velocity v, time t_2 can be estimated. Twenty-six fuzzy subsets to describe t_2 and 52 singletons for p_c and p_n are chosen to accurately (and smoothly) approximate the preview steering action δ_{pr} (at step changes in the radius of curvature).

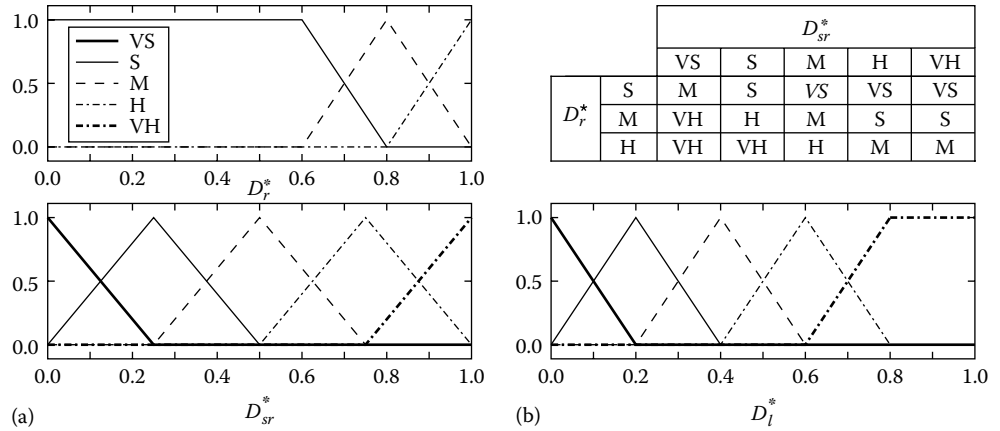
The gain scheduling rule base is designed to infer the final front wheel steering angle command δ_s from v to account for more gentle steering commands at higher speed. Both the feedback and preview rule bases are designed at three velocities $v_1 = 5$ m/s, $v_2 = 12.5$ m/s, $v_3 = 20$ m/s. Thus, the rule

$$\text{IF } V \text{ IS } A_V \text{ THEN } \delta_s = \delta^i_{fb} + \delta^i_{pr}, \quad A_V \epsilon \left\{ SMALL, MED, HIGH \right\} \tag{38.46}$$

schedules the gains between the parameterizations at v_i ($i = 1,2,3$) and the corresponding $\delta^i_{fb}, \delta^i_{pr}$ for the current velocity v; for membership functions, see [72].

The FLC driver model in [73] not only performs steering inputs but also provides braking events. The model is trained to both curve following and collision avoidance.

Compared to [72], different input information is used in [73] (see Figure 38.7a,b), in particular the left, right, straight-ahead, straight-left, and straight-right distances (D_l,D_r,D_s,D_{sl},D_{sr}) from the CG of the vehicle to the roadway borders. Two FLC modules control steering and braking. The amount of steering necessary to guide the vehicle consists of the contribution from preview, resulting from the anticipation of the incoming curve, and may be described by



$$\text{IF } \begin{matrix} D_{sl} > D_{sr} \\ D_{sr} > D_{sl} \end{matrix}, \quad \text{THEN } \begin{matrix} \text{left} \\ \text{right} \end{matrix} \text{ steering is required} \tag{38.47}$$

and of the contribution of the control of the deviation of the CG of the vehicle from the roadway border

$$\text{If } \begin{matrix} D_l > D_r \\ D_r > D_l \end{matrix}, \quad \text{then } \begin{matrix} \text{left} \\ \text{right} \end{matrix} \text{ steering is required} \tag{38.48}$$

The steering module consists of the left and right steering part. For the normalized inputs that cause left steering, $D^*_r = 1 - 2D_r/D_w$ and $D^*_{sr} = D_{sr}/D_{sr,max}$ (where D_w is the road width and $D_{sr,max}$ the maximum allowable value for D_{sr}), the membership functions are shown in Figure 38.8a. Following the interference rules in the same figure (right, top) with five different subsets ("very small", "small", "med", "high", "very high") for D^*_l a crisp value δ_l for the left steering part can be assigned by applying the membership functions (right, bottom), with $D^*_l = \delta_l/\delta_{max}$ (where δ_{max} is the maximum allowable steering angle).

The right steering part is handled analogously. For running straight-ahead on the road centerline, the steering angles from both parts equalize each other. It should be mentioned that no steering output can be associated with low values of D^*_r in this way and what should simulate the human driver behavior of tolerating a small shift from the road centerline.

D_r^* \ D_{sr}^*	VS	S	M	H	VH
S	M	S	*VS*	VS	VS
M	VH	H	M	S	S
H	VH	VH	H	M	M

FIGURE 38.8 (a) Membership functions and (b) fuzzy interference rules for left steering module of FLC driver. (From Zeyada, Y. et al., Driver modeling using fuzzy logic controls for human-in-the-loop vehicle simulations, in: *Current Advances in Mechanical Design and Production VII*, Hassan, M.F. and Megahed, S.M., Eds., Elsevier Science Ltd., Oxford, U.K., 2000.)

For simplicity, the braking module uses only one sensing variable, that is, normalized $D_s^* = D_s / D_{st}$. D_{st} is the stopping distance from the initial velocity v_0 at the time of brake application to a complete stop by maximum braking and is approximated by $D_{st} = v_0/(2a_{dec})$; the assumed constant maximum deceleration is set to $a_{dec} = 0.8g$. The corresponding membership functions with five different subsets for D_s^*, simple interference rules, and five membership functions for the output, the normalized braking command, are omitted here (see [73]). The FLC of the braking model is parameterized in a way that the braking system will respond only for values of D_s less than or equal to three times the expected stopping distance at the current vehicle speed v_0.

In order to get precise fuzzy reasoning rules, a self-organizing method is proposed for the FLC driver model in [74]. The input variables for the fuzzy controller are yaw velocity and lateral position of the vehicle with respect to the desired maneuvers, single- and double-lane change. Normal distribution shapes are considered for membership functions, which are determined by a fuzzy statistical approach (by interviewing many drivers). Each fuzzy variable is denoted by 7 linguistic fuzzy variables, and thus, a total of 49 rules are required, which are then refined by a self-organizing method. Therefore, the 7 linguistic values for the three fuzzy variables, C for steering angle, Y for lateral displacement, and R yaw rate, are denoted by –3, –2, and –1, 0, 1, 2, 3, respectively. To adjust the 49 rules, a revising factor α is introduced in the rule:

$$C = -\langle \alpha Y + (1-\alpha)R \rangle,\ 0 \le \alpha \le 1 \tag{38.49}$$

where $\langle x \rangle$ represents a minimum integer whose absolute value is larger than or equal to x and whose *sign* is the same as x. Computing a set of appropriate α associated with the 49 fuzzy rules provides an ideal fuzzy reasoning rule base.

The lateral component of the FLC driver model in [12] is similar to the aforementioned one [74], as the used input variables are the same. This driver model includes also a longitudinal FLC, which is explained here in more detail as an example for a more humanlike longitudinal motion control compared to the often applied simple velocity controllers. The task of the driver is defined to drive as fast as possible through a given course, which is approximated by straight lines and segments of circles. The strategy, which is further the basis for the fuzzy rules, is in a linguistic rule formulation:

- Brake before the curve as late as possible with maximum braking force, in order to attain maximum possible velocity (determined by radius and arc angle of curve) when entering the curve
- Drive through the curve with maximum velocity (determined by radius and rest of arc angle of curve)

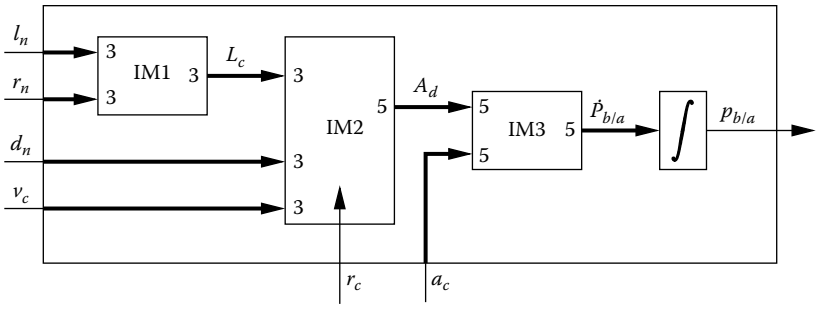


FIGURE 38.9 Longitudinal FLC driver model (From Jürgensohn, T., *Hybride Fahrermodelle*, Pro Universitate Verlag, Berlin, Germany, 1997, ISBN 3-932490-22-3 (in German)); thin lines represent crisp variables, and thick lines linguistic variables; numbers at the input/output of Mamdani interference machine IM (including trapezoidal membership functions) correspond to the number of fuzzy subsets.

- Accelerate at the beginning of a section with maximum possible acceleration until the maximum possible velocity is achieved
- Consider subsequent short curves as a unit

and constitutes the required input variables for the longitudinal FLC in Figure 38.9: arc angle length l_n and radius r_n of the next curve, distance d_n to next section, current velocity v_c and acceleration a_c, and radius r_c of the current curve. The fuzzy output of interference machine IM1 is curve length L_c that denotes an internal, "subjective" variable and is introduced to take into account that drivers can go through short curves with higher speed within the lane width than through long curves of same radius.

As the actuation of the brake or accelerator pedal directly affects the acceleration of the vehicle, the author considers the introduction of an internal desired acceleration A_d, psychologically and physiologically motivated. The current acceleration a_c is then processed to IM3 to follow the internal desired acceleration A_d. Longitudinal acceleration can be (haptically) quickly perceived and controlled by the driver. Therefore, the internal control quantity is the change of the pedal position with respect to time, $\dot{P}_{b/a}$, and consequently, IM3 generates no absolute position but a change, as the driver does when he or she wants to change speed. Defuzzification and integration yield $p_{b/a}$.

Another driver model using FLC and utilizing longitudinal and lateral control is [75] but is referred to Section 38.3.2 for its "course decision process" module. Further FLC driver models are, for instance, shown in [76,77].

The longitudinal virtual test driver in [78] is based on artificial NNs to represent human driving behavior. It is the task of the model to follow a given velocity profile, in this case standardized drive cycles. A conventional feedback controller is responsible for appropriate braking commands, while the throttle command is the output $u(t)$ of two NN controllers (see Figure 38.10).

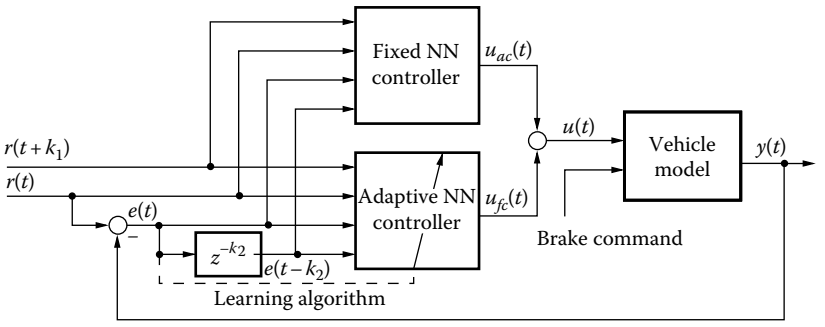

FIGURE 38.10 Longitudinal virtual test driver. (From James, D.J.G. et al., *Proc. Artif. Life Robot.*, 7, 170, 2002.)

The objective of the fixed (parameter) forward NN is to model a human driver following the reference velocity $r(t)$. This is achieved by training the NN with input/target data collected during experimental tests including a human driver. Considering the error $e(t) = r(t) - y(t)$, where $y(t)$ is the velocity of the vehicle, four inputs to the NN are chosen: $e(t)$, $r(t)$, previewed $r(t + k_1)$, and time-delayed $e(t - k_2)$ with $k_1 = 1.1$ s, $k_2 = 0.4$ s. The training process takes into account that both accelerator and brake pedal should not be applied at the same time. The adaptive NN controller is incorporated to enable the driver model to adapt to changes in the vehicle and/or road conditions. This controller is continuously updated to compensate for speed errors $e(t)$. Therefore, $e(t)$ is used in the cost function to optimize the weights and biases of the NN adopting standard backpropagation training. The NN architecture can be seen in Figure 38.12 (with hyperbolic tangent activation function F_1, linear F_2), where more on using NN for driver models can be found in that context.

Besides "transfer function," (optimal) state-space, FLC, and NN modeling methods for setting up a virtual driver, there are still more methodical alternatives, for example, identification methods.

The parameters of an autoregressive moving average with external inputs (ARMAX) model, incorporating structured uncertainties to account for driver model uncertainty due to variation across different drivers, are identified using data from driving simulator tests ([79], also [80]); for the same task, but applying model reference adaptive control (MRAC), see [81]; for online estimation of the ARMAX model parameters, see [82]. Hybrid models are considered in the subsequent sections.

Rather autonomous approaches for driver models are, for example, [83], or the driver model in [84] on a flow chart basis.

Most of the aforementioned driver models apply for a wide variety of applications and have often been introduced in literature rather with exemplary applications. To conclude this section, some implementation examples of mentioned or similar virtual test driver models with respect to the previously stated areas of application are given in [38,39,85–90].

38.3 APPLICATIONS WITH FOCUS ON THE DRIVER

This section addresses driver models and their applications whose interest and concern are mainly related to typical driver tasks and who claim to contribute to a better understanding of (individual) driver behavior.

38.3.1 Understanding Driver and (Individual) Driving Behavior

As already mentioned before, the proposed classification of driver models to specific sections is not distinct and models from other sections may be allocated here as well. In particular, driver models based on the artificial NN approach are qualified for here, as they are often considered to represent adaptive human control behavior and enable the modeling of specific driver/vehicle control interactions. A review of applications of NNs in vehicle systems in general is given in [71]. Although autonomously (humanlike) guided vehicles are not addressed here, synergetic effects may be interesting in this context as well, for example, in [91–99] (or [100–102] with FLC).

Since about 1990, the capabilities of NNs to emulate the human driving behavior have been investigated [103]. Directional control as well as path planning strategies have been modeled by a single-layer functional-link NN (to improve training time and error) and a two-layer feedforward NN, respectively. In [104], a driving assistant system to support overtaking is presented. Input parameters of the system are distances to collision on the left and right lanes and the lateral position and speed of the vehicle. The driver and/or the support system decides on the appropriate accelerator/brake pedal position and steering wheel angle. When the driver takes over the control, a comparison of the decisions is displayed (driver assistant). The signals can be used to teach the NN support system to evaluate the performance of the driver, to teach novices as a trainer, or maybe even to fully substitute the driver (autopilot). A combination of functional-link

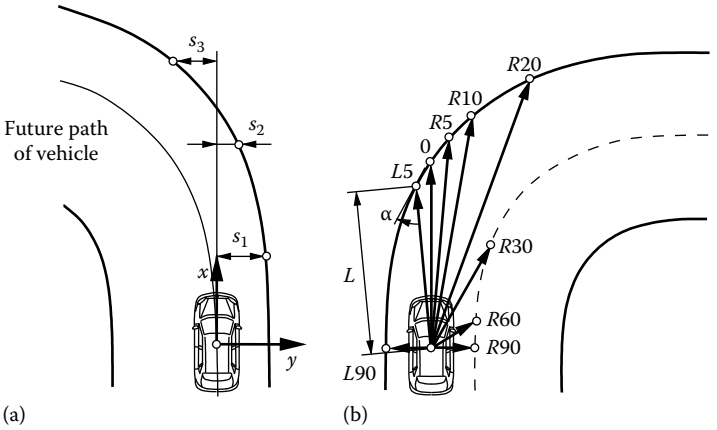

FIGURE 38.11 Radar sensor measurements (a: From MacAdam, Ch.C. and Johnson, G.E., *Vehicle Syst. Dyn.*, 25, 3, 1996) (b: From Kageyama, I. et al., *Vehicle Syst. Dyn. Suppl.*, 33, 122, 1999).

and backpropagation network is preferred to achieve a good compromise between fast-learning and accurate decision-making characteristics.

In [105], an NN-based driver model is both trained by a simple driver model that maps the steering angle as a function of the time-delayed lateral deviation and heading angle and by a human driver in a simulator environment. The input to the NN is the lateral deviation from the desired course and is derived from a simplified view at four points 20, 40, 60, and 80 m ahead of the vehicle; four views are memorized at each time step resulting in 16 data points for the complete input. Required maneuvers for teaching the NNs are analyzed and accuracy of the NNs is compared.

The goal in [106] is the identification of driver steering behavior based upon NNs. The relative lateral displacements s_i ($i = 1, 2, 3$) between the forward projection of the vehicle's longitudinal body axis and the road border (see Figure 38.11a) represent the previewed sensor inputs at time t. One sensor is placed very near to the front end of the vehicle, and the remaining two samples are located at two points ahead of the vehicle. By this specific choice of sensor location and measurements, information about vehicle motion and orientation with respect to the roadway is provided to the NN. To extract further time derivative information from the same basic sensor measurements, time-delayed versions of these signals are utilized. Thus, the augmented set of network inputs, which include $\{s_1(t), s_2(t), s_3(t)\}$ and two corresponding sets of their time-delayed responses $\{s_1(t-\tau_1), s_2(t-\tau_1), s_3(t-\tau_1)\}$, $\{s_1(t-\tau_2), s_2(t-\tau_2), s_3(t-\tau_2)\}$ with $0.1 \le \tau_1 \le \tau_2 \le 0.6$, contains also the key feedback cues required by "classical" driver models for path regulation.

A basic approach to represent nonlinear system behavior for one output is the two-layer NN shown in Figure 38.12. M input signals s_k are processed through weighting values w_{kj}^1 ($k = 1 \ldots M$, $j = 1 \ldots N$) and nonlinear functions F_1 to y_j, which are processed further through weighting values w_{j1}^2 and a linear function F_2 to the final network output z; c_j^1, c_1^2 denote constant bias. In [106], $M = 9$ input signals are applied, further $N = 3$ is chosen, and the sigmoid function $f(u)$ in (38.50) represents the nonlinear contribution of F_1. The network is trained with the backpropagation method, where the training data are obtained from a driver/vehicle numerical simulation, a basic (desktop) driving simulator, and experimental on-road tests.

A similar goal of investigation is followed up in [107], although for different maneuvers (kinds of lane change and slalom, sinusoidal maneuvers). Therefore, the applied discrete-time input vector to the NN is composed of the yaw angular velocity, roll angle and angular velocity, lateral displacement, velocity and acceleration, and a preview lateral offset; the output includes steering angle and steering angular velocity. Different NN architectures are compared, and it is reported that the (Gaussian) radial basis function network (RBFN) showed the best performance with respect to training time and accuracy.

The NN architecture presented in Figure 38.12 is also used to identify driver longitudinal control by representing driver manual control of throttle position during headway keeping tasks [108].

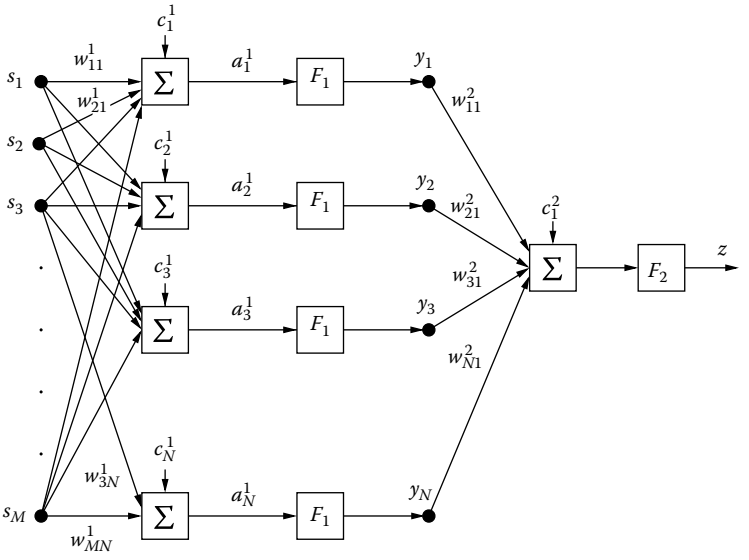

FIGURE 38.12 Two-layer NN architecture (for a single output).

Here, the distance between host and lead vehicle and its time derivative (and their time-delayed counterparts) are combined in the NN to the output for the throttle position. As a kind of adaptive control modeling technique, the NN can then have utility within the context of warning/control packages that require a continuously updated characterization of driver behavior.

In the same paper [108], a similar NN representation of the driver is analyzed to classify specific families of on-highway longitudinal control behavior based on different levels of displayed aggressiveness, respectively, the willingness to pass, follow, or be passed by other vehicles. For this purpose, the pattern recognition ability of certain NN architectures is utilized to automatically identify and classify observed patterns into appropriately defined driving-style categories.

The relationship between human factor and cause of accidents is examined in [109] by using a driver model based on NN. Specific curves, where many accidents are reported, are analyzed with respect to the acquisition of environmental recognition and level of practice to the course. The structure of the applied NN with one hidden layer (of 30 neurons) is similar to the one in Figure 38.12 but with three outputs, in particular steering torque, valve opening of throttle, and braking force. The information used for recognition of the course is derived from the relative position of the environment to the vehicle position using a radar sight description (see Figure 38.11b). The position of the vehicle is mapped by 13 measured lengths to the lane edge L and 13 corresponding angles α, to predict the road shape ahead. Besides these 26 inputs to the NN, further 68 inputs mapping the vehicle behavior are processed. These are 17 current state variables (angles, angular velocities, and angular acceleration for yawing, rolling, pitching, and steering; the velocities and accelerations for the longitudinal and lateral directions; and the sideslip angle of the vehicle), and the same variables 0.2, 0.4, and 0.6 s delayed.

Learning data for the NN are obtained from on-road tests including the curves to be analyzed with respect to accidents. Taking into account the nonlinear relationship between inputs x_i and output y for a single neuron with internal state u

$$u = \sum_i w_i x_i, \quad y = f(u), \quad f(u) = \frac{1}{1+\mathrm{e}^{-u}}, \tag{38.50}$$

the contribution of a respective input on the total output can be extracted. Proceeding with all neurons analogously, the amount and change of amount of input(s), for example, the information from

radar site (length and angle), to a particular output quantity, for example, the steering torque, with respect to time can be evaluated, for instance, with respect to its significance in the environmental recognition process.

The previously described method is extended to characterize the effects of experience and age on driving behavior in [110]. Further, a mental-workload model is proposed to be used to evaluate driver support systems.

The authors of [111,112] introduce a driver model that is established on a method for reinforced learning where the steering angle, as the control variable, is derived from the evaluation of a reward function. For several future time steps, states are estimated based on an internal vehicle model that is represented by a 3-layer NN. The reward depends on the (estimated) distance of the vehicle CG from the road borders.

A class of driver models that claim to mimic human driving behavior in particular are hybrid models (or integrated models). Although there is no common definition of this terminus, it is referred here to models that are composed by more than one modeling method to account for the complexity and multilayered human behavior, [12], on a psychological and physiological basis.

Early approaches are [113–115], the latter similar to the "STI compensatory driver model" [34], but considering thresholds to account for error tolerance behavior of the driver, see summary in [16]. Also [116] can be considered as an early attempt to describe and model different strategies of the driver.

At the hybrid driver model in [12], the previewed curvature ahead of the vehicle is preprocessed through NNs, resolving the curvatures into classes of "concepts" (straight line, curve, S-curve) [117], which are assembled to driver actions by FLC.

The hierarchical driver model presented in [118] is applied in 2-lane highway traffic simulations and is hybrid in the way that it divides the driver behavior into four layers, which are "decision making", "task planning", "maneuver", and "action". "Task planning", for example, for "overtaking", is typically rule based (if-then), while "action" is based on controllers, for example, preview controllers for "gap control" or "speed tracking". For avoiding any prompt danger, for example, a collision, a danger observer is set up. The execution of a "maneuver" will then be interrupted, the "decision-making" layer informed and, for example, the "avoidance" task selected. These safety judgment models are made up with the help of FLC.

A similar task of analyzing car-following and overtaking behavior of the human driver on a highway is performed in [119]. The hybrid model is composed of a "strategic", "tactical", and "operational" level, following Michon's description of driving behavior [9]. The "perception module" provides information on range and range rate with a leading vehicle (LV), which allows the simulated driver to choose a behavior among a set of possible behaviors, such as "following" or "overtaking". Part of the "tactical" module is the "driving behavior database", which allows for a quick retrieval of knowledge associated with a driving situation. In the "categorization" process, the current driving situation is matched with appropriate driving schema in the knowledge database; evaluation of aforementioned modules yields decision maps that define dangerous, critical, and comfortable regions as functions of range, range rate, and velocity. In the "operational" module, the feedback errors, for example, with respect to a desired time gap to the LV, are resulting from sliding mode controllers and are subsequently transformed to control inputs to the vehicle.

Such driver representations are called cognitive models. They embody both the abilities and constraints of the human operator, for instance, abilities such as memory storage and recall, learning, perception, and motor action and constraints such as memory decay, foveal versus peripheral visual encoding, and limited motor performance [120]. The architecture of cognitive models on the basis of an own model is described in more detail in [120]. Here, interesting in the context of the aforementioned controller-like "virtual test driver" models, a specific feature is mentioned. The control component of the driver model manages the perception of lower level visual cues and manipulates the vehicle's (longitudinal and lateral) controls. The lateral steering control is based on the perception of two visual points: The "near point" represents the vehicle's current lane position,

used to judge how close the vehicle is to the centerline of the roadway, and the "far point" indicates the curvature of the upcoming roadway used for anticipation and predictive compensation at a near-future position [121].

The hybrid and cognitive driver model in [122] is developed on the basis of theories on information processing [123,124]. Information processing, visual and vestibular, is described by two queueing systems. The visual information sources from traffic-relevant fixation points only generate an arrival event at the queue when the driver looks at a fixation point. An assumed relation, adapted to the different road fixation points, on the event rate at which the driver looks at the road fixation points, is used, typically 2–6 Hz. Events from fixation points inside the vehicle are modeled as disturbances. Each event is characterized by priority (urgency) and service time (how long the eyes look at fixation points without interruption). Due to queuing, events are sequentially served following priority; short-term memory is modeled with the strategy that all events that stay in the queue for longer than a specific period of time will be removed. The longitudinal and lateral controllers calculate their output (e.g., steering wheel angle) from the data in the short-term memory (e.g., velocity, lateral displacement), whether they are actual or not refreshed. The information for the vestibular perception queue is classified into longitudinal and lateral acceleration, yaw rate, and acceleration. Based upon the perceived driving situation, a suitable control action is selected from the driver's knowledge base (long-term memory). From there, reference values that depend on road layout and individual driver, for longitudinal and lateral control, are derived. The reference value (desired velocity) for the longitudinal controller, for instance, is determined by means of a finite state machine (Mealy automat) (Figure 38.13). Each state represents a different driving action. After the initialization at state "0", the state may switch to "5" if the vehicle is travelling in a curve (curvature $\kappa \neq 0$); otherwise, it switches into state "1", a straight path. The reader may continue intuitively in the graph (from "5" to "6", it is considered that the driver may accelerate before leaving the curve),

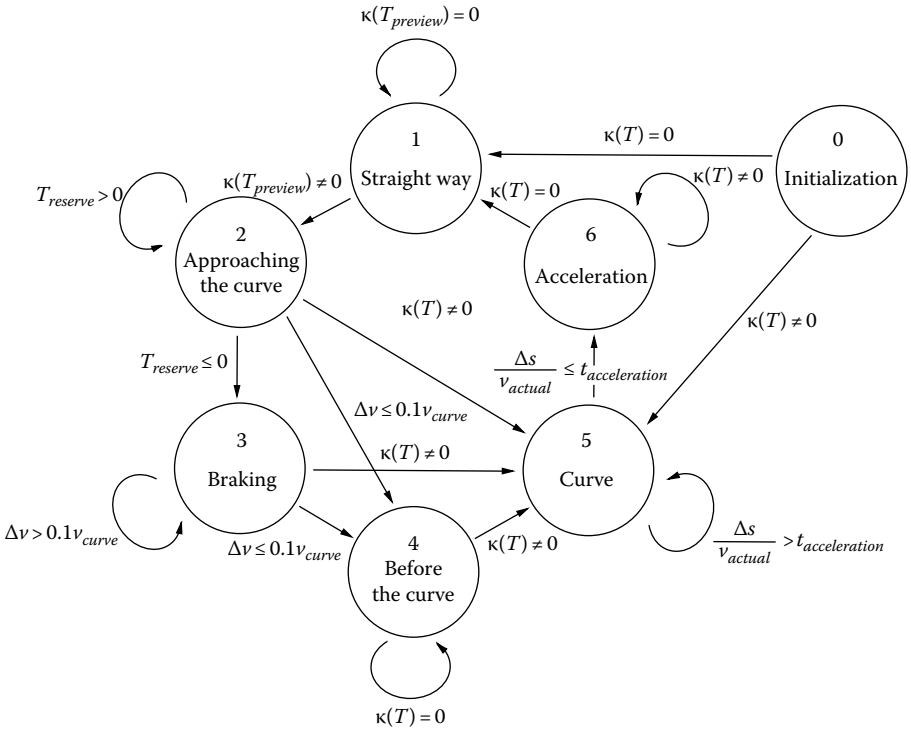

FIGURE 38.13 State graph of velocity controller. (From Kiencke, U. et al., *Control Eng. Pract.*, 7, 985, 1999; Kiencke, U. and Nielsen, L., *Automotive Control Systems*, Springer Verlag, Berlin, Germany, ISBN 3–540–23139–0.)

following his or her own driving experience (details in [122]). Finally, two discrete-time general predictive controllers (GPCs) are designed for longitudinal velocity control and lateral control to minimize the lateral displacement of the vehicle from a reference lane. The controllers calculate the suitable control variables that are accelerator pedal position, brake pedal force, and steering angle, from the information on the actual driving state, provided by the information acquisition and selection, the information on the future course path, and the reference values. More details on the driver model are to be found in [125].

For a further application based on the state-machine approach, see [126] and Section 38.3.2.

The change of driving strategies may also be represented by adapted identification methods. An example is the investigation of the stopping behavior of the driver in [127].

Authors in [128] propose that driver steering skill level is defined as the extent to which the driver possesses an understanding of the nonlinear vehicle dynamics. An internal model, which is considered to be a representation of the dynamics of the vehicle in the central nervous system, is used by the driver to predict the future vehicle motion within the preview horizon; the internal model concept is incorporated in different (mostly linear) ways in many of the driver models in Section 38.2. It is postulated in [128] that the driver learns and stores an understanding of the nonlinear vehicle dynamics by linearizing the dynamics around incremental operating points. The number of operating points corresponds then to skill and number of internal models used by the driver. For each linearized internal model, a predictive controller is designed and the most relevant selected and changed by the driver if applicable.

The behavior of drivers, especially in emergency situations, such as in the case of sudden encountering of an obstacle during driving, is analyzed in [129] for a better understanding of reasons of traffic accidents. The driver is mathematically described by a basic preview model in Laplace notation:

$$\frac{\delta_s(s)}{\Delta y(s)} = G_h(1+T_L s)\frac{1}{1+T_I s}, \quad \Delta y(s) = y_d(s) - \left[y(s) + vT_{pr}\psi(s) \right] \tag{38.51}$$

with the current and desired lateral displacement y and y_d, respectively. While parameters T_L and T_I are supposed to be constant, the steering gain G_h and preview time T_{pr} are considered to be variable under emergency situations. Their changes are obtained from searching for optimal solutions, based on the payoff function:

$$J = \int \left[a(y_d - y)^2 + b\delta_s^2 + c\dot{\delta}_s^2 + d\dot{G}_h^2 + e\dot{T}_{pr}^2 \right] \mathrm{d}t \tag{38.52}$$

with weighting factors *a, b, c, d, e*, by applying a genetic algorithm (GA). For avoiding the obstacle only by steering, a gene is composed of the distance between the vehicle and obstacle, the angle between the longitudinal axes of the vehicle, and the connection line between the vehicle and obstacle, the steering gain G_h, and the preview time T_{pr}; for the case of steering and braking, the gene is extended.

38.3.2 Path and Speed Planning, Optimized Driver/Driving Behavior

Path and speed planning as an internal driver task may be a priori incorporated in the driver model (see, e.g., [75] in this section or respective models in Section 38.3.1) or considered as a separate feature of the model. Many driver models (see Section 38.2) require a "desired path" to follow that is assumed to be given or to be the roadway centerline or to result just from a separate tool. For the latter case, some examples are cited here, whether they are part of a specific driver model or considered independently.

A desired path may be regarded as an optimized path. In this respect, either the total maneuver or course can be optimized (e.g., [68,70,130,131] and others as follows) or, from the driver point of view, toward an optimization horizon, some previewed seconds in advance [132,133], and after the driver has followed, optimization is started again. A variety of optimization criteria are treated in [132], which can be combined by respective weights to account for specific preferences by the driver:

Time optimal	To reach the destination as fast as possible
Acceleration optimal	To minimize horizontal accelerations, e.g., to enhance passenger riding comfort (to be combined with previous criterion to reach destination)
Brake optimal	To minimize the use of the brake to avoid unnecessary energy dissipation or brake disk overheating
Keep right/left	To stay in the preferred lane, if there is other traffic in the neighboring lanes
rpm optimal	To keep a certain engine speed, e.g., to avoid noise or to allow for enough engine power required for overtaking
Velocity optimal	To reduce the deviation from a given speed profile, e.g., to meet a posted speed limit

The optimization is performed considering basic prediction models of the vehicle's longitudinal and lateral dynamics and the tire behavior. A very similar approach is pointed out in [134], including considerations on the controller to track the optimized trajectory in [133].

The proposed path planning algorithm in [135] operates with polar curves applied to a line–arc–line transition at different speed conditions. A reference trajectory is derived that corresponds to the driver behavior, whose aim is assumed to avoid lateral acceleration variations during curve negotiation; therewith, a continuous curvature behavior constraint is guaranteed. The polynomial parameters of the reference trajectory are fuzzy (Mamdani based) determined with respect to database information (radius and turn angle of the curve) and specific constraints to account for different kinds of driving styles (novice, experienced driver) observed by driving tests. The path planning feature is a part of a navigation-aided driver-aid system, which locates the vehicle on the road by utilizing differential global positioning system (DGPS) and may either warn the driver, if an inappropriate driving condition in terms of the vehicle's speed and/or trajectory is detected, or may correct these situations.

The accuracy and generality of the driver trajectory model are improved in [136] by identifying the membership functions of the fuzzy interference system (now Sugeno based) from experimental data using an optimization algorithm.

The reference speed for the curve is determined considering the tolerated lateral acceleration (depending on the driver and vehicle) and on the instantaneous curvature of the trajectory followed and is thus not constant in the curve [126]. When negotiating the curve, it is assumed that the driver accomplishes a braking sequence to reach the reference speed for curve negotiation, a negotiation sequence nearly with a constant speed, and an acceleration sequence when leaving the curve depending on the road profile ahead. The cognitive mechanism is realized with a state machine, similar to Figure 38.13 (details in [126]).

In the context of speed choices in curves, the review [137] of various proposals thereof might be interesting as well (other proposals in [138]).

In [75], a driver model is constituted that incorporates the course decision process of the driver as well. It is assumed that the main information required for course decision is the risk feeling of the driver from a forward view. The risk level cannot be measured, but a high correlation thereof with the heart rate of the driver is presupposed. From experimental tests, it is concluded that the driver selects the course with minimum risk level. The risk level on a forward view is thus adopted and

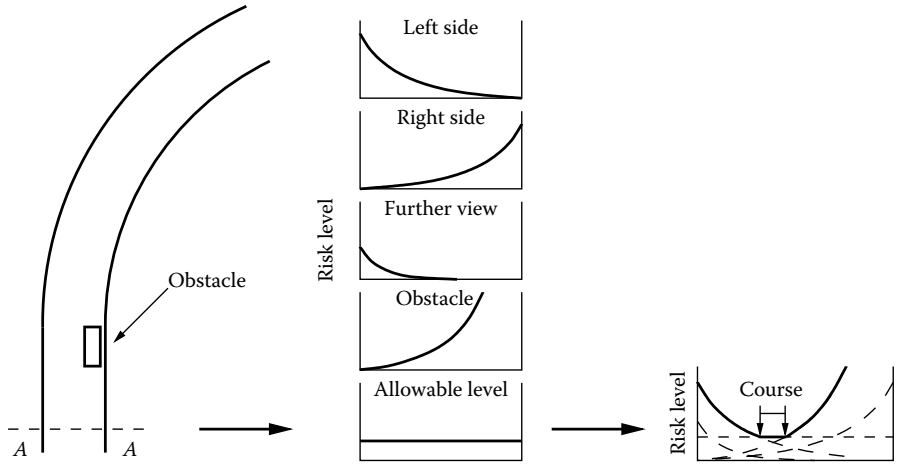

FIGURE 38.14 Driving course decision based on minimum risk level. (From Kageyama, I. and Pacejka, H.B., *Vehicle Syst. Dyn. Suppl*., 20, 314, 1991.)

composed of four parts that consider the distance from the left and right road border, obstacles, and the further view such as curves (Figure 38.14). These risk levels are described by exponential functions, whose parameters depend on velocity, boundary conditions, road width and road condition, etc., and are based on fuzzy reasoning.

The driver's steering angular velocity is then obtained from the risk level and its rate at a certain viewpoint ahead by applying FLC; from the actual steering angle and the desired steering angular velocity, a steering torque for the lateral control of the vehicle is derived. For the longitudinal control of the vehicle, respectively the decision of speed, the minimum risk level at the viewpoint is considered again.

To simulate a closed-loop ISO-lane change at the same maximum speed, an experienced human driver is able to perform, is not only a big, if not so far impossible challenge for a driver model. Finding a time-optimal trajectory, which the driver (model) has to follow (with time lag), is a solution to some extent but may fail on the extreme. The reason is the mismatch between the highly nonlinear vehicle behavior and an inadequate representation thereof by the driver model's internal prediction model and the fact that generally the driver behavior (e.g., time delay, limits) is ignored in the determination of the optimal trajectory. Considering the task in the latter way, different solution methods for the time-optimal maneuver or race circuit trajectory for the respective driver controls have been proposed.

In [139,140], parallel shooting method for solving the optimal control problem is applied. An optimized steering angle behavior is computed (by adaptive simulated annealing (ASA) method) in [141] for the ISO-lane change at a maximum speed performed by human test drivers; the same task is studied with a trajectory deformation method by iteratively deforming inputs in [142]. A generic algorithm is applied to the Customer Union (CU) short-course maneuver in [143]. The performance function in [144] for optimal steering and/or braking strategies at an obstacle avoidance maneuver consists of steering effort (steering angular velocity) and workload of the tires (combined friction coefficients) besides path constraints; direct shooting method is proposed for optimization.

Various performance indices with time-variant weighting coefficients on steering angle and angular velocity, yaw rate, roll rate, and deviation from road centerline, are adapted in [145] by trial and error to match the simulation results with the measured control action of a driver when passing through a double-lane change. The improved performance indices are then used as a quantification to explain the respective driving strategy of the driver.

In [146], the parameters of a vehicle and driver model, which is based on the observation of lateral displacement and yaw angle, are identified by applying an AR model for a closed-loop

single- and double-lane-change maneuver on experimental test data. In this way, an aimed separation of vehicle and driver behavior is realized.

The evaluation function for the optimization of a double-lane-change maneuver in [147] takes into account criteria for the minimum time to pass, the minimum margin between the border of the course and the corner of the vehicle, and the average steering wheel rate to represent the driver's physical effort; the predicted lateral displacement is used as input for an included basic driver model. Different weighting factors in the evaluation function are analyzed to conclude for intentions of the driver.

A driver model is developed for the ISO-lane-change maneuver in [148], where driving is seen as a model predictive control task in such a way that the driver accumulates knowledge about his or her vehicle's handling properties. Therefore, two (heuristic) fuzzy logic controllers are designed for the output variables steering wheel angular acceleration and accelerator pedal position. For lateral control, the input variables, position error, yaw error, and curvature error, are provided as a combination of their actual and predicted values and gains are determined to minimize the aforementioned errors.

In [149], also [150], two optimal driving policies are compared in particular at a limit handling maneuver, characterized by combined steering and acceleration, to achieve obstacle avoidance while maximizing speed and maintaining stability. The first, called general optimal control (GOC) technique, is working with vehicle states and road/obstacle geometry limits simultaneously, to provide the optimal sequence of steering, brake, and throttle actions to give the best obstacle avoidance. A nonlinear four-DOF handling vehicle model is employed, but there is no internal representation of the driver. The second, called dual-model (DM) technique, incorporates a generic driver model for closed-loop maneuvers and aims to provide near-optimal driver control inputs that are insensitive to driver model assumptions that may have an influence on the closed-loop performance evaluation. Therefore, a set of optimal controls is initially determined for a simple nonlinear particle model of the vehicle with mass-center acceleration constraints only. These results provide a reference input to a more realistic simulation that consists of a vehicle handling model coupled to a generic driver model:

$$\dot{u}_1 = \frac{(a_0 - \dot{u})}{\tau_1}, \quad \dot{u}_2 = k_1(\omega_0 - r) + k_2\sigma(\beta\dot{\beta})\dot{\beta},$$
$$\sigma(\beta\dot{\beta}) = \begin{cases} 1 & \text{if } \beta\dot{\beta} > 0 \\ 0 & \text{if } \beta\dot{\beta} \le 0, \end{cases} \tag{38.53}$$

with the acceleration command signal $u_1(t)$, which is converted to a drive force or braking torque, and the steering angle $u_2(t)$; u, r, β denote longitudinal velocity, yaw rate, and sideslip angle of the vehicle, respectively; τ_1, k_1, k_2 are the control parameters for demanded acceleration $a_0(t)$ and angular velocity $\omega_0(t)$ resulting from the particle model-based reference. From deviations between particle and driver–vehicle simulations, effective friction limits are estimated, which provide a modified set of conditions to revisit the reference optimization until no significant changes in controls are observed and an approximately optimal input is obtained.

38.4 APPLICATIONS WITH FOCUS ON VEHICLE/DRIVER COMBINATION

This section is concerned with application features that keep an eye on the combined vehicle/driver couple. The same tasks can be found in other sections as well, but while, for instance, the design of the controller for a certain driver support system may be the main concern for including a virtual test driver model into a simulation environment in Section 38.2, the application is presented in this section if reactions of these systems on the driver behavior or design criteria from the driver point of view, etc., are covered as well.

38.4.1 Vehicle Handling Dynamics with Respect to the Driver

The closed-loop system road–vehicle–driver is analyzed in [151] for an exemplary lane-change maneuver. The capabilities of the driver, as a basic controller of the previewed positional error, are limited by maximum attainable steering wheel angular movement parameters. If any of these limits are violated, the model continues in an open-loop mode, where the steering wheel movement is directed by the maximum possible movement parameters. Emergency trajectories are generated until the driver steers again in closed-loop mode or crashes. For the presented maneuver, evaluation criteria are stated both with respect to performance and to the driver's

Mental effort:

- Based on the abruptness of vehicle movements, like maximum yaw angles and yaw velocities, and sideslip angles of the vehicle
- Based on the task-dependent driver's foresight (phase angle difference between steering wheel motion and individual vehicle reaction), like width of the hysteresis loops of $\dot{\psi}/\delta_s$, $\dot{\psi}/a_y$, β/a_y, and integral phase lag criterion computed as integral of the difference between normalized steering angle and normalized curvature of the CG's trajectory, etc.

Physical efforts:

- Like maximum steering wheel velocities, accelerations and steering wheel torque, total angular movement of the steering wheel, mean steering wheel velocity, maximum steering wheel power, mean positive steering wheel power

In [152], an analytical approach to predict the subjective rating of handling qualities of actively controlled vehicles is presented and experimentally tested for the evaluation of 2/4-wheel-steered vehicles. Handling qualities are understood here as qualities of the vehicle that affect ease and accuracy in performing assigned driving tasks and imply thus the driver, in particular task performance and driver's workload. The transfer function–based driver model

$$\delta(s) = K_{\psi}(T_{L\psi}s+1)\left[K_y(T_{Ly}s+1)y_e(s) - \psi(s)\right]\frac{e^{-\tau_r s}}{(T_I s+1)} \tag{38.54}$$

with the lateral position error y_e and yaw angle ψ includes the gains K_y, K_{ψ} and the lead time constants $T_{Ly}, T_{L\psi}$ to account for the adaptation of the driver to the vehicle characteristics and assigned task, while the time delays τ_r, T_I are assumed not to be subjected to any changes due to the driver's intention. The driver's subjective rating is represented by an objective function J with appropriate weights q_1, q_2, q_3:

$$J = q_1\int_0^{t_f} y_e^2 dt + q_2\int_0^{t_f}\delta^2 dt + q_3(T_{Ly}+T_{L\psi}) \tag{38.55}$$

that takes into account the task performance (accuracy) and the driver's physical (steering effort) and mental workload (required lead time constants). The parameters K_y, K_{ψ}, T_{Ly}, $T_{L\psi}$ that minimize the value of J are determined by numerical optimization, and J_{min} serves as a predicted value for the subjective ratings in accordance with experimental tests. Specific design parameters that influence vehicle handling behavior are then evaluated with respect to their effect on the rating J_{min} and its constitutive elements.

By analyzing driver model and vehicle behavior, a design strategy for a steer-by-wire (SBW) system is presented in [153] to improve vehicle stability while preserving handling performance during

lane change at a given constant speed. Therefore, a driver model, which incorporates both steering wheel angle δ_s and steering torque M_d, is introduced by

$$\frac{\delta_s}{K_\delta} + \frac{M_d}{K_M} = \Delta y_{pr} e^{-\tau_r s} \quad \text{and} \quad \Delta y_{pr} = y_d - (y + L\psi) \tag{38.56}$$

with future lateral position error Δy_{pr}, desired lateral position y_d, driver's delay time τ_r, preview distance L, current lateral position y, and yaw angle ψ. For $K_M = \infty$, the driver controls the vehicle with the steering angle only; for $K_\delta = \infty$, with the steering torque only; and for $0 < (K_\delta, K_M) < \infty$, with a combination of these. It is further assumed that $e^{-\tau_r s} \approx 1/(1 + \tau_r s)$ and that moment of inertia and viscous friction of the steering system are small and negligible; thus, $M_d = -M$, where M is the steering torque from the vehicle. The addressed improvements derive from an optimized steering angle gain k (with a performance function based on lateral position error and lateral acceleration of the vehicle) and the compensation of the system delay time, made up by vehicle and driver delay. To attain this objective, the free design parameters of the SBW system are chosen to realize lead steering, $\delta_f(s) = k(1 + \tau_{rs})\delta_s(s)$ (with front wheel steering angle δ_f), and/or feedback of the driver's steering torque derivative including the gains K_δ, K_M and the time delay τ_r of the driver model in (38.56).

In [154], a driver-articulated vehicle model is described to study and adapt the vehicle design with respect to different driver skills. Figure 38.15 illustrates the proposed multiloop structure of the driver/vehicle system, where the path input may be either the lateral displacement or the path orientation.

The inner control loop signals comprise the lateral acceleration of the lead unit, articulation rate of the combination, and roll angle of the sprung mass of the trailing unit to employ sensitivity of the driver to both tractor and trailer. The components of the compensatory function of the driver are $H_L(s) = K_L e^{-\tau_L s}$ and $H_H(s) = K_H e^{-\tau_H s}$, respectively; the preview block $P(s) = e^{T_p s}$ represents the preview function for a single-point preview strategy. The driver's prediction function for the lateral displacement $B(s)$, like stated in (38.2) before, represents the driver's prediction ability of the vehicle motion. The prediction functions in the internal loops are defined by $F_i(s) = K_{pi} e^{\tau_{pi} s}$ ($i = 1, 2, 3$) and are intended to indicate the driver's direct and/or indirect perception of the vehicle motion: For direct perception of the motion arising from either experience or subconscious knowledge of vehicle response, τ_{pi} assumes a positive value; indirect perception of motion, realized through monitoring the vehicle state, yields a negative value of τ_{pi}, since the delays associated with measurement, signal processing, display, and detection are longer than the driver's prediction time. It is further postulated

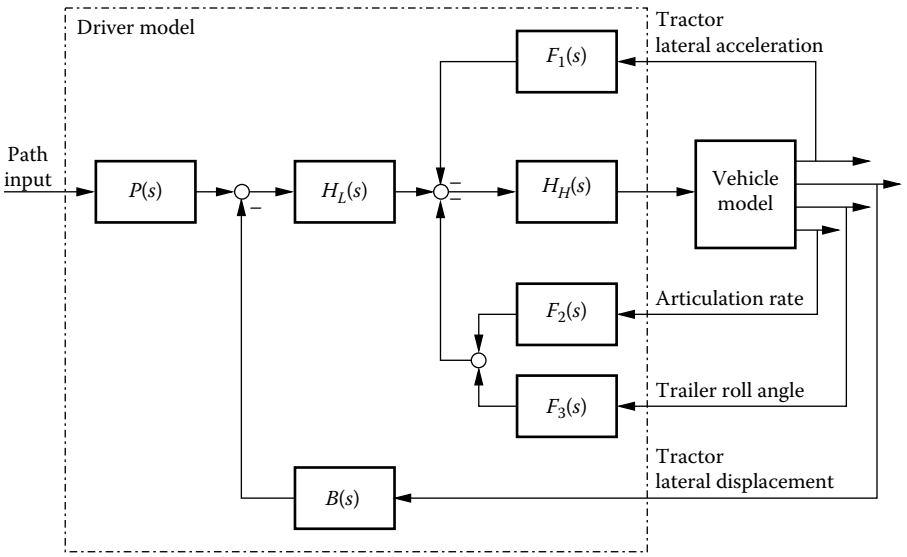

FIGURE 38.15 Driver model for articulated vehicles. (From Yang, X. et al., *J. Mech. Des.*, 123(1), 132, 2001.)

that the driver's control limits in terms of reaction time, preview distance, compensatory gain, and steering input vary considerably with individual skills, test conditions, and environmental factors.

A performance index based upon the vehicle path tracking, the directional response characteristics, and the driver's steering effort is formulated and minimized to derive the desirable ranges of vehicle parameters that could be adapted for drivers with varying skills. A detailed description of driver model for articulated vehicles is given in [155].

38.4.2 Accident Avoidance, Active Safety, Driver Support Systems

Similar to the just previously referenced task in [153], the adaptation of SBW parameters to the steering characteristics of (in particular) aged drivers is investigated in [156]. For that purpose, the parameters of the driver model according to (38.51), but with $\Delta y(s) = y_d(s) - y(s)$, are determined by minimizing a cost function composed of the deviation between calculated and measured data for lane-change maneuvers; the target path y_d is considered as a step input. A further optimization (for minimal deviation between actual and desired lateral distance) is then applied, to find the parameters of the feedforward SBW system for the closed-loop system to follow an ideal vehicle trajectory. For the lane-change maneuver, a double integration of a pure sinusoidal acceleration, with the magnitude corresponding to the lane width and the frequency corresponding to lane-change distance and velocity, is chosen as an ideal path.

A driver model based on multiple inverse models of the dynamics of the vehicle is used in [157] for the design of a driver support system to assist the driver in an obstacle avoidance scenario. A general description of an "integrated driver model" for driver safety assist systems is discussed in [158].

The focus of the study [159] is on the adaptation process of driving behavior when using an adaptive cruise control (ACC) system. ACCs are capable of automatically maintaining a constant intervehicle distance and speed, which are selected and set by the driver. To account for different individual extents of skilfulness of drivers, a feedback-error learning scheme is introduced as driver model based on an NN and two feedback proportional controllers. The inputs of the NN are the road curvature, a preview distance ahead; the velocity of the vehicle; the difference between desired and actual distance to the lead vehicle; steering angle; lateral deviations from the road centerline (at three distances ahead); and the on–off signal for ACC use; output quantities are steering angle and velocity of the vehicle. The simulation model is then used for predicting the control performance of a skilled driver using ACC. Headway time for lane changing in a row, FFT analysis of the steering angle, and lateral deviation from the road centerline are considered for driver behavior description during ACC use and manual driving, respectively.

The results of the development of a driver assisting system as a monitoring and warning aid for the driver on highways are presented in [160–162]. The basic outline of the system is given in [161]. The "reference driver module" (based on state automata in [161], on petri nets in [162] representing a statistically average driver behavior) extracts from the incoming data of machine vision and sensors a symbolic description of the actual situation. In addition, it calculates and outputs situation-specific action boundaries. The "discrepancy interpretation module" judges the driver's actions with respect to these boundaries, thereby also taking into account the situation-specific output of the "model of actual driver." In case of an actual danger coming up, the "warning device" is triggered to issue an appropriate warning, which is presented to the driver through haptic displays. The "model of actual driver" accounts for the adaptivity to the individual driver, where the actual driver's normal driving style is extracted from observations of his or her behavior during a learning period. Therefore, statistical approach and NN approach are compared in [160,161], and an NN approach based on fuzzy adaptive resonance theory (ART) architectures is introduced in [162].

In [163], "hidden Markov dynamic models" (a set of dynamics models sequenced together by a Markov chain) are used to recognize human driving behavior from sensory data and to predict the most likely driver's behavior over three seconds; the human is considered as a device with a large number of internal mental states, each with its own particular control behavior and interstate

transition probabilities. By observing the temporal pattern of the driver's control action behavior and comparing it to the action models, the initiated action of the driver can be determined and may be used for collision avoidance systems ([164], also [165,166]). A further approach for predictive action recognition applying probabilistic networks for ACC is outlined in [167]. A model of driver intention recognition based on a fuzzy associative memory system is described in [168].

A kind of hybrid driver model is proposed in [129,169] to simulate and understand the driver's strategy at the instance of a sudden stopping of the preceding vehicle. A set of linear polynomials is used to describe the steering amount based on sensory information of range and range rate of the vehicles and their lateral displacements. The coefficients of these polynomials as well as the parameters, which define the switching condition between the "modes" with respect to the range between the vehicles, are identified from data and observed stopping strategies using a driving simulator environment. Driving characteristics of the novice and expert driver are compared.

The use of steering control as a driver assistance function in collision situations is addressed in [170]. For that purpose, a basic preview steering control is applied to stabilize the trajectory of the vehicle at postimpact maneuvers.

In [171], the gear selection problem of automatic transmissions (ATs) is analyzed, and a learning algorithm is proposed to improve the vehicle behavior and driver satisfaction. To optimize vehicle performance with multiple antagonistic criteria, locally and globally over time, a parametric discriminant function is considered, depending on an evaluation of the driver satisfaction, and the so-called driver-style state functions, as a reward for the system, and a reinforcement learning algorithm are applied, derived from Q-learning method. Supervised learning directly from the driver is performed when the driver selects AT ratio in manual mode; that allows the embedded controller to customize memorized strategies when resuming AT in automatic mode (based on a backpropagation NN). Each driver may possess a personal driving style and may also be characterized by different physical states, which are represented by a class creation/selection mechanism for unsupervised learning.

38.5 APPLICATIONS WITH FOCUS ON THE ENVIRONMENT/TRAFFIC

The final section is concerned with applications of driver models that consider the environment of the vehicle–driver combination, in particular the interaction with one or more other vehicles. In this respect, topics such as understanding the system "traffic", traffic flow, and car following come into view. Car following itself forms one of the main processes in all microscopic simulation models as well as in modern traffic flow theory, which attempts to understand the interplay between phenomena at the individual driver level and global behavior on a more macroscopic scale [172]. Applications like ACC and automated highway systems (AHSs) entailed a rich series of publications and as long as the "driver" is the main concern and not automated driving (or "intelligent cruise control" that may consider only partial aspects of the human driver); some early elementary as well as some recent papers are presented in the following. Giving an overview of some principal modeling methods and typical applications, rather than insight, is attempted here; related models and topics have also already been addressed before.

Already in 1950, the longitudinal behavior of a traffic line or platoon of vehicles was investigated by Reuschel [173] on a kinematic basis. The LV initiates the longitudinal states of the following vehicles (FVs) at a given rule for the gap Δs between the vehicles:

$$\Delta s(t) = \Delta s_0 + qv(t) \tag{38.57}$$

with a predefined gap Δs_0 between preceding and FV at standstill and velocity $v(t)$ of the FV; q is fixed to 3.6 (for the conversion of v in km/h to m). The case of a sudden deceleration to standstill and the effect on the following platoon has been treated as well. Since then, the topic attracted a growing interest along with growing traffic, and more complex models to simulate traffic flow have been developed.

A longitudinal driver model for simulating traffic lines is included in [174]. Considering transfer functions for the longitudinal vehicle dynamics and driver behavior

$$\frac{s\alpha(s)}{\Delta v(s)} = \frac{k_M}{s}\frac{(1+T_{L,1}s)(1+T_{L,2}s)}{1+T_N s} \tag{38.58}$$

with the accelerator pedal position $\alpha(s)$, range rate $\Delta v(s)$, and driver parameters k_M, $T_{L,1}$, $T_{L,2}$, T_N, stability aspects of traffic lines are analyzed.

The simplified version of the "precision model" (see (38.7) [30]) is proposed in [175] to model driver behavior for noncritical car-following situations. The identification of the driver parameters is presented as well as evaluation with experimental data.

The determination of the range/gap between two successive vehicles as a kind of rule or demand characteristic for the driver (and often referred to as longitudinal "driver model") in car-following situations has been studied theoretically and experimentally in numerous publications. In 1953, a linear transfer behavior is suggested in [176] by specifying the acceleration $\dot{v}_{k+1}$ of the vehicle $(k + 1)$ proportional to the relative velocity $(v_k - v_{k+1})$ to the preceding vehicle k. The idea is extended in [177] by a time lag τ_r (reaction time of the driver), so the basic leader–follower model reads

$$\dot{v}_{k+1}(t) = \lambda\left[v_k(t-\tau_r) - v_{k+1}(t-\tau_r)\right] \tag{38.59}$$

with constant λ called the sensitivity factor of the driver. One example of the numerous applications of the model is [178], where the effects on traffic flow characteristics (string stability) and environment (fuel consumption) are analyzed, when semiautomated vehicles with automatic vehicle-following capability operate together with manually operated vehicles.

The nonlinear type of this model became well known and is often referred in literature as GM model or Gazis–Herman–Rothery (GHR) model [179]:

$$\dot{v}_{k+1}(t) = C v_{k+1}^m \frac{v_k(t-\tau_r) - v_{k+1}(t-\tau_r)}{\left[x_k(t-\tau_r) - x_{k+1}(t-\tau_r)\right]^l} \tag{38.60}$$

For suggestions on the choice of the parameters C, l, m, including some references of many published modifications of the model, see [172] or more recently [180].

Another modification, known as (simplified) Helly model [181]

$$\begin{aligned}\dot{v}_{k+1}(t) = {} & C_1\left[v_k(t-\tau_r) - v_{k+1}(t-\tau_r)\right] \\ & + C_2\left[(x_k(t-\tau_r) - x_{k+1}(t-\tau_r)) - D(t)\right]\end{aligned} \tag{38.61}$$

$$D(t) = \alpha + \beta v_{k+1}(t-\tau_r) + \gamma \dot{v}_{k+1}(t-\tau_r) \tag{38.62}$$

with a desired following distance $D(t)$ and where C_1, C_2, α, β, γ are parameters to specify the characteristic of the traffic flow, is also used up to now, for example, even in a neural fuzzy framework in [182].

A state-space formulation is chosen in [183] to derive with optimal control theory constant feedback gains, which modify the dynamics of the follower in a way that the resultant system response approaches that of a given model (of the leader). Examples are presented for aircraft dynamics. The method is transferred to the car-following problem in [184]. A quadratic performance criterion function guarantees that

deviations from some desired spacing $\Delta s_d = kv_f$ and the relative velocity Δv are minimized and that minimum energy is required; then the optimal control becomes (with the speed v_f of the follower)

$$u(t) = C_s[\Delta s(t) - C_c v_f(t)] - C_v \Delta v(t) \tag{38.63}$$

After including the driver's reaction time τ_r and vehicle nonlinearities (which are not specified any further), the parameter set C_s, C_c, C_v, τ_r is identified from highway data. With a switching method also, more preceding vehicles may be considered.

Another often cited car-following model to mimic real traffic was presented by Gipps in 1981 [185]. When it is assumed that the driver travels as fast as safety and limitations of the vehicle permit, the speed v_n of vehicle n at position x_n is given at time $(t + \tau_r)$ by

$$v_n(t+\tau_r) = \min \begin{cases} v_n(t) + 2.5a_n\tau_r\left(1 - \dfrac{v_n(t)}{v_{n,0}}\right)\sqrt{0.025 + \dfrac{v_n(t)}{v_{n,0}}} \\ b_n\tau_r + \sqrt{b_n^2\tau_r^2 - b_n\left[2(x_{n-1}(t) - s_{n-1} - x_n(t)) - v_n(t)\tau_r - \dfrac{v_{n-1}(t)^2}{b}\right]} \end{cases} \tag{38.64}$$

The parameters required for the model are listed in Table 38.1.

The first constraint to vehicle n in (38.64) is that it will not exceed its driver's desired speed and its acceleration should first increase with speed as engine torque increases and then decreases to zero as the vehicle approaches the desired free flow speed $v_{n,0}$.

The second constraint takes into account that the driver of the FV selects his or her speed to ensure that he or she can bring his or her vehicle to a safe stop should the vehicle ahead came to a sudden stop. That's the way models of this type are called safety distance or collision avoidance models; an early contribution of this type is [186].

In this way, the model combines the two competing goals of keeping a safe distance from the preceding vehicle and to converge to the driver's desired free flow speed.

The approach in [187] is based on (38.59) ($\tau_r = 0$) where v_k is replaced by an optimal velocity function $v_{opt}(\Delta x)$:

$$v_{opt}(\Delta x) = v_0\left[\tanh m(\Delta x - b_f) - \tanh m(b_c - b_f)\right] \tag{38.65}$$

with headway $\Delta x = x_{k+1} - x_k$ and the parameters v_0, m, b_f, b_c to be determined from observed data of the individual behavior of vehicle k.

TABLE 38.1
Parameters of Gipps Car-Following Model

a_n	Max. acceleration that the driver of vehicle n wishes to undertake
b_n	Max. deceleration that the driver of vehicle n wishes to undertake
$\hat{b}$	Estimated value of b_{n-1}
$v_{n,0}$	Speed at which the driver of vehicle n wishes to travel
s_n	Save distance to vehicle $n-1$
τ_r	Reaction time

Source: Gipps, P.G., *Transport. Res. B*, 15B, 105, 1981.

Validation of the aforementioned models [177,179,184,185,187] as well as the car-following model for traffic flow in [188] is done on the basis of two databases with field measured car-following data in [189]. The Gipps model is reported to be able to fit the highest number of maneuvers; nonetheless, in [55], an improved version of the Gipps model has been proposed. In particular, when traffic density is high, and the vehicle behavior is dominated by the second constraint in (38.64), the Gipps model is corrected not to overestimate traffic flow. The updated model is then used to evaluate the impact of ACC vehicles on traffic flow (see also [190]).

An overview of a similar group of car-follower models as mentioned earlier is discussed in [191] with respect to stability issues. The authors criticize on missing human factors in the models and refer to [192], where car following is described from a physiological/psychological point of view; a model is presented in [193]; [192] is written as a comment to [172] that gives a historical review on car-following models from the beginnings to 1999. In return, [194] is a reply on [192] and focuses on the implications of satisficing, the determinism assumed in engineering-inspired models of car following, and the role that individual differences in perceptual and cognitive performance, as well as motivation, must play in future accounts of traffic behaviors such as car following.

Other comparative studies including previous or similar type of models for traffic flow or ACC investigations are, for example, [195,196] or [197].

Traffic simulation models make assumptions about the safety-related behavior of drivers. The authors of [198] state that these assumptions may or may not replicate the real behavior of those drivers, who adopt seemingly unsafe behavior, for instance, when following the vehicle in front too closely. Consequently, the paper explores the questions associated with the choice of values for safety-related parameters of various simulation models in literature.

The transition from free traffic flow to synchronized flow at a highway bottleneck is studied with two empirical microscopic traffic flow models in [199].

With respect to other or more specific applications, [200] is noted, where the driver of a heavy-duty vehicle is considered following another vehicle. Based on measured data, a basic feedforward and feedback model is developed. The applied multiple linear regression method (similar to the driver model for steering in [110]) is used to set a linear relationship between input variables (information on preceding vehicle, FV, and relative to each other) and an output (throttle position); derived coefficients are then analyzed with respect to the importance of each information to the driver.

The behavior of non-truck drivers is modeled in terms of their interactions with trucks in a traffic stream in [201]. The car-following and lane-changing logics of the microscopic highway traffic flow model [202] are therefore extended. Based on the survey data, the car–truck interactions are described with a fuzzy logic–based model by associating a "discomfort level" for the non-truck driver in the vicinity of trucks.

In [203], night driving behavior is investigated. For the optimal velocity v_{opt} in the car-following model

$$\dot{v}_{k+1} = C_a[v_{opt}(\Delta x) - v_{k+1}] + C_b[v_k - v_{k+1}] \tag{38.66}$$

with parameters C_a, C_b, the same approach as given in (38.65) is chosen but adapted with thresholds. Therewith, stability analysis of traffic clusters is done.

The conceptual paper in [204] shows another kind of application for driver models. A driving simulator and a macroscopic traffic simulator are linked together in real time, interacting with a further microscopic traffic simulator. Therein, a driver model is included to generate response to traffic environment with other vehicles, respectively, to interfere with the real driver in the driving simulator.

Longitudinal car-following driver models have also been introduced in driver warning systems for vehicle collision avoidance (e.g., [205]) similar to the objectives for the lateral case in Section 38.4.2.

A different kind of modeling approach for the car-follower problem is the application of NNs [108], which has already been outlined in Section 38.3.1. The recent study in [206] compares the efficiency of a backpropagation NN and a radial basis function (RBF) NN for modeling car-following behavior. Also FLC has been used to develop knowledge-based models of traffic behavior (e.g., [201,207]).

In [208], a stochastic modeling of mixed traffic flows on a multilane road is presented. For saturated flows, in a "stop and go" mode, it is taken into account that a great number of vehicles may change to another lane. Stability aspects are discussed, and methods to estimate energy consumption and intensity of accompanying pollutant emissions are proposed.

In constitutive equations of basic car-following models (e.g. (38.60)), it is presupposed that the driver of the following car reacts, on the one hand, to arbitrarily small changes in the relative speed and, on the other hand, even at very large spacings [209]. Therefore, in these equations, it is assumed that there is no response as soon as speed differences disappear, which is considered not realistic in [209], and "psychophysical" models are proposed there instead: Drivers are subject to certain limits on the stimuli to which they respond; for example, at large spacings, the driver of an FV is not influenced by the amount of the speed difference. Only when these perceptual thresholds are reached, the driver will be able to perceive the change in the apparent size of the LV and react to changes in the kinematic variables; the achievements presented in [210] are based on this idea, also in [211]. At close headways, where the speed difference is likely to be below a threshold, spacing-based thresholds become relevant ("action point" models).

An (if-then) rule-based cognitive model is realized in [212] to give an example for a descriptive modeling approach.

Taking into account that drivers rely chiefly upon visual information, the visual system's ability to detect the onset of the LV's braking and to monitor and track the FV's approach to the LV is studied and quantified in [213]; an early contribution in this respect is [214]; see also [215] and references in [213]. Visual cues include

- Monocular expansion of the LV's image in the FV driver's field of view (looming)
- Texture dilation (as the LV approaches the FV, the fine detail of its surface features comes more sharply into focus)
- Binocular cues
- LV brake light ignition

In [213], the looming cue is focused exclusively, represented by the rate of change of the angle θ as defined in the right plot of Figure 38.16.

The human driver model of the LV braking scenario is illustrated in Figure 38.16. The sensory input to the visual system, the monocular image expansion, is represented by $\dot{\theta}$ with added noise. Pure time delays are also associated with the visual system that is provided by the block $e^{-s\tau}$. Then the signal passes through a filter. The FV driver's perception of $\dot{\theta}, \dot{\theta}_p$ is then sent to the "cognitive process" block, along with a judgment by the "criterion detector" as to whether LV braking is present. If $\dot{\theta}_p$ exceeds C, the "criterion detector" judges that LV braking has been initiated and a braking strategy is initiated. Otherwise, some other strategy (e.g., car following) is pursued. The criterion value used in assessing $\dot{\theta}_p$ is a function of the expected costs and benefits of the decision outcomes, which in general will depend upon the particular driving conditions, the observation noise, and the minimum expansion rate to be detected. Neuromuscular models of human leg and foot movement will be incorporated into the cognitive and neuromuscular blocks in Figure 38.16, completing the human driver model.

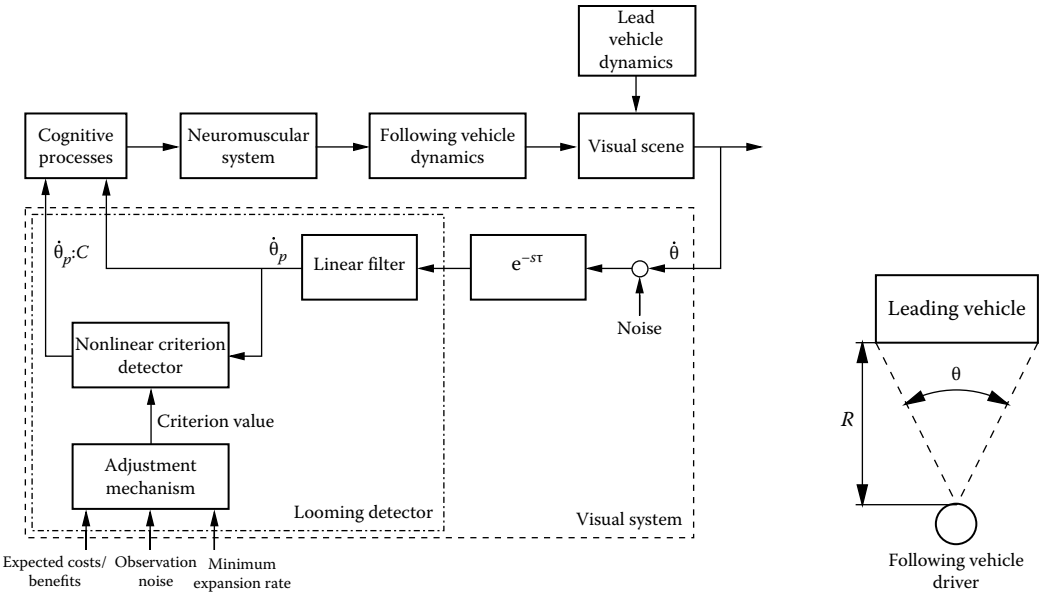

FIGURE 38.16 Human driver model of LV braking scenario and definition of visual angle θ. (From Barton, J.E. et al., Towards a complete human driver model: The effect of vision on driving performance, *Proceedings of the American Control Conference*, Minneapolis, MN, pp. 2591–2598, 2006.)

38.6 CONCLUSION

The reviewed articles reveal a very wide spectrum of mathematical methods applied to model the driver for understanding and improving automobile dynamics and for studying human driving behavior. Technical issues are predominant with respect to application, and it may be noted that the human factor in the coupled system vehicle–driver receives not always adequate attention. In a way, the technical understanding of the automobile is still far beyond the representation of the *human* driver. Nevertheless, physiological and psychological considerations determine many driver models to a certain extent, and much effort can be noticed in incorporating knowledge from human sciences to compensate for the mathematical theories and more technical understanding of driving. Although experimental validation lags somewhat behind the advanced mathematical methods, driver models became considerably important in VSD.

The wide variety of mathematical methods applied to determine the behavior of the driver may not only result from particular preferences of the individual research scientist but follow the wide variety of different areas of application, as could be observed in this chapter. Conclusions from an application to a conclusive mathematical method may not be drawn, although some specific modeling approaches seem to be more effective with respect to the number of applications and publications than others, but *the* driver model for a certain kind of application is not apparent as it is the case for other models in VSD. And for good reason, driving is a complex physical and mental individual process and will keep scientists interested and inventive to simulate and understand human (driving) behavior.

39.1 INTRODUCTION

The main purpose of this chapter is to provide an overview of the dynamics and control issues related to the handling of vehicles driving on paved roadways. The division of this section of the handbook ("Intelligent Vehicle Systems") into a longitudinal and a lateral chapter is somewhat artificial—there are very close interactions between vehicle lateral and longitudinal dynamics. Vehicle controls coordinating lateral/yaw and longitudinal motions simultaneously are obviously beneficial and are even necessary in tasks such as merge assistance for automated highway systems. In addition, there will be unavoidable overlap with several chapters of Part V of this handbook. Here is the basic idea in delineating the material to be covered in this chapter: lane position. Control of horizontal vehicle motion could include important functionalities such as lateral stability to prevent spinout or plow-out, which is covered very nicely in Part V. For this chapter, it is assumed that the lane position is detected and used in vehicle motion regulation. If this is not the case, the related topics will not be included. We will try to provide a self-contained introduction

of the current state-of-the-art development in the area of intelligent vehicles related to vehicle handling and lane keeping functionalities. We will also highlight the issues related to the coordination between the vehicle and the roadway infrastructure when appropriate.

The term "intelligent vehicle and highway systems" was created in the late 1980s in the United States to encompass an array of applications related to the deployment of advanced information, electronics, and control technologies to improve the efficiency and safety of highway vehicles. This umbrella term covers a wide range of technologies, and the subarea closely related to the material to be covered in this chapter is known as "advanced vehicle control systems" (AVCS). In the early 2000s, a more focused set of efforts was selected and supported within the USDOT's Intelligent Vehicle Initiative (IVI). Identified research challenges related to this chapter include (1) lane keeping function, (2) precision maneuver (e.g., docking of buses or parking in tight spaces), and (3) lane departure warning and prevention. These three areas encompass the majority of the recent progress in the "lateral" direction of intelligent vehicle research. The status of these three function areas will be discussed in the remainder of this chapter.

39.2 LANE KEEPING

39.2.1 Background and Literature Review

Lane keeping systems require the integration of sensing and control systems so that the controlled vehicle automatically follows the detected road markers, which usually delineates a lane of a roadway. We chose not to discuss much about the vehicle lane change functions because of two reasons: (1) Lane change is mainly a decision problem considering traffic flow and relative longitudinal motion of the vehicles in adjacent lanes (in other words, even though the final control maneuver executed is a steering action, the key challenge lies within the longitudinal domain rather than in the lateral domain) and (2) once the decision to make a lane change is made, the lateral control maneuver can be viewed as a special case of lane keeping, with a planned lane position. In other words, once the fundamental sensing and dynamic control problems for lane keeping is solved, the lane change problem is a simple extension of the same problem. Even though there were quite a few papers published recently in the area of lane changing [1–3], we chose not to cover those topics in this chapter.

The automatic lane keeping problem of a vehicle was studied as early as the late 1950s. Gardels [4] addressed the automatic steering control problem using electronic sensors at the General Motors Research. Cardew [5] performed automatic steering tests and achieved position accuracy of ±2 cm on straight roads. These early efforts demonstrated the viability of automatic lane keepings and inspired continuing research in this area. Substantial efforts were made by Fenton and his colleagues through the 1970s [6,7]. They first designed control algorithms using classical control methods [6] and validated their designs by experiments. The classical design approach is adopted due to the fact that digital control technologies were not readily available. Nevertheless, they were able to demonstrate automatic driving on curves with mild lateral accelerations at 0.2–0.3 g. In the late 1980s, the linear–quadratic (LQ) approach was investigated by Fenton et al. [7], and the results were evaluated in a laboratory study where an analog computer was used to simulate the vehicle dynamics. In both [6] and [7], a feedback controller was used to carry out the lane following task, which was treated as a regulation type of control problem. They relied on the disturbance rejection capability of the feedback controller to track curved roads.

The automatic lane keeping function receives a lot of attention under the umbrella of intelligent vehicle and highway system research, starting from the late 1980s and culminated in the late 1990s. Important efforts include the PATH program in the United States [8–11], ASV/AHS in Japan [12,13], and PROMETHEUS/Drive/CARTS programs in Europe [14,15]. These efforts were driven by a surge in the interest and research funding in the area of intelligent vehicles and transportation systems. The PATH program was mainly supported by the California Department of Transportation

(Caltrans) and to a lesser degree by federal and industrial funding. This research program was started in 1987 and now operates at a smaller but still significant level. Japan's ASV project began in 1991 under the leadership of the (former) Ministry of Transport (MOT). The first two phases of the ASV project span from 1991 to 1995 and 1996 to 2000. Under the coordination and guidance of the MOT, participating Japanese automotive companies developed a wide variety of advanced technologies to enhance safety. The Japan AHS project was led by the Ministry of Construction and was carried out jointly with car companies through the public–private partnership "AHSRA." They conducted an AHS demonstration at the Public Works Research Institute (PWRI) in 1995 and on a stretch of public highway in 1996. It is important to point out that the full name for the Japan "AHS" effort is now "Advanced Cruise-Assist Highway System," which seems to be a gentle way to acknowledge the fact that the focus was no longer on fully automated highway systems. This is an obvious departure from the meaning of AHS used in the United States. PROMETHEUS is a research program approved as a EUREKA project and was launched by the European automotive industry in 1986. This project group is then continued through a number of follow-up projects. Automatic steering concepts seem to receive less attention in the European compared with the U.S./Japanese projects. Systems that deal with automatic steering functions, such as those described in [14,15], are of relatively small scale.

A notable achievement of this era, in comparison with the achievement up to the early 1980s, includes sensing systems that are easier to retrofit to existing roads, more reliable and smoother steering controls through advanced control methodologies, and extensions to diverse vehicle types and maneuvers. Key advancements in these areas are explained in the following subsections.

39.2.2 Sensing Systems

To achieve accurate and smooth lane keeping, two types of information are critical: instantaneous vehicle lateral position and orientation and future roadway geometry. Among these variables, the lateral position must be measured, because of vehicle observability requirement. In other words, the latter two variables can be estimated based on the lateral displacement (at the price of time delay), but the opposite is not true. Most of the pre-1980 research prototype systems rely on sensing systems that do not look ahead. Examples include magnetic wires [6,7] and side-looking radars. In other words, these sensing systems focus on obtaining the vehicle lateral position, which can be used to infer vehicle orientation information. However, future road geometry (curvature) cannot be derived. Even when someone takes double derivative of the measured lateral displacement signal, a noisy and impractical approach, what was obtained is the instantaneous curvature error, which is a poor estimation for future road curvature. This fact severely limited the real-world performance of the early downward-looking and side-looking sensing and lane keeping systems, because they essentially drive without looking ahead! Driving while looking at roadways ahead, that is, "previewing," is included in almost all the newer designs in the post-1990 research programs [8–13]. By looking ahead, future road curvature information is used to determine proper steering function while making the overall steering smoother. Previewing is possible by using sensing systems such as vision [16–19], magnetic markers [20,21], and differential GPS plus maps [22,23]. The functioning principles and technical challenges of these sensing systems were amply discussed in the literature and are beyond the scope of this chapter. It is, however, important to summarize the ballpark performance of these sensing systems, their key challenges, and potential for further improvement. The comparison is shown in Table 39.1.

A comprehensive real-world testing and evaluation on lateral positioning and sensing system was done by the Japan AHS-i program [24]. From 1999 to 2001, two promising methods—magnetic markers and passive multiplier radio wave markers—were selected for detailed evaluation. Three new methods were added for evaluations in 2001: pseudo-satellite, direction of arrival (DOA), and dedicated short-range communication (DSRC). The discrete magnetic lane marker system was

TABLE 39.1
Comparison of Vehicle Lateral Position (and Yaw) Sensing System

	Lateral Position Accuracy (cm)	Yaw Angle Accuracy (deg)	Preview Distance and Quality	Reliability	Key Challenges
Vision	2–7 cm	1°–3°	120 m, poor	Poor	Computation, ambient lighting, snow, lane delineation
Magnetic markers	0.5–4.0 cm	0.2°–1.5°	Very long (precoded), good	Excellent	High installation cost
DGPS map	3–10 cm	No direct measurement	Very long (database), good	Good (urban canyons can cause problems)	Accuracy, urban canyon, DGPS stations

found to provide accurate lane position information (4 cm) under varying road surface conditions, weather, road construction, and traffic environment. The positioning accuracy is dependent on the road construction survey and installation accuracy and strength of the magnetic markers. The accuracy (4 cm) reported in [24] is based on markers with intensity of 170 μT with the sensing heads placed 30cm above road surface. This accuracy is somewhat inferior compared to that reported by the California PATH program (0.5 cm, [20]), which is, however, obtained from a short test track. The markers in [20] were installed in specially designed capsules with the markers installed off-center. The markers were then precisely aligned by rotating the markers around the capsule center to achieve precise lateral accuracy. For large-scale installations, much higher installation errors are expected. The high survey/installation cost remains an issue for large-scale implementations of magnetic (and other types of) markers.

The pseudo-satellite technology is designed to augment GPS. Stations at strategically selected locations receive and retransmit GPS signals to cover shadow areas where GPS satellites are known to be blocked, for example, at urban canyons created by high-rise buildings. This technology likely will not provide accuracy beyond that of existing GPS and DGPS techniques. The other two methods (DOA and DSRC) do not seem to be accurate enough for lateral control purposes (lateral position accuracy >1.5 m) and thus are not discussed here.

It is important to point out that the discussion earlier mainly focuses on non vision systems; CCD camera-based vision systems are still a popular choice for automated guided vehicles. Recent examples of vision-based lane tracking systems include [25–28], which represent just a short list of the huge literature in this area. Their inability to deal with snow/ice and the problem of blocked view by adjacent vehicles severely limited their acceptance and practicality for safe day-to-day operations, especially for vehicle control tasks. However, due to the fact that the vision sensor contains rich information useful for other purposes, it will remain a stronger contender, at least as a redundant sensing system.

39.2.3 Advanced Control Concepts

The importance of choosing a sensing system that can look ahead is quite intuitive and can be explained by analyzing the basic control system architecture. Figure 39.1 shows a $2\frac{1}{2}$ degree-of-freedom (DOF) picture of the vehicle road following scenario. The 2 DOF are the vehicle lateral and yaw motions, and the "$\frac{1}{2}$" DOF is the vehicle forward speed, which is assumed to be constant (slow varying), thus treated as a parameter rather than a dynamic state variable in the overall model. It is known that vehicle lateral–yaw–roll dynamics are coupled; thus, this $2\frac{1}{2}$-DOF model assumption

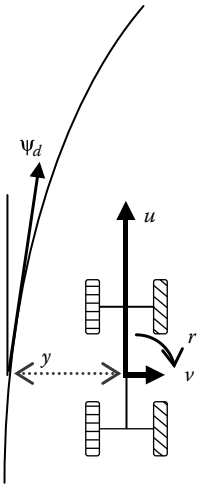

FIGURE 39.1 Road following of a vehicle described by the "bicycle model."

implies that the vehicle roll motion is small and is neglected. In Figure 39.1, u, v, and, r denote vehicle longitudinal speed, lateral speed, and yaw rate, respectively. y is the lateral displacement of the vehicle center of gravity (CG), measured sideways along the y-axis of the vehicle-fixed coordinate system. Integrating vehicle yaw rate, we obtain the vehicle yaw angle (orientation angle) with respect to the earth-fixed coordinate system. If we denote the vehicle yaw angle as $\psi(t)$, it will be possible to define a "desired vehicle yaw angle" $\psi_d(t)$, which is defined as the orientation of the tangential line of the instantaneous road trajectory.

The relationship between $\psi_d(t)$ and the actual road geometric variable, that is, the road radius of curvature, $R(t)$, is $\dot{\psi}_d(t) = r_d(t) = u(t)/R(t)$. The $2\frac{1}{2}$-DOF model can then be described in the state-space form as

$$\frac{d}{dt}\begin{bmatrix} y \\ v \\ \psi - \psi_d \\ r \end{bmatrix} = \begin{bmatrix} 0 & 1 & u & 0 \\ 0 & -\dfrac{C_{\alpha f} + C_{\alpha r}}{mu} & 0 & \dfrac{bC_{\alpha r} - aC_{\alpha f}}{mu} - u \\ 0 & 0 & 0 & 1 \\ 0 & \dfrac{bC_{\alpha r} - aC_{\alpha f}}{I_z u} & 0 & -\dfrac{a^2 C_{\alpha f} + b^2 C_{\alpha r}}{I_z u} \end{bmatrix} \begin{bmatrix} y \\ v \\ \psi - \psi_d \\ r \end{bmatrix} + \begin{bmatrix} 0 \\ \dfrac{C_{\alpha f}}{m} \\ 0 \\ \dfrac{aC_{\alpha f}}{I_z} \end{bmatrix} \delta + \begin{bmatrix} 0 \\ 0 \\ -1 \\ 0 \end{bmatrix} r_d \tag{39.1}$$

where

m is the vehicle mass
I_z is the yaw moment of inertia
$C_{\alpha}f$ and $C_{\alpha r}$ are the front and rear cornering stiffness (per axle)
δ is the front wheel steering angle
a and b are the distance from vehicle CG to front and rear axles, respectively

It can be seen that the road curvature (or radius of curvature) enters this road following dynamic system as a disturbance input. In addition, by examining the input matrices associated with δ and r_d, it is obvious that the steering input does not influence the vehicle dynamics through the same channel as the road curvature input. Therefore, it is impossible to completely cancel the effect of road curvature by using the steering input, that is, perfect control (achieving zero

tracking error) is impossible, even when the available bandwidth of the control system is infinite. What distinguishes this road following dynamics from many other vehicle control applications is the fact that the road curvature is fixed and could be known in advance. Therefore, using "preview" type of control algorithms makes perfect sense and was found to improve the lateral tracking performance significantly [8,20,21]. In fact, using the road curvature in a previewed fashion helps to achieve not only more precise lateral tracking but also smoother ride (reduced peak lateral acceleration). Optimal preview control law based on the linear–quadratic control theory was found to exhibit an out–in–out behavior similar to what a professional driver will do, in order to achieve a trade-off between accurate tracking and smooth ride. The preview control concept lays a solid foundation for the California PATH's lateral control architecture from the late 1980s until the early 2000s [8,22]. Solutions of the preview control algorithm are somewhat mathematically involved and thus were not included in this chapter. Interested readers can refer to [8] for details. It is also worthwhile to point out that the preview control formulation shown in [8] is based on the calculus of variations, and the solution looks more complicated than the optimization results used in the well-known preview driver model developed by MacAdam [29,30], which is incorporated in the CarSim software. The simpler preview solution in the MacAdam formulation works quite well and could be used if a road following is the main concern. The formulation of [8], however, is more flexible and can include more general control objectives in the cost function, for example, ride quality.

39.2.4 Lane Keeping Assist

When the steering control system is designed for "lane keeping assist" (LKA), rather than "automated driving," the control concept, architecture, and algorithm become quite different, even though these two systems share a similar goal (lane keeping). In the LKA case, a human driver is not only in the loop, he or she also has the ultimate authority and responsibility. Therefore, it is necessary to design the system architecture so that the control actions of the automatic system and the human driver can be added in a coherent and robust fashion. In a very fundamental level, one can argue that the best way to harmonically integrate the human and control actions is to use low gains for the control action under normal situations and use higher gains when the driver seems to relinquish the driving task and the vehicle is departing from the lane inadvertently. In [31], it was argued that steering torques from driver/machine can be added together much more easily than steering angle commands. However, since steering torque acts upstream of the (significantly nonlinear) steering system, which commonly includes an integrator in its dynamics, designing a control system that guarantees robust performance is not trivial. A lane keeping support system was developed based on combining the steering torque with CCD camera measurement in [25]. Test results show that the lane keeping performance can be significantly improved, with much reduced steady-state lateral displacement, while the driver workload, measured through the frequency distributions of electromyograms of the upper arm muscles, is lowered by about half.

Despite of these positive results on combining steering torque from a human driver and the automatic control system, it is still not clear dealing with steering torque provides any advantage over steering angles. Not only is dealing with steering angle easier, in terms of vehicle dynamic equation formulation. Furthermore, combining steering angles from driver/control system is very straightforward. For example, a linear actuator to move the rack position relative to the vehicle chassis is a simple way to inject additional steering angle to the driver's steering angle.

The LKA concept has been combined with adaptive cruise control (ACC) to form a semiautomated driving system in Japan [32]. This design concept is somewhat more aggressive, in terms of market targeting, compared with the less-authoritative lane departure warning system. However, similar to the comparison between ACC and collision warning (CW) system design, CW design is, in many aspects, a more difficult engineering problem than that of ACC. This is because LKA type of systems exerts low level but continuous effort to ensure that the vehicle is operating in a safe

manner, instead of issuing a warning signal at the last moment. Therefore, if a simple and cheap actuation mechanism can be identified, LKA concept may have an easier time to gain wider acceptance compared with the lane departure warning systems.

Due to the fact that both human drivers and an automatic control system coexist, the LKA system must be designed and evaluated to ensure the system remains human centered. Driving should remain a fun task and the driver should actively participate in the driving task instead of easily falling asleep. These subtle and semisubjective requirements make it much harder to assess the performance of LKA systems.

39.2.5 Vehicle State Estimation

The bicycle model shown in Equation 39.1, even though extremely simple, very nicely represents the fundamental vehicle handling dynamics involved in the lane keeping functions. From simple observability analysis of the state-space equation, it is clear that the vehicle lateral displacement is unobservable from other measurements. In other words, lateral displacement needs to be measured, instead of being estimated. Once the lateral displacement signal is available, all the other three state variables can be estimated. Frequently, the vehicle yaw rate is also measured, which is useful for other purposes such as electronic stability program (ESP). While vehicle lateral speed can be directly measured by instrumental sensors such as optical sensors or GPS sensors, there are practical issues such as cost, accuracy, and reliability that prohibit production vehicles from using these sensors at present and in the near future. Therefore, the estimation of vehicle lateral speed based on other vehicle input/output signals is an important topic and has been widely discussed in the literature. The estimation of the other two variables (yaw rate, yaw angle error), if they are not measured, proves to be much less challenging. For example, excellent estimation of yaw rate using lateral displacement from a CCD camera is presented in Mouri et al. [33].

The problem of lateral speed estimation is equivalent to sideslip angle estimation, studied widely in the literature because of its application in ESP or four-wheel-steering applications. Senger and Kortum [34] developed a vehicle handling model and tire model to estimate the lateral speed. Their approach assumes that the tires operate in the linear region with known cornering stiffness. Kaminaga and Naito [35] applied a standard Lyapunov-based adaptive observer technique for sideslip estimation—which is equivalent to estimating vehicle lateral speed. The algorithm was found to provide satisfactory robustness for cornering stiffness variation on flat road surfaces. Experimental results provided in their paper show that the sideslip angle estimation error is below 3°. Liu and Peng [36] proposed an identification scheme for simultaneous state and parameter estimation to overcome the problems caused by unknown vehicle parameters. However, the observer stability is only proven for the case with constant cornering stiffness and/or road surfaces. It is further observed in their paper that the proposed methodology requires one to two cycles of vehicle maneuvers before the estimation converges to satisfactory performance with time-invariant cornering stiffness.

Farrelly and Wellstead [37] proposed both a physical modeling approach and a kinematics modeling approach. In their physical modeling approach, the observer can be fine-tuned to perform well even under changes of certain parameters. For example, it can be designed to be robust under cornering stiffness variation in the front axle or in the rear axle. However, the observer will not work reliably when both front and rear cornering stiffness are unknown and/or varying. As for their kinematics approach, the observer has been shown to provide satisfactory performance when the vehicle yaw rate is nonzero. Fukada [38] suggested a combined observer/direct integration method. The method strived to balance the robustness of modeling error (provided by direct integration) and that of signal bias (provided by tire model feedback). A road bank/slant estimate was also provided. In this dual approach, the lateral velocity estimate depends on the road bank estimate that, in turn, depends on the lateral velocity estimate. The experimental results on flat road show excellent performance in a double-lane change maneuver but significant error (about 40% less than the actual)

in a J-turn maneuver. The J-turn maneuver on snow is inherently difficult for this approach since the signal to noise ratio was small (as vehicle side-drifted slowly) and the tires operate in nonlinear regions. This method was subsequently refined and integrated into a vehicle stability control system [39]. The reported results suggest that the estimation algorithm was improved and performs satisfactorily.

Hac and Simpson [40] developed an algorithm that uses wheel speeds and vehicle lateral acceleration measurement, and a friction coefficient estimation scheme enhanced nonlinear vehicle model to estimate yaw rate and lateral speed simultaneously. The experimental results, especially those on icy surfaces, are impressive. However, the effect of another important factor, road bank angle, is not adequately addressed.

From the aforementioned literature review, it can be seen that the lateral speed (or sideslip angle) estimation problem has been actively studied over the last decade. A key finding, which becomes apparent in the crystal ball of hindsight, is that in order to obtain good lateral speed estimation, it is important to first obtain good measurement or estimation of the instantaneous road bank angle (superelevation). Road bank angle can be either obtained through the combined use of DGPS and lookup tables containing roadway geometric information or estimated.

In the following, the basic ideas of three different approaches for lateral speed estimation will be reviewed. These methods include a transfer function approach, the state-space approach by Liu and Peng [36], and the kinematics approach by Farrelly and Wellstead [37]. In addition, a method for dynamic road bank angle estimation [41] will also be reviewed.

39.2.5.1 Kalman Filter Method

The concept of this estimation method is again based on the bicycle vehicle model shown in Equation 39.1. However, to include the effect of an important disturbance input—the road bank angle into the dynamic equation—it is modified slightly:

$$\frac{d}{dt}\begin{bmatrix} y \\ v \\ \psi-\psi_d \\ r \end{bmatrix} = \begin{bmatrix} 0 & 1 & u & 0 \\ 0 & -\dfrac{C_{\alpha f}+C_{\alpha r}}{mu} & 0 & \dfrac{bC_{\alpha r}-aC_{\alpha f}}{mu}-u \\ 0 & 0 & 0 & 1 \\ 0 & \dfrac{bC_{\alpha r}-aC_{\alpha f}}{I_z u} & 0 & -\dfrac{a^2C_{\alpha f}+b^2C_{\alpha r}}{I_z u} \end{bmatrix}\begin{bmatrix} y \\ v \\ \psi-\psi_d \\ r \end{bmatrix} + \begin{bmatrix} 0 \\ \dfrac{C_{\alpha f}}{m} \\ 0 \\ \dfrac{aC_{\alpha f}}{I_z} \end{bmatrix}\delta + \begin{bmatrix} 0 \\ 0 \\ -1 \\ 0 \end{bmatrix} r_d + \begin{bmatrix} 0 \\ g \\ 0 \\ 0 \end{bmatrix}\gamma \tag{39.2}$$

where γ is road superelevation angle in radian. The small-angle assumption is again used so that this equation remains linear. By assuming that the vehicle is roughly aligned with the tangential direction of the roadway, the gravity force, acting through the small road bank angle, directly influences the vehicle lateral motion but not the yaw motion. The standard Kalman filter technique can be applied to Equation 39.2 to obtain the lateral speed estimation. In this problem formulation, both the steering angle and road curvature were assumed to be known inputs. The road bank angle, on the other hand, was assumed to be a Gaussian and white disturbance. Commonly, two vehicle motion sensors are used to provide crucial measurements for lateral speed estimation—vehicle lateral displacement (y) and yaw rate (r). A direct application of this standard technique using Equation 39.2, however, was found to produce unsatisfactory results. There are two major reasons. First, as stated before, the road bank angle directly influences the vehicle lateral motion, and, thus, without an accurate representation of this important variable, it is very difficult to obtain good estimation of the lateral vehicle speed. Secondly, the vehicle yaw rate measurement may contain unknown offset arising from alignment, fluctuation of vehicle electrical potential, etc. These two problems can be dealt with by augmenting the original bicycle model with two extra state variables [42], namely,

$$\frac{d}{dt}\begin{bmatrix} y \\ v \\ \psi-\psi_d \\ r \\ r_{bias} \\ \gamma \end{bmatrix} = \begin{bmatrix} 0 & 1 & u & 0 & 0 & 0 \\ 0 & -\frac{C_{\alpha f}+C_{\alpha r}}{mu} & 0 & \frac{bC_{\alpha r}-aC_{\alpha f}}{mu}-u & 0 & g \\ 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & \frac{bC_{\alpha r}-aC_{\alpha f}}{I_z u} & 0 & -\frac{a^2C_{\alpha f}+b^2C_{\alpha r}}{I_z u} & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \end{bmatrix} \begin{bmatrix} y \\ v \\ \psi-\psi_d \\ r \\ r_{bias} \\ \gamma \end{bmatrix} + \begin{bmatrix} 0 & 0 \\ \frac{C_{\alpha f}}{m} & 0 \\ 0 & -1 \\ \frac{aC_{\alpha f}}{I_z} & 0 \\ 0 & 0 \\ 0 & 0 \end{bmatrix} \begin{bmatrix} \delta \\ r_d \end{bmatrix}$$

$$+ \begin{bmatrix} 0 & 0 & 0 \\ \frac{C_{\alpha f}}{m} & 0 & 0 \\ 0 & 0 & 0 \\ \frac{aC_{\alpha f}}{I_z} & 0 & 0 \\ 0 & 0 & 1 \\ 0 & 1 & 0 \end{bmatrix} \begin{bmatrix} \delta_{dist} \\ \dot{\gamma} \\ \dot{r}_{bias} \end{bmatrix} \tag{39.3}$$

In Equation 39.3, the measured steering angle δ and road curvature are grouped as the known input vector. Three unknown disturbance inputs are assumed to exist: an unknown steering term, road bank angle rate, and yaw rate bias rate. The augmented system was found to provide improved estimation mainly due to a more accurate representation of the two augmented state variables [42].

39.2.5.2 Transfer Function Method

The vehicle lateral speed can be estimated without using the four-state bicycle model. Instead, the more traditional two-state system can be used. The two-state system, of course, implies that we are not aware of (or do not care about) the road following performance of the vehicle. In addition, if (a big if!) the road bank angle is negligible, the two-state bicycle model can be written as

$$\begin{bmatrix} \dot{v} \\ \dot{r} \end{bmatrix} = \begin{bmatrix} -\frac{C_{\alpha f}+C_{\alpha r}}{mu} & \frac{bC_{\alpha r}-aC_{\alpha f}}{mu}-u \\ \frac{bC_{\alpha r}-aC_{\alpha f}}{I_z u} & -\frac{a^2C_{\alpha f}+b^2C_{\alpha r}}{I_z u} \end{bmatrix} \begin{bmatrix} v \\ r \end{bmatrix} + \begin{bmatrix} \frac{C_f}{m} \\ \frac{aC_f}{I_z} \end{bmatrix} \delta \tag{39.4}$$

If we rewrite Equation 39.4 in a simpler form,

$$\begin{bmatrix} \dot{v} \\ \dot{r} \end{bmatrix} = \begin{bmatrix} a_1 & a_3 \\ a_2 & a_4 \end{bmatrix} \begin{bmatrix} v \\ r \end{bmatrix} + \begin{bmatrix} b_1 \\ b_2 \end{bmatrix} \delta \tag{39.5}$$

then it is straightforward to write the transfer functions from steering angle δ to the two states as

$$H_{\delta \to v} = \frac{sb_1 - a_4 b_1 + a_3 b_2}{s^2 - s(a_1 + a_4) + a_1 a_4 - a_2 a_3} \tag{39.6}$$

and

$$H_{\delta \to r} = \frac{sb_2 + a_2 b_1 - a_1 b_2}{s^2 - s(a_1 + a_4) + a_1 a_4 - a_2 a_3} \tag{39.7}$$

The basic idea of the transfer function method is as follows: we can first use the available measurements (steering angle and yaw rate) to obtain a least squares fit for the transfer function shown in Equation 39.7 in real time. This optimal ARMA model (see Chapter 6), which best describes the vehicle yaw motion in a discrete-time format of Equation 39.7, will then be converted into the continuous time where best-guess parameters of the transfer function for the yaw rate output (Equation 39.7) can be obtained. Since the parameter b_2, which is the coefficient of the "s" term of the numerator polynomial of Equation 39.7, is related to the front tire cornering stiffness in a simple form ($b_2 = aC_f / I_z$, see Equations 39.4 and 39.5), it is straightforward to calculate a best-guess front axle cornering stiffness, C_f, the value of which can be used to compute $b_1 = C_f/m$. These values can then be plugged into the constant term of the numerator polynomial of Equation 39.7, $a_2 b_1 - a_1 b_2$, to calculate the rear axle cornering stiffness C_r. Finally, using the computed axle cornering stiffness values, the numerator polynomial of the lateral speed transfer function shown in Equation 39.6 can be calculated. Since the two transfer functions share the same denominator, the transfer function in Equation 39.6 is completely known, based on which the vehicle lateral speed can be estimated.

Since the discrete-time ARMA identification process requires only measured variables in three history steps, the adaptation for tire–road characteristics change is very fast. It is important to point out that the basic idea of this approach is simple. In practice, it was found that the identified least squares model may become unstable or very lightly damped, especially when the vehicle yaw rate rises quickly, responding to fast steering input. Under these circumstances, a commonly adopted practice is to discard these unstable models and just keep using the non updated (but stable and well-damped) model. This modification is necessary to keep the estimated tire cornering stiffness positive and to ensure that the model prediction stays within the reasonable region. The selection of the threshold value was found to have significant effect on the final estimation results [43].

39.2.5.3 State-Space Method

The idea presented in Section 39.2.5.2 can be extended to obtain best estimate of a state-space method, based on which vehicle lateral speed can be estimated. However, this two-step approach heavily relies on the structure of the transfer function and is frequently sensitive to uncertainties, such as variation in other vehicle parameters (m, I_z, etc.). In the following, the adaptive algorithm developed in [36] is described. This state-space algorithm was developed to estimate states and unknown parameters simultaneously for nonlinear time-invariant systems that depend affinely on the unknown parameters. The lateral speed estimation problem turns out to have the required structure, due to the fact that the tire cornering stiffness of the two axles is generally unknown and is the main source of model uncertainties. It is thus possible to estimate vehicle lateral speed and the affine road friction parameter simultaneously. Equation 39.4 can be rewritten in the linearly parameterized form as

$$\dot{x} = Ax + u_c \theta \tag{39.8}$$

$$y = r$$

where

$$x = \begin{bmatrix} v \\ r \end{bmatrix}$$

$$A \equiv \begin{bmatrix} a_1 & a_3 \\ a_2 & a_4 \end{bmatrix}$$

u_c is the front axle steering angle

$$\theta = \begin{bmatrix} \frac{2C_f}{m} & \frac{2aC_f}{I_z} \end{bmatrix}^T$$

The adaptive observer is then

$$\dot{\hat{x}} = (A_n + \Delta\hat{A}_x)\hat{x} + \Delta\hat{A}_y r + \begin{bmatrix} -u \\ 0 \end{bmatrix} r + u_c\hat{\theta} + K(y - \hat{y}) \tag{39.9}$$

where

$$\hat{x} = \begin{bmatrix} \hat{v} & \hat{r} \end{bmatrix}^T$$

$$\hat{y} = \hat{r}$$

$$A_n = \begin{bmatrix} -\left(\frac{2C_{fn} + 2C_{rn}}{um_n}\right) & \left(\frac{-2a_nC_{fn} + 2b_nC_{rn}}{um_n}\right) \\ \left(\frac{-2a_nC_{fn} + 2b_nC_{rn}}{uI_{zn}}\right) & \left(\frac{-2a_n^2C_{fn} - 2b_n^2C_{rn}}{uI_{zn}}\right) \end{bmatrix}$$

$$\Delta\hat{A}_x = \begin{bmatrix} \Delta\hat{a}_1 & 0 \\ \Delta\hat{a}_2 & 0 \end{bmatrix}$$

$$\Delta\hat{A}_y = \begin{bmatrix} \Delta\hat{a}_3 & \Delta\hat{a}_4 \end{bmatrix}^T$$

The subscript "n" is used to denote the nominal parameters. For example, C_{fn} is the nominal value of C_f. The unknown variables $\Delta\hat{a}_i$ denote the deviation of a_i from their nominal values (entries in the A_n matrix), which are to be estimated. If the observer gain is selected as $K = [k_1, k_2]^T / u$, that is,

$$A_n - KC = \frac{1}{u}\begin{bmatrix} -\left(\frac{2C_{fn} + 2C_{rn}}{m_n}\right) & \left(\frac{-2a_nC_{fn} + 2b_nC_{rn}}{m_n}\right) - k_1 \\ \left(\frac{-2a_nC_{fn} + 2b_nC_{rn}}{I_{zn}}\right) & \left(\frac{-2a_n^2C_{fn} - 2b_n^2C_{rn}}{I_{zn}}\right) - k_2 \end{bmatrix} \tag{39.10}$$

where C = [0 1], then the closed-loop state matrix is stable when k_1 and k_2 are properly selected, according to the nominal vehicle parameters. When ΔA_x, ΔA_y, and θ are constant (slow varying), these unknown parameters, as well as the state variables, are estimated by using a standard state

observer (which uses estimated parameters for its model), together with a parameter update law, which is gain varied based on the calculation of a set of augmented states. The equations are too numerous to recite completely in this chapter. Interested readers are referred to the original paper by Liu and Peng for details. This estimator, like most other adaptive algorithms, requires persistent excitation condition to achieve small estimation errors. In other words, when the vehicle is driving straight, the vehicle parameters will not be updated accurately. In other words, if the transition from high-friction to low-friction road surfaces occurs during a straight section of the roadway, this algorithm will need some time to update its estimation and thus might suffer slow convergence transiently. The most important design parameters of this estimator were found to be the observer gains k_1 and k_2, which need to be tuned properly according to the trade-off between noise rejection and convergence speed. We also found it necessary to constrain the estimated parameter values, to ensure that they stay within reasonable values governed by the physical parameters.

39.2.5.4 Kinematics Method

The kinematics approach proposed by Farrelly and Wellstead [37] is promising as the stability of the observer/convergence of estimation error has been shown for nonzero yaw rate. In the following, their methodology is integrated with a physical model-based observer to avoid unobservability and the drifting issues (as described in [37]) during near-zero yaw rate conditions. The implemented observer arbitrates between a kinematics model-based observer and a dynamical model-based observer depending on the magnitude of the yaw rate—the dynamical model will be used only when the vehicle yaw rate is large enough. The model is described in the following:

If ($|r| > r_c$ deg/s),

$$\begin{bmatrix} \dot{\hat{u}} \\ \dot{\hat{v}} \end{bmatrix} = \begin{bmatrix} 0 & r \\ -r & 0 \end{bmatrix} \begin{bmatrix} \hat{u} \\ \hat{v} \end{bmatrix} + \begin{bmatrix} a_x \\ a_y \end{bmatrix} + \begin{bmatrix} k_1 \\ k_2 \end{bmatrix} (\hat{u} - u) \tag{39.11}$$

where

$$k_1 = 2|\alpha|r,\ k_2 = (\alpha^2 - 1)r,$$

else

$$\dot{\hat{v}} = -ur + \hat{a}_y,\ \hat{u} = u$$

where

$$\hat{a}_y = \frac{[2C_f(\tan^{-1}((\hat{v} + ar)/u) - \delta) + 2C_r \tan^{-1}((\hat{v} - br)/u)]}{m}$$

Note that r_c and α are design parameters and δ, *u, r,* a_x, and a_y are measured variables. Since the sensor measurements of current generation of vehicle stability controller usually include δ, *u, r,* and a_y but not a_x, we further adapt this method to accommodate current sensor platform by approximating a_x with vehicle speed information, that is, $a_x = du/dt$. While this approximation adds sensor measurement noise/error in the longitudinal acceleration signal, a_x, used in the observer, there are also other real-world sensor noises in vehicle speed and longitudinal and lateral acceleration measurements due to wheel slip, sensor drift, cross talk induced by vehicle motions, and road noise. In the following, we analyze the estimation performance of the modified F&W approach (henceforth

referred as the kinematics approach) under these sensor noises, that is, u, a_x, and a_y. Equation 39.11 can be rewritten in the following form:

$$\begin{bmatrix}\dot{\tilde{u}}\\ \dot{\tilde{v}}\end{bmatrix}=\begin{bmatrix}-2\alpha|r| & r\\ -\alpha r & 0\end{bmatrix}\begin{bmatrix}\tilde{u}\\ \tilde{v}\end{bmatrix}+\begin{bmatrix}a_{xn}\\ a_{yn}\end{bmatrix}+\begin{bmatrix}-2\alpha|r|\\ -\alpha r\end{bmatrix}u_n \tag{39.12}$$

where the variables with ~ denote estimation error. If we use a Lyapunov function $V=(\alpha^2\tilde{u}^2+\tilde{v}^2)/2$, it can be seen that

$$\dot{V}=-2\alpha^3|r|\tilde{u}^2+\alpha^2\tilde{u}\cdot a_{xn}+\tilde{v}\cdot a_{yn}+[2\alpha^3|r|\tilde{u}+(\alpha^2-1)r\tilde{v}]\cdot u_n$$

Unlike the original analysis in [37], *dV/dt* is no longer negative definite when sensor uncertainties exist, and the design parameter α influences the significance of sensor measurement noise. Furthermore, from Equation 39.12, we have $G_{a_{xn}\to\tilde{v}}=-\alpha^2 r/(s+\alpha|r|s)$, $G_{a_{yn}\to\tilde{v}}=s+2\alpha|r|/(s+\alpha|r|)^2$, and $G_{v_{xn}\to\tilde{v}}=(\alpha^2-1)rs-2\alpha r|r|/(s+\alpha|r|)^2$. From these equations, it is obvious that the design parameter α influences the error propagation speed of longitudinal acceleration noise, the sensitivity to lateral acceleration noise, and the sensitivity to vehicle speed noise. It can also be seen that the steady-state error contributed from our approximation of longitudinal acceleration signal is $-v$ since the approximation error we introduced is in the amount of vr and the steady-state gain is $1/r$. In other words, the estimated lateral speed will eventually be washed out to zero if the derivative of vehicle speed is used in place of longitudinal acceleration. On the other hand, the estimation error during transient events (which are most critical for real-world vehicle stability control) is negligible if we keep the observer gain α small.

With real-world environment noise, a trade-off decision has to be made for the observer gain α since increasing the observer gain increases the robustness to measurement noise of a_y and u but decreases the robustness (of estimation during transient events) to measurement noise of a_x.

39.2.5.5 Road Bank Angle Estimation

As stated earlier, the road bank angle estimation problem is related to the lateral speed estimation problem. They use the same (similar) set of vehicle lateral dynamic equations, and an accurate road bank angle information will dramatically help the lateral speed estimation. This is true for estimation problems based on the four-state bicycle model [42] and the two-state bicycle model [43]. There is a chicken-and-egg problem here: Road bank angle estimation problem is frequently solved by assuming certain lateral speed condition (e.g., $\dot{v}\approx 0$). The estimated road bank angle is then used to estimate lateral speed, to verify whether the assumption is correct or not. Alternatively, the road bank angle can be estimated based on concepts similar to the transfer function approach described in 39.2.5.2, which are less restrictive but in the meantime are also more sensitive to measurement noise and transient response—transfer function is fundamentally a steady-state response method, so its performance during transient is not guaranteed. An approach to combine the dynamic equation (assuming $\dot{v}\approx 0$) and transfer function method is described in the succeeding text, which is nothing but an excerpt of the work shown in [41].

Expanding Equation 39.4 to include road bank angle effect, we have

$$\begin{bmatrix}\dot{v}\\ \dot{r}\end{bmatrix}=\begin{bmatrix}-\dfrac{C_{\alpha f}+C_{\alpha r}}{mu} & \dfrac{bC_{\alpha r}-aC_{\alpha f}}{mu}-u\\ \dfrac{bC_{\alpha r}-aC_{\alpha f}}{I_z u} & -\dfrac{a^2C_{\alpha f}+b^2C_{\alpha r}}{I_z u}\end{bmatrix}\begin{bmatrix}v\\ r\end{bmatrix}+\begin{bmatrix}\dfrac{C_f}{m}\\ \dfrac{aC_f}{I_z}\end{bmatrix}\delta+\begin{bmatrix}g\\ 0\end{bmatrix}\sin(\phi)$$

$$\equiv\begin{bmatrix}a_1 & a_2\\ a_3 & a_4\end{bmatrix}\begin{bmatrix}v\\ r\end{bmatrix}+\begin{bmatrix}b_1\\ b_2\end{bmatrix}\delta+\begin{bmatrix}g\\ 0\end{bmatrix}\sin(\phi) \tag{39.13}$$

based on which the transfer function from steering angle and road bank excitation (*sin*(φ)) to vehicle yaw rate and lateral acceleration can be found:

$$G_{\delta \to r} = \frac{b_2(s-a_1)+a_3b_1}{s^2-(a_1+a_4)s+a_1a_4-a_2a_3} \tag{39.14}$$

$$G_{\delta \to a_y} = \frac{s\left[b_1(s-a_4)+a_2b_2\right]+u\left[b_2(s-a_1)+a_3b_1\right]}{s^2-(a_1+a_4)s+a_1a_4-a_2a_3} \tag{39.15}$$

$$G_{\sin(\phi)\to r} = \frac{a_3 g}{s^2-(a_1+a_4)s+a_1a_4-a_2a_3} \tag{39.16}$$

$$G_{\sin(\phi)\to a_y} = \frac{sg(s-a_4)+ua_3g}{s^2-(a_1+a_4)s+a_1a_4-a_2a_3} \tag{39.17}$$

where u is the vehicle forward speed, and the relationship $a_y = \dot{v} + ur$ is used. Given these transfer functions, the measured vehicle yaw rate and lateral acceleration signals can be written as

$$r_{measured} = r_{actual} + r_{noise} \approx G_{\delta \to r} \cdot \delta + G_{\sin(\phi)\to r} \cdot \sin(\phi) + r_{noise} \tag{39.18}$$

$$a_{y_{measured}} = a_{y_{actual}} + a_{y_{noise}} \approx G_{\delta \to a_y} \cdot \delta + G_{\sin(\phi)\to a_y} \cdot \sin(\phi) + a_{y_{noise}} \tag{39.19}$$

Notice that in Equations 39.18 and 39.19, the approximate sign "≈" was used because of the fact that transfer functions do not capture transient response and that the actual vehicle response might be nonlinear. Based on Equations 39.18 and 39.19 and assuming that the sensor noise is Gaussian white and thus cannot be easily dealt with, two road bank estimations can be obtained:

$$\sin(\hat{\phi}_r) = G_{\sin(\phi)\to r}^{-1}\left(r_{measured} - G_{\delta \to r} \cdot \delta\right) \tag{39.20}$$

$$\sin(\hat{\phi}_a) = G_{\sin(\phi)\to a_y}^{-1}\left(a_{y_{measured}} - G_{\delta \to a_y} \cdot \delta\right) \tag{39.21}$$

It should be noted that the inverse of the transfer functions $G_{\sin(\phi)\to r}^{-1}$ and $G_{\sin(\phi)\to a_y}^{-1}$ is noncausal. In reality, these noncausal continuous-time transfer functions can be approximated by causal discrete-time operators, or steady-state gains. In [41], a third road bank angle estimation is suggested, which is based on the assumption $\dot{v} \approx 0$:

$$\sin(\hat{\phi}_v) = \frac{\left(u \cdot r_{measured} - a_{y_{measured}}\right)}{g} \tag{39.22}$$

Since all three estimations are based on certain simplification assumptions, they are accurate only within certain operational conditions. By figuring out the current situations, these three estimates can be selected or combined to obtain the best estimation.

39.3 PRECISE LATERAL MANEUVER

While low-speed operations can be challenging for longitudinal controls due to the nonlinearities of power train, tire, and braking systems, low vehicle forward speed poses very different challenges to lateral controls. At higher speeds, the steering angle becomes a more potent input to influence vehicle lateral motions. The lateral control algorithm designed for operating under high vehicle forward speeds thus needs to accurately model the tire forces and vehicle rigid-body dynamics. Due to the higher level of lateral accelerations, the coupling between vehicle roll motion and lateral/yaw motions becomes non negligible.

Some researchers argued that the bicycle model, used extensively in this chapter, fails to capture the frequency response of vehicle lateral acceleration around 1–2 Hz [44], especially when the vehicle has a soft suspension, a high CG (e.g., a bus), or both. A lateral controller to achieve precise tracking performance, or robust operations, thus may need to be designed based on a 3-DOF (lateral, yaw, and roll) model, instead of the bicycle model [44,45]. Since this argument is supported by experimental data, it seems to be hard to argue against. However, the author wishes to provide an alternative view in the following.

If the main purpose of the vehicle model is to describe the vehicle lateral motion, relative to the roadway (which is the case for automatic lane following), then the vehicle lateral acceleration, measured by an accelerometer installed on the sprung mass, is a poor measurement. This is because the measured signal is contaminated by the sprung mass roll motion and thus does not reflect the lateral motion that we truly care about. In [44], experimental comparison of both yaw rate and lateral acceleration is provided. If we focus on the yaw rate comparison, it can be seen that the 2-DOF (bicycle) model and the 3-DOF model are almost identical up to 2 Hz. At higher frequencies, the linear 3-DOF model may not be trustworthy, because it did not capture load transfer and associated nonlinear tire dynamics. Therefore, the value of using the linear 3-DOF model for the design of lateral control algorithm is limited. Its true value perhaps lies in other applications. For example, for modern vehicle without an underbody frame, it is very hard, if not impossible, to install an accelerometer "on the unsprung mass." The 3-DOF model can be used for signal processing purposes to provide the lateral acceleration of the "unsprung mass," load transfer, etc.

At low forward speeds, a very different problem arises—the vehicle lateral dynamics quickly become uncontrollable as the vehicle forward speed decreases. This can be understood by examining the extreme case—when the vehicle forward speed is zero, steering angle loses its effectiveness in generating lateral forces—and thus the ability to manipulate vehicle lateral motions. Therefore, at a low forward speed, large steering angle needs to be used, which introduces a new sort of problems—nonlinearities due to the steering and suspension system, tire mechanics, and frictions. The duo problem—the vehicle also becomes unobservable as forward speed becomes zero—is less intuitive. There are two ways this can be understood: First, frequently we rely on vehicle lateral displacement (1st state of Equation 39.1) to "observe" the lateral speed and/or yaw angle error (2nd and 3rd state of Equation 39.1). When vehicle speed is zero, a car is parked, and, thus, the same lateral displacement could correspond to infinitely many yaw angle error values. Secondly, since the vehicle forward speed appears at the denominator of the state matrix, zero forward speed corresponds to singularity of several matrix elements. The second way to look at the vehicle observability relies more on mathematics and is more rigorous.

At low forward speeds, a vehicle becomes "less controllable" and "less observable" and thus both control and state estimation may become much more challenging. It is a good idea to stop using modern full-state feedback algorithms and revert back to simple, output (lateral displacement) feedback control algorithm at very low forward speed.

Due to the reduction of dynamic forces at lower forward speeds, the vehicle lateral control problem changes from dynamic to a kinematic one and becomes an easier problem from that aspect. So why are we choosing to have a separate section on "precise maneuver," instead of devoting the

section to other areas with more abundant literature (e.g., lane change [1–3])? The reason is that this is an area that imposes its own technical challenges. Lane change, as we have argued before, is mainly a decision problem involving several vehicles in multiple lanes. The decision is more dependent on vehicle longitudinal positions than lateral motions. If the coordination with vehicle longitudinal motion is not considered (e.g., assuming some other systems were trusted with that decision), lane change is nothing but a simple extension of lane following technique, involving trajectory planning for smooth operations or special methods to address the sensing issues. Therefore, we do not think it warrants another section to discuss about lane change modeling and control.

Two low-speed applications that are likely to see adoption in the near term are urban bus automations and automated valet systems. These two concepts are described in the following subsections.

39.3.1 Automated Buses

Automated buses are concepts competing with existing alternatives such as light rails and human-controlled buses. Through automation, buses can mimic the operation of light rails and achieve very precise maneuvers. Precise tracking performance is important when the cheaper and less-intrusive "unprotected configurations" are used, that is, no fence/barricade will be installed to separate the buses with other vehicles/pedestrians. When the (either protected or unprotected) lanes are instrumented and dedicated to be used by automated buses or in some cases coexist with manually driven buses, a bus rapid transit (BRT) system with reliability and capacity approaching that of rail transit systems becomes possible. This new transit concept promises much reduced capital investment, increased routing and rerouting flexibility, and much lower operation and maintenance costs.

Automated buses working based on magnetic markers were found to achieve a "docking" accuracy of less than 1 cm. This level of accuracy is much better than that achievable by human drivers and offers improved safety in an unprotected environment. The accuracy is obtained at slow speeds, where vehicle controllability and observability are low.

39.3.2 Parking Assist and Automated Valet

Two closely related concepts are discussed in this section. Parking assist addresses a task that is among the most dreadful to novice drivers. Parallel parking, involving back-and-forth maneuvering, sometimes in a very tight spot, requires good feel of the vehicle position and precise timing of the reversal of large steering action. Sometimes the available parking space is just a little wider and/or longer than the vehicle, and, thus, multiple back-and-forth maneuvers need to be planned and executed sequentially.

One of the earliest parking assist system concepts was developed by Aisin Seiki [46,47] and implemented on the Japanese version of Toyota Prius model introduced in September 2003. This system utilizes an electrical power steering system and backup guide monitor technology and can be used for parallel or garage parking. The system hardware consists of a rearview camera, steering angle sensor, vehicle speed sensor, display, speakers, yaw rate sensor, and an electronic control unit.

In both the "normal" mode (garage parking) and the "parallel parking" mode, the rearview camera calculates and projects the vehicle motion and overlays important features (e.g., rear bumper, "parking frame") or guidance curves onto the display. The basic idea is that the projected vehicle trajectory can be used by the human driver, who controls the steering to move the projected vehicle trajectory into the parking space. In the parallel parking case, the operation is somewhat more complicated because a reverse in steering action is necessary. The details are omitted here and interested readers can refer to [46].

The basic concept of automated valet systems, which are not yet available commercially, is quite different from parking assist systems. As the name implies, a human driver will not be present and the valet system is expected to drive the vehicle automatically and safely by itself. Both vehicle speed and steering will be controlled and mostly under very low speed. Automated valet is a natural

extension of the parking assist system but is expected to be confined in a small niche market. To replace the human driver, it is necessary to ensure that the operation is under one of these two conditions: (1) either enough intelligence and robustness can be included in the system, through accurate obstacle/environment detection, classification, and control, or (2) when the required level of intelligence/robustness is not available, ensure that both the parking facility and the vehicles are highly structured and heavily instrumented. Option (1) is much more challenging but in the meantime has much larger potential in the near term. Option (2) already exists in certain primitive form as automatically guided robots. The need for customized infrastructure and highly instrumented vehicles will severely limit its applications.

One possible design concept for automatic valet system will rely on centralized sensing systems to reduce the need of expensive on-vehicle equipment. For example, an overhead camera installed to watch over the parking space can provide information for individual vehicle position as well as the environment, including available spaces, vehicles moving in a blind spot, or oncoming in an intersection. When drive-by-wire becomes widely available, this centralized sensing plus decentralized control architecture will make automatic valet systems a reality.

39.4 LANE DEPARTURE WARNING AND PREVENTION

Lane departures are important vehicle handling problems because they frequently result in serious accidents, including run-off-road crashes, head-on collision with oncoming vehicles, or collision with highway divider guard rails or posts. Road departure crashes are one of the leading causes of highway fatalities in the United States. The USDOT defines an "off-roadway crash" as one in which the first harmful event occurs off the roadway. An estimated 6.1 million police-reported crashes involving light vehicles occurred in the United States in 2000, causing approximately 41,000 fatalities [48]. Of these crashes, the USDOT estimates that approximately 1.12 million are associated with a single vehicle departing the roadway due to inadvertent lateral drifting or loss of control and account for about 41% of all fatalities. Thus, road departure accidents not only form a significant portion of all police-reported accidents but also involve more fatalities than other accidents.

Lane departures usually arise from driver inattention, relinquished steering (due to physiological reasons such as falling asleep, drug or alcohol, or seizure), or loss of directional control due to adverse road condition, high vehicle speed, or sudden evasive maneuvers. An effective lane departure warning or prevention system, therefore, will necessarily play the role of a "backseat driver" that constantly watches the vehicle handling motion and issues warnings or intervenes when a lane departure is determined to be imminent.

The basic function of the lane departure warning/prevention system is to project vehicle trajectory and compare with the perceived road geometry (obtained from vision systems) to calculate a performance metric. A classic metric for determining impending road departure is time-to-lane crossing (TLC), which can be understood as the time until the vehicle CG will cross either edge of the roadway under certain conditions [49]. This definition of TLC in its truest sense usually results in an extremely large value of TLC for most driving conditions. This is because the vehicle is controlled by a human driver who is, most of the time, doing a good job. If the driver relinquishes steering so that the vehicle drives an open loop (which can be easily experimented on an open highway), due to various disturbances (road crown, wheel alignment, etc.), TLC is generally around 8–12 s. If this (unsafe) experiment is done with a passenger on board, he or she likely will speak out when TLC approaches 3–4 s. Based on these observations, human-centered lane departure warning/prevention systems can be designed to keep track of TLC, for values up to about 4–5 s, with the warning/intervention threshold set at about 1–2 s. The statistical distribution of TLC can be obtained by keeping track of TLC histogram for typical human drivers; one such histogram can be found in [50]. The calculation of TLC will be discussed in Section 3.1

To project the vehicle future trajectory accurately (so that TLC can be computed), we need to update vehicle parameters (speed, cornering stiffness, etc.) and estimate dominant external

disturbances (road superelevation). The estimation of external disturbances, however, also depends on the vehicle parameters. Therefore, on-line estimation of road/tire characteristics and road superelevation is crucial for the TLC calculation and the overall lane departure warning system. Since the road superelevation (a.k.a. bank angle) estimation has been discussed in Section 39.2.5.5, we will only focus on the estimation of tire–road friction or cornering stiffness in Section 39.4.1.

39.4.1 Calculation of Time-to-Lane Crossing

Here, in this section, we will assume that the problem at hand is as follows: Given all the vehicle/road parameters (mass, inertia, CG location, forward speed, cornering stiffness, road bank angle, and future road curvature) and the available onboard measured signals (steering angle, lateral displacement, yaw rate, and lateral acceleration), calculate TLC accurately.

As stated before, TLC is defined as the time until the vehicle CG is projected to cross either edge of the roadway. There are two ways TLC can be calculated. A simpler way is to calculate TLC from [42]

$$\begin{aligned} \dot{y} &= u \cdot (\psi - \psi_d) + v \\ \text{TLC} &\equiv \frac{y'}{\dot{y}} \quad \dot{y} \neq 0 \end{aligned} \tag{39.23}$$

where

y is the vehicle lateral displacement from the center of the road
u is the vehicle forward speed
$\psi - \psi_d$ is the relative heading angle
v is the vehicle lateral speed

y' is defined as $y \pm$ *lane width*/2, and depending on the sign of $\dot{y}$, only the one that is reducing to zero is used in the calculations. This calculation is based on linear extrapolation, that is, assuming the rate of change of the lateral displacement $\dot{y}$ remains constant into the foreseeable future. This assumption is reasonable when the vehicle is slowly drifting away on a straight roadway, but will not be accurate when large road curvature or steering is involved. Obviously, to implement Equation 39.23, two vehicle state variables need to be estimated: $\psi - \psi_d$ and v. These estimations can be obtained from the vehicle state estimation algorithms discussed in Section 39.2.5 and thus will not be repeated here.

The second, popular way to calculate TLC is to use a vehicle model and keep integrating the model into the future [51]. For example, based on Equation 39.3, a model with no unknown disturbances can be constructed:

$$\frac{d}{dt}\begin{bmatrix} y \\ v \\ \psi - \psi_d \\ r \\ r_{bias} \\ \gamma \end{bmatrix} = \begin{bmatrix} 0 & 1 & u & 0 & 0 & 0 \\ 0 & -\dfrac{C_{\alpha f} + C_{\alpha r}}{mu} & 0 & \dfrac{bC_{\alpha r} - aC_{\alpha f}}{mu} - u & 0 & g \\ 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & \dfrac{bC_{\alpha r} - aC_{\alpha f}}{I_z u} & 0 & -\dfrac{a^2 C_{\alpha f} + b^2 C_{\alpha r}}{I_z u} & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \end{bmatrix} \begin{bmatrix} y \\ v \\ \psi - \psi_d \\ r \\ r_{bias} \\ \gamma \end{bmatrix} + \begin{bmatrix} 0 & 0 \\ \dfrac{C_{\alpha f}}{m} & 0 \\ 0 & -1 \\ \dfrac{aC_{\alpha f}}{I_z} & 0 \\ 0 & 0 \\ 0 & 0 \end{bmatrix} \begin{bmatrix} \delta \\ r_d \end{bmatrix} \tag{39.24}$$

If the future road curvature is known (from the forward-looking sensor) and the steering angle is assumed to be fixed, both of the two input signals (δ and *rd*) are known. Therefore, Equation 39.24 can be integrated into the future until the lateral displacement is found to cross either of the two lane edges. The time at this lane crossing event is then the TLC. Under normal conditions, TLC may be very large, so this forward simulation can be terminated at, say, 4–5 s. Beyond this value, the situation is safe and it is not necessary to pinpoint the actual value of TLC.

When one implements a lane departure warning/prevention system, TLC needs to be calculated within the control sampling time, for example, 0.1 s. So direct integration of Equation 39.24 may not be possible on embedded automotive ECUs. The computation burden can be greatly reduced by calculating state transition matrices of linear dynamic systems off-line, namely, for a linear system

$$\begin{aligned} \dot{x} &= Ax + Bu \\ y &= Cx \end{aligned} \tag{39.25}$$

If the system has initial condition x_0 and a constant input over the horizon $[0,t]$ is applied to the system, then $x(t) = e^{At}x_o + \int_0^t e^{A\eta}Bud\eta$ and $y(t) = Cx = Ce^{At}x_o + C\left[\int_0^t e^{A\eta}d\eta\right]Bu$. By defining $F(t) = Ce^{At}$ and $g(t) = C\left[\int_0^t e^{A\eta}d\eta\right]B$, these matrices can be computed off-line at predetermined intervals, for example, every 0.1 s; then the output variable $y(t)$ can be calculated quickly from simple multiplications and additions from $y(t) = F(t)x_o + g(t)u$. This process can be repeated for $t = [0.1, 0.2, ...t_f]$, where t_f is the upper bound for TLC calculation.

39.4.2 Estimation of Tire Cornering Stiffness

In the previous section, TLC was calculated by assuming the state matrix and input matrix of the linear system is known. In reality, some of the vehicle parameters may change, and, among them, the tire cornering stiffness is perhaps the most difficult to estimate. Cornering stiffness is a lumped parameter that could be influenced by tire normal load (thus road roughness and vehicle load), tire pressure, road material and surface condition, temperature, etc. One estimation scheme, which assumes that the 2-DOF bicycle model is a good approximation of the vehicle handling dynamics, was introduced in Section 39.2.5.2. This method uses the vehicle lateral/handling response for cornering stiffness estimation, thus providing slower estimation. A recent research uses DGPS and lateral dynamics for cornering stiffness estimation report convergence in about 5–10 s [52]. This level of response rate may not be fast enough for lane departure applications.

In the literature, most of the tire–road friction estimation schemes use features of tire behavior (e.g., wheel speed, wheel acceleration, aligning moment, tire noise) as the basis of the estimation. For example, Eichhorn and Roth [53] used optical and noise sensors at the front end of the tire and stress and strain sensors inside the tire's tread and studied both "parameter-based" and "effect-based" road friction estimation methods. Ito et al. [54] used the applied traction force and the resulting wheel speed difference between driven and non driven wheels to estimate the road surface condition. Pal et al. [55] applied the neural network-based identification technique to predict the road frictional coefficient based on steady-state vehicle response signals. Pasterkamp and Pacejka [56] developed an on-line estimation method based on lateral force and self-aligning torque measurements. Gustafsson [57] developed a model-based approach and used the difference between driven and undriven wheels to detect tire–road friction. Liu and Peng [58] applied the special structure of the brush tire model and used wheel speed signal to estimate road friction coefficient and cornering stiffness.

The paper by Umeno et al. [59,60] is based on a very different concept. They observed that the wheel speed measurement actually contains a vibration component around 40 Hz, which arises from torsional compliance at the wheel hub. When the power spectrum of the wheel speed measurement is plotted, a peak around 40 Hz is very obvious when the tire drives on dry asphalt. The magnitude of this resonance is much reduced when the road surface is icy. Therefore, by detecting the strength of the resonance at 40 Hz, road friction can be detected. An extremely important benefit of this method lies in the fact that the vehicle can be cruising with very small longitudinal slip, yet the torsional vibration and its resonance can still exist. Therefore, this detection algorithm works without the need of large longitudinal excitations. A drawback of this method is its heavy computational requirement. The same vibration phenomenon has also been successfully applied to detect change of tire pressure [61], another important phenomenon that influences tire cornering stiffness.

After the tire–road friction coefficient is computed, cornering stiffness can be updated and TLC can be more accurately computed.

39.4.3 Warning and Control Algorithms

One reason the TLC is a popular metric for warning/control action is the fact that it clearly indicates the threat level, measured in time [62]. In addition, the threat is detected before a danger occurs. This is a big improvement over the current practice—roadside rumble strips (which give warning after a lane departure has occurred). Recently, a future offset distance (FOD) warning algorithm is proposed [63], which can be understood as constructing a virtual lane boundary as the basis for warning. When the vehicle is projected to cross the virtual lane boundary, warning will be triggered. This can be understood as a virtual (or variable) rumbling strips (VRS) concept [64].

When the threat metric is selected, the next question is as follows: What is a proper threshold level for warning? The threshold value needs to be selected to avoid frequent nuisance alarm while if still leaves enough time for the driver to react. The threshold value depends on the specific systems, including the vehicle, driver, and roadway characteristics. For example, the meandering behavior of drivers is an important factor to be considered, in order to reduce nuisance alarms. From several experimental studies [65], the lane position variance of human drivers is found to be between 0.24 and 0.61 ft^2. Intelligent algorithms to reduce the negative effect of spontaneous lane position offset to nuisance alarms are thus needed. Results reported in [66] show that a TLC of 1 s was able to prevent 92% of passenger car crashes and 60% of heavy vehicle crashes with less than 1 nuisance alarm per hour. A higher threshold value will improve crash prevention rate at the price of increased false alarm and nuisance alarm rates. Threshold value much lower than 1.0 s will leave little time for the driver to react and thus may not be advisable.

When it comes to the selection of warning mechanisms, no definite conclusion has emerged. In [67], through extensive simulator tests at the Daimler–Benz driving simulator and on-the-road experiments, it was found that the most desirable warning mechanism is through the use of simulated rumble strip sound. In [50], three warning concepts were tested and compared: a haptic warning with a slightly oscillating steering wheel; a corrective, haptic warning with an additional torque leading back to the middle of the lane; and an acoustic warning, the rumble strip sound. Eighteen professional truck drivers were interviewed after their 30 min test drive, and the acoustic warning was found to be the preferred mechanism. In [68], 28 drivers were asked to test drive a vehicle with both haptic feedback and acoustic feedback mechanisms. The acoustic feedback was found to be annoying. Sato et al. [69] found that pulse-like steering torque serves as an effective warning method and reduces the lateral deviation of the vehicle significantly. Suzuki and Jansson [70] argued that warning effectiveness and ease of recognition (of the warning) should be discussed simultaneously. By using a driving simulator, they found steering vibration to be the best mechanism, measured by steering reaction time and maximum steering angle. These findings, of course, depend on the specific design and refinement of the individual algorithms and selection of critical threshold values (timing and magnitude of warning). Much research is needed until a practical system can be assembled.

39.5 CONCLUSIONS

This chapter provides a review on recent developments and the current state-of-the-art approaches of vehicle lateral control systems. Some very important works in this immensely large and active field may have been left out. The realization of many of the ideas described in this chapter depends, to a great extent, on the progress of underlying enabling technologies, such as sensing systems, new concept of system architecture, and consideration of dominant system uncertainties. In addition, the associated economic (cost/benefit) and legal issues will continue to be important factors to be considered, especially for the U.S. market. Finally, the increasingly pressing issue of identifying sustainable future ground transportation methods cannot be ignored. If and when a big change of personal transportation mode occurs, the lateral/handling control problems may also become quite different. In any case, the lateral control of ground vehicles is an exciting and active area. The author feels quite honored to have the opportunity to know and work with many of these excellent researchers.

40.1 INTRODUCTION

This chapter provides basic insights into the longitudinal control (LC) of roadway vehicles. It relates fundamental physical concepts involving desired range clearance, speed control, and acceleration/deceleration performance to control system features. The systems discussed extend classical notions of vehicle dynamics to the dynamics of vehicles with systems for increasing driver comfort and convenience on the one hand, and/or for improving efficiency, stability, or active safety on the other. These systems provide driver assistance and extend the domain of vehicle control applications by employing remote sensing and information gathering concerning the driving environment outside of the motor vehicle itself. Nevertheless, LC has been a driver activity, and current driver assistance systems involve driver decision-making and supervision at the very least. To the extent that we know how people control vehicles, we will use that knowledge in evaluating the performance of driver assistance systems.

This chapter is aimed at complementing other sections in this handbook by providing basic insights into LC systems in a manner that will aid either in the design and creation of new systems or in the evaluation of currently existing systems. In keeping with these aims, simplified analyses and models are used for coping with the complexity of real systems and the features of their hardware and software. After certain fundamental concepts are presented and discussed, the chapter concludes with annotated literature sources that are pertinent to advanced treatment of LC topics.

40.2 BASIC STRUCTURE OF LONGITUDINAL CONTROL SYSTEMS

Figure 40.1 is a generic block diagram containing the basic functional elements of an LC system. These elements are the traffic–roadway subsystem, the command and control unit (which may be driver or vehicle based), and the vehicle and its actuators. These three subsystems constitute the elements of an LC system that employs remote sensing to perceive the driving situation. This same form of diagram has been applied to manual driving in which the driver performs the sensing, perceiving, deciding, and controlling (commanding) functions shown in Figure 40.1. In addition, this form of diagram could be applied to lateral control systems as well, but the variables, as indicated here, pertain to the inputs and outputs of LC elements.

Specifically, the pertinent variables are as follows:

V, vehicle velocity, is the speed of a controlled (LC-equipped) subject vehicle.
V_p is the velocity time history of the motion of the vehicle in front of the subject vehicle.
R, range clearance, is the inter vehicular distance as shown in Figure 40.2. The range clearance is the difference between the longitudinal position X_p of the preceding vehicle and the position X of the subject vehicle with respect to a reference location ($R = X_p - X$).
R_{dot}, range rate, is dR/dt, the time rate of change of R and the relative velocity between a vehicle pair. See Figure 40.2. $R_{dot} = V_p - V$, and R equals the integral of R_{dot}.
U, control command, is the control input used to command vehicle speed and/or acceleration.
V_{dot} is dV/dt, the acceleration/deceleration of the subject vehicle.
V equals the integral of V_{dot}.

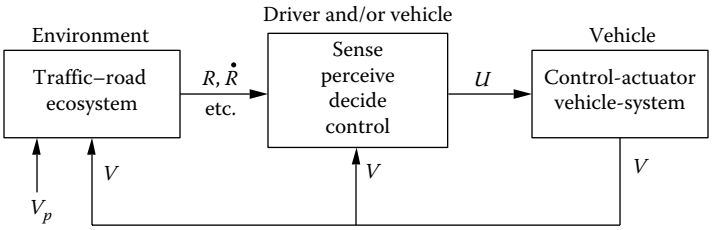

FIGURE 40.1 Basic diagram of a LC system.

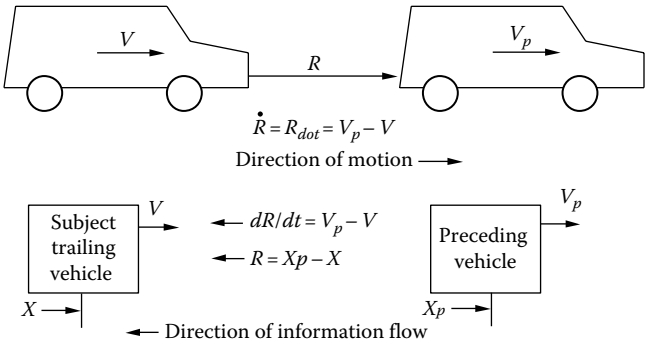

FIGURE 40.2 Illustrated variables.

Figure 40.2 illustrates the geometric and kinematic relationships between a subject (LC) vehicle and its preceding vehicle. For many LC applications, the simple kinematic relationship, describing the relative velocity between the subject vehicle and its preceding vehicle, is a crucial factor in understanding the driving situation, viz.,

$$R_{dot} = V_p - V \tag{40.1}$$

If V_p is greater than V, R_{dot} is positive and range is increasing. In this case, the vehicles are separating. If V is greater than V_p, R_{dot} is negative and range is decreasing. In this situation, the trailing LC vehicle is closing on the preceding vehicle. To maintain a desired range, R_{dot} must be zero. If R_{dot} remains close to zero and averages approximately zero over an extended period of time, the situation is referred to as following. Separating, closing, and following are the basic roadway situations considered in the longitudinal aspects of driving.

The hardware employed in LC systems consists of sensors, command and control units, actuators, and, of course, the vehicle itself. Generally, sensors are required for measuring range R, range rate R_{dot}, and velocity V. Also the acceleration V_{dot} (also symbolized as A) is often measured since it is used in certain control laws to formulate acceleration commands. The command and control units use the outputs of the sensor units to compute control commands (generally represented by U in Figure 40.1). The actuation mechanisms related to LC control are in the braking system and engine/driveline system of the vehicle. These mechanisms are viewed as providing the tire forces that decelerate or accelerate the vehicle. We will use simplified models to represent the vehicle and its braking and accelerating capabilities. Other sections of this handbook treat those topics in detail.

40.3 INSIGHT INTO SYSTEM DESIGN AND EVALUATION

Ideas involved with system design and system evaluation are used in this chapter to help organize the material and to establish an overall context supporting the discussion. Figure 40.3 presents an overview of the design and evaluation process [1]. The levels of abstraction in going from functional purpose and concept-ideas to a real system are indicated in Figure 40.3. Depending on the choices made at any of the levels of abstraction shown in Figure 40.3, a wide variety of final system configurations and capabilities is possible. A key area in developing a unified design, which fits together well, is the creative process of unifying function with form and form with function. We will indicate how unity may be achieved by discussing in a simplified way the characteristics of the components used in developing LC systems.

Clearly, commercial systems are often designed with particular vehicles in mind, and the sensors may have been previously chosen. In this sense, component characteristics represent constraints on

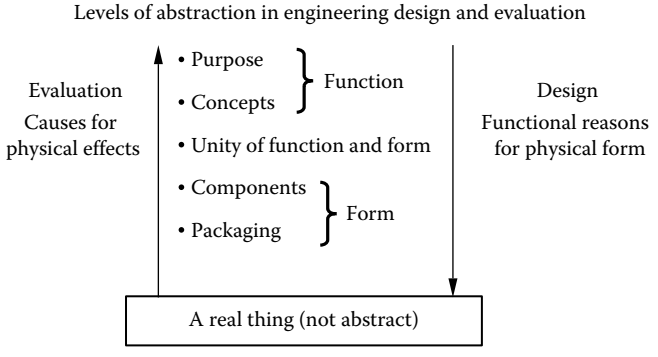

FIGURE 40.3 From abstract functional concepts to the creation of a real system.

the design options available in creating a system. In practice, the order of the levels of abstraction shown in Figure 40.3 does not imply a time sequence of events in developing or evaluating a system. For example, the existence of new types of sensors for measuring range and range rate may be the first step that initiated the design process for a particular adaptive cruise control (ACC) system. Generally, designers may jump around from one level of abstraction to another in the development of an LC system as they iterate toward a design.

Although conventional cruise control (CCC) is considered to be a system that was developed before the new classes of driver assistance systems were introduced, we wish to consider it here to illustrate how to employ the higher levels of abstraction in discussing LC systems. In addition, there are a number of basic ideas that are well illustrated by this example. After all, CCC, engine control systems, and antilock braking systems were precursors to the electronic control systems used in intelligent vehicle systems today. (These specific systems are treated in detail in Chapter 39.)

Usually, our discussions will be top down, emphasizing the higher levels of abstraction in our examples. The functional purpose of the CCC system is to maintain a driver-selected traveling velocity. This is called the set speed "V_{set}" for the CCC system. The driver is to be responsible for turning the system on and off. If a slower moving vehicle or some other obstacle obstructs the driver's path, the driver is to brake, and this will turn the CCC function off, as well as control the situation.

With regard to functional concepts, information flow diagrams and system block diagrams provide convenient means for expressing basic ideas. Figure 40.4 illustrates the basic ideas underlying a CCC system.

The input is V_{set}, and it is compared to the actual speed V to form an error signal for the control system. This indicates the need for a sensor to measure V. At this level of abstraction, we treat the sensor as being accurate and ignore any sensor dynamics or errors involved. Those items would be something to look at in component engineering. If we choose a simple model for the vehicle and its braking and accelerating actuators, the control system concepts would appear as shown in Figure 40.4. The equations pertaining to Figure 40.4 are as follows:

For the vehicle and actuators,

$$M_e V_{dot} = F_c + F_R + F_G \tag{40.2}$$

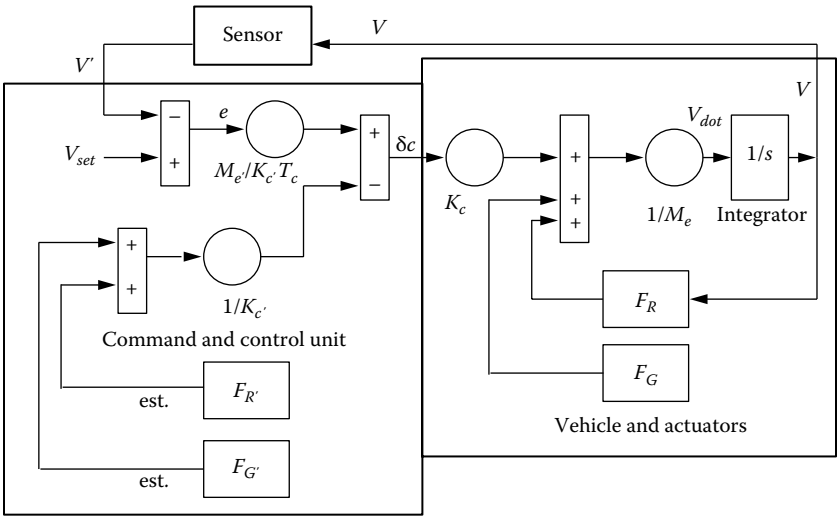

FIGURE 40.4 Concept diagram for a CCC system.

where

M_e is the effective mass of the vehicle and drive-train and engine or brake components and tires
V_{dot} is the vehicle acceleration/deceleration
F_c is the actuation force (which will be discussed further)
F_R is the natural retardation due to rolling resistance and aerodynamic drag
F_G is the influence of the highway grade on longitudinal acceleration

In Figure 40.4, the actuation force is represented by the following simplified equation:

$$F_c = K_c \delta_c \tag{40.3}$$

where

K_c is a gain factor
δ_c is the control input signal

Equation 40.3 is an abstraction used at the conceptual level. It is well removed from the real thing.

The simplifications used in these abstract equations indicate that detailed considerations will need to be treated before a real operating system can be established. For example, the actuation force F_c is really a combination of the longitudinal tire force produced by the braking system and that produced by the engine and drive-train. These systems have their own gains, nonlinearities, and dynamics. There are other interesting abstractions associated with the effective mass and its relationship to velocity, the natural retardation, and the grade influences that will need to be specifically treated before a system meeting the functional purpose of the CCC system is realized.

The control and command unit in Figure 40.4 is represented by the following equations:

$$e = V_{set} - V \tag{40.4}$$

Once the driver selects V_{set}, it is considered to be constant and, hence, $de/dt = -V_{dot}$. And the following equation can be used in planning a speed regulator:

$$T_c \frac{de}{dt} + e = -T_c V_{dot} + (V_{set} - V) = 0 \tag{40.5}$$

Equations 40.4 and 40.5 are of the form of a simple proportional control system. However, if we have knowledge of how the vehicle and its actuators perform, we can unify the design with regard to function and form. We can use knowledge of the vehicle and actuator components to determine the actuator input δ_c, viz., by combining Equations 40.5, 40.2, and 40.3 algebraically, one obtains

$$\delta_c = \left(\frac{M_e'}{K_c' T_c} \right) e - \frac{\left(F_R' + F_G' \right)}{K_c'} \tag{40.6}$$

The primed quantities in Equation 40.6 represent estimations of the parameters and the natural retardation and grade factors pertaining to the actual vehicle situation. At least in concept, Equation 40.6 represents the idea of compensating for the way the vehicle works in order to get the vehicle to do what we want it to do. The idea is to arrange the CCC system such that the following differential equation provides a reasonable approximation of the system's performance:

$$T_c V_{dot} + V = V_{set} \tag{40.7}$$

Examination of Figure 40.4 indicates that we plan to cancel the effects of M_e, K_c, F_R', and F_G'. This plan may not be straightforward to accomplish. In practice, the effective mass M_e may depend

upon V in a complicated manner. The natural retardation will depend upon vehicle weight as loaded and ambient wind conditions as well as vehicle velocity. In component design, there is an issue of whether measuring wind speed and current weight is worth the cost and complexity. And highway grade changes continuously, depending upon the local terrain. Whether or how the system will adjust for grade is a design choice.

There are a number of practical design choices to be resolved in the design of the command and control unit. For example, simple proportional control might be augmented with some integral control to correct for the effects of long sustained grades or constant head or tail winds. The control system might involve parameter identification features that find good values for approximating M_e, K_c, F_R, and F_G or the parameters of a more complete model of the vehicle and its actuators. An adaptive control approach might be used. Sliding mode control might be applied with throttle valves and brake valves being used to approximate the gain and quickness needed for use with sign(e) types of terms. It is beyond the resources of this article to go further into these matters. See control system texts such as [2] for explanations of the theory of possible approaches. For references in the literature dealing with CCC systems, see [3] for examples.

The sensor component may introduce system deficiencies through magnitude errors, dynamic effects, and delays. In the CCC case treated here, forward velocity is the main variable required to be measured in the basic concept of the system. Since measurement and display of velocity have been traditional in highway vehicles, there may well be velocity information available for use in the CCC application. Modern powertrain controllers, antilock braking systems, and other features of modern vehicles may have sophisticated electronic means for assessing forward speed.

(A modern powertrain controller may have provision for engine and transmission control systems. Transmission controls use measurements of throttle angle and vehicle speed in determining the shift point and lockup operation point. Engine control systems provide a number of functions and use sensor signals for measuring a variety of quantities including vehicle speed, longitudinal slip, and vehicle acceleration. Antilock braking systems use measurements of wheel speed to modulate brake pressures in a manner that aids in preventing wheel lockup while maintaining good stopping performance. For further description of these systems and references, see [3] or other college texts.)

These types of systems operate using digital communication. For example, velocity data might be updated every 0.1 s with a resolution of approximately 0.2 m/s (0.5 mph). This means that for a one resolution-unit change in the velocity value, the output of a zero-order hold would change by 0.2 m/s. When the sampling period is taken into account, this translates approximately into 0.2 m/s/0.1s of acceleration, that is, 0.2 g. For CCC applications, this might be acceptable if T_c is large enough, but for ACC and tighter speed control situations, such jumps in acceleration commands may cause driver dismay and discomfort. A reduction in the level of these pseudo-acceleration pulses to 0.04 g would be much better. Although it might cause some design difficulties, a resolution of 0.04 m/s (i.e., 0.1 mph) in velocity could improve the situation.

Also due to the introduction of electronic communications in vehicles and the associated vehicle buses, information flow diagrams are often used in illustrating the connections between components. Besides giving an overview of the components included in a particular system, these diagrams provide a basis for seeing synergistic connections between other existing, (or recently proposed systems) and the particular system currently under design consideration. Figure 40.5 is an example showing an information flow diagram for the CCC design previously portrayed in Figure 40.4.

The communication bus (also known as "vehicle bus") clearly plays a central role in Figure 40.5. (For an explanation of the meaning of this term, look up "vehicle bus" at wikipedia.org on the World Wide web. In particular, see the Background section.) To illustrate possible synergy with other systems, a global positioning system (GPS) has been added. It is shown at the lower right of the diagram. Otherwise, the components and their interconnections follow from the previous discussions. As an example for this case, information from the GPS is to be applied in estimating the grade. The vertical velocity determined from GPS measurements is combined with the measured forward velocity to estimate grade. Perhaps it would be just as easy to use the GPS measurement of horizontal velocity, but that is not the plan chosen here.

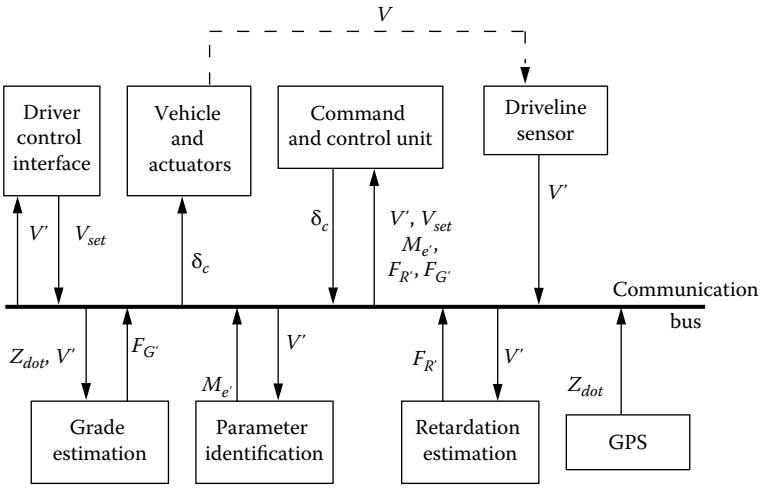

FIGURE 40.5 Information flow diagram for a CCC system.

This may appear to be a far-fetched way to estimate grade. A far simpler solution is just to ignore grade and let the driver work around it. However, if the vehicle already has a GPS that puts the needed information on the communication bus, the added cost for estimating grade may not be very large.

From a mechanical dynamics standpoint, the introduction of electronic communications (vehicle buses) opens up many opportunities for employing sensors, actuators, and control units without the need for linkages, mechanical cables, and hydraulic and pneumatic lines. And there is greater flexibility in the types of control features that digital controllers can readily provide.

40.4 ADAPTIVE CRUISE CONTROL

40.4.1 Adaptive Cruise Control Using the Elements of a CCC System

Recent ISO [4] and SAE [5] standards for ACC systems describe ACC as an extension of CCC. The functional purpose of the ACC system is to maintain a desired range clearance between an ACC-equipped vehicle and its preceding vehicle, when one is present. If there are no preceding vehicles within a reasonable range, the system is to perform as a CCC system.

In the example presented next, the extension from CCC to ACC is envisioned as employing the features of an existing CCC system in the conceptual design of the ACC system. For pragmatic and practical purposes, the CCC system is considered to be one of the components of the ACC system. See Figure 40.6 showing a CCC unit in the lower right area of the diagram.

Figure 40.6 resembles Figure 40.5 except that there are separate boxes for ACC and CCC command and control units and there are sensors for measuring pertinent features of the driving scene (labeled R' and R'_{dot}). The scene sensors are presumed to work well so that $R' = R$ approximately and $R'_{dot} = R_{dot}$ approximately and $dR'/dt = R'_{dot}$ approximately. The command input to the CCC unit comes from the ACC unit, and it is called V_c, where this command may ask for a speed that is less than the value of V_{set} chosen by the driver. In this system, V_{set} is the maximum speed that the ACC control will command. The ACC controller may command less than V_{set} in order to satisfy the range clearance purpose of the ACC system.

A number of the boxes involved in the CCC system diagram (Figure 40.5) are omitted in Figure 40.6 because it is assumed that the CCC system is well approximated by Equation 40.7 with V_{set} replaced by V_c, which is the output of the ACC controller, viz.,

$$T_c V_{dot} + V = V_c \tag{40.8}$$

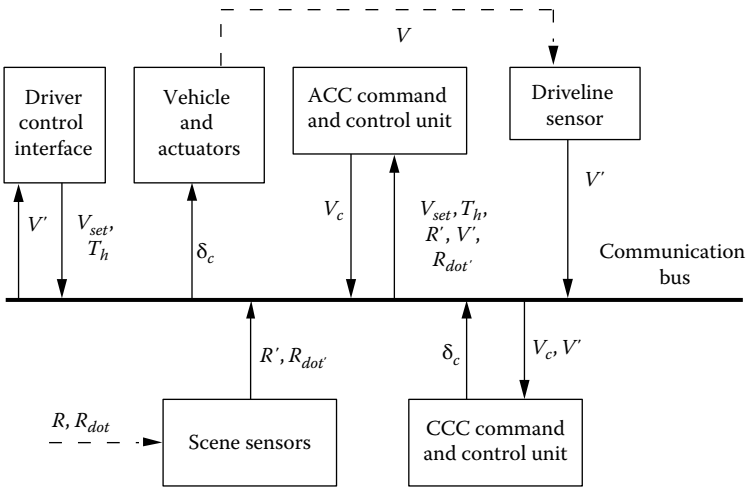

FIGURE 40.6 Information flow diagram for an ACC using CCC directly.

A point, which is subtly presented by Figure 40.6, is that there are inner (sub) and outer (main) control loops corresponding to the functions of the CCC controller and the ACC controller, respectively.

The ACC system diagram in Figure 40.7 makes these loops much more apparent, and it provides insight into the concepts underlying the design of a particular ACC controller. The inner sub loop is identified by the velocity feedback arrangement in the CCC unit. The outer main loop is identified by the velocity feedback path that goes through the traffic kinematics and then through the remote sensing block into the ACC command and control unit. (Information and concepts concerning traffic kinematics are indicated in the traffic kinematics block in Figure 40.7.)

The equations describing the nature of the ACC system portrayed in Figure 40.7 are as follows:

Equation 40.8, describes the function of the CCC unit (i.e., $T_c\, V_{dot} + V = V_c$).

As in Equation 40.1, traffic kinematics matters are described by $R_{dot} = V_p - V$.

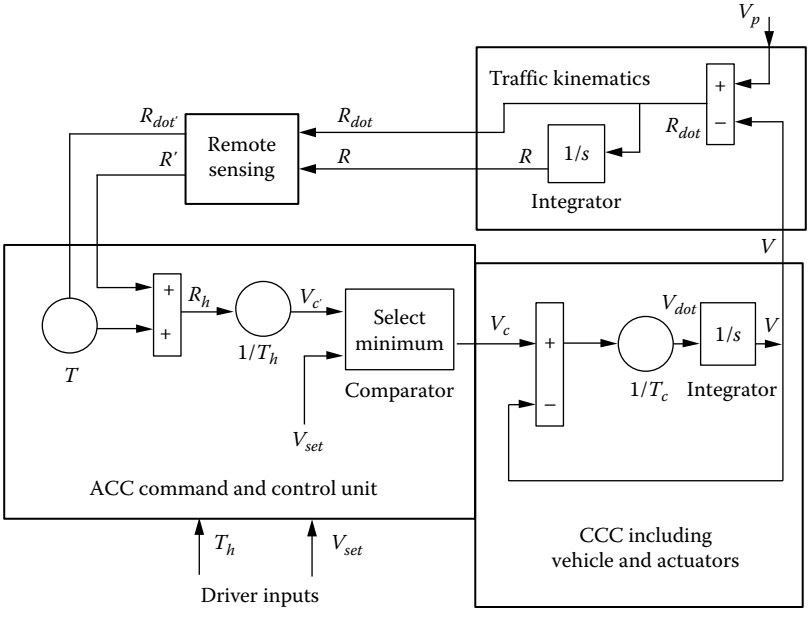

FIGURE 40.7 Concept diagram for an ACC system using CCC.

The functions of the ACC command and control unit may be expressed as follows:

$$R_h = R + T\ R_{dot} \tag{40.9}$$

R_h is the desired range for steady following of a preceding vehicle. And

$$V_c' = \frac{\left(R + T\ R_{dot}\right)}{T_h} \tag{40.10}$$

T_h is the desired time gap chosen by the driver.

The driver also chooses a value for V_{set}. V_{set} is the maximum speed that the driver chooses to use on the road currently being traveled. A comparator–limiter is employed so that V_c is always less than or equal to V_{set}.

There are concerns over the values of V_{set} and T_h that are appropriate for use in ACC systems. In particular, the maximum value of V_{set} and the minimum value of T_h are currently considered issues. For example, a maximum value of V_{set} might have a design value of 85 mph (38 m/s) in the United States. Also the minimum value of V_{set} might be about 30 mph (13 m/s) since the ACC and CCC systems may be designed to quit functioning below its minimum speed. (Hence, the driver is required to drive manually in low-speed situations.) The time gap parameter may have a restricted range of settings from ~1.0 to 2.0 s, although many drivers follow at less than 1.0 s when driving manually at freeway speeds. The reasons given for these restrictions on V_{set} and T_h have to do with highway safety, but the issues are subtle and universally acceptable compromises are not easily justified.

The space of sensor measurements (R' and R'_{dot}) may be displayed in a range versus range rate phase plane diagram. This type of diagram is useful for explaining the reasoning behind Equations 40.9 and 40.10 used in the ACC controller. In Figure 40.8, the vertical axis is the range R and the horizontal axis is the range rate R_{dot}. Measured values of R and R_{dot} could fall anywhere in this R–R_{dot} space at any time, depending upon the relative position and relative velocity at that particular time.

The diagonal straight line shown in Figure 40.8 represents Equation 40.9. This line represents a linear first-order differential equation as displayed in this phase plane. The arrows on the line show the direction of motion along this line starting from any point on this line. The point at $R = R_h$ and $R_{dot} = 0$ is a stable equilibrium point since R_{dot} is negative for $R > R_h$ and R_{dot} is positive for $R < R_h$.

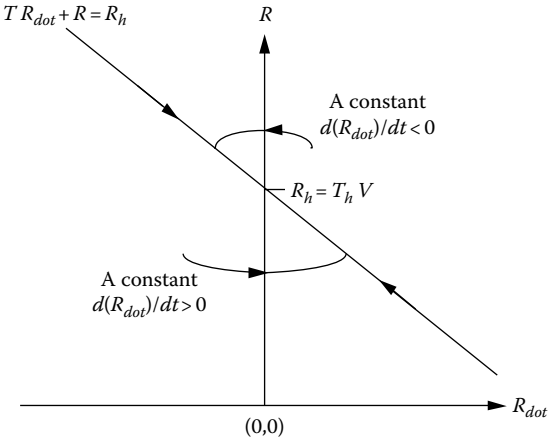

FIGURE 40.8 Phase plane for R and R_{dot}.

The slope of this line is equal to $-T$, where T is the time constant of the hypothetical first-order differential equation portrayed in Figure 40.8. If the current values of R and R_{dot} were to lie on this line, the ensuing trajectory would slide along the line $T\,R_{dot} + R = R_h$ (a sliding surface in the two-dimensional space of R and R_{dot}).

The point at $R = R_h$ and $R_{dot} = 0$ represents the desired range at a given speed, that is, we want $T_h\ V = R_h$. Equation 40.10 simply indicates that V_c' is the desired speed conforming to a constant time gap policy where T_h is the desired time gap. In other words, the value of R_h shown in Figure 40.8 changes with velocity, and consequently the line, $T\,R_{dot} + R = R_h$, changes its R- intercept as velocity changes. In this context, it may be said that the control philosophy is to ask for a speed V_c that will lead to what you want. Clearly, this requires knowing what you want to do. The line $T\,R_{dot} + R = R_h$ represents the plan for getting to R_h, which is where you want to be driving during steady following.

The two curved lines in Figure 40.8 represent lines of constant $d(R_{dot})/dt$. They are lines of constant relative acceleration. For cases in which $V_{p\,dot} = 0$ approximately, $d(R_{dot})/dt = -V_{dot}$ approximately and $d(R_{dot})/dt > 0$ represents braking. As indicated in Figure 40.8, braking (when the preceding vehicle is traveling at nearly constant speed) will cause range to decrease during closing and then cause separating to occur once V falls below V_p. For constant deceleration cases, the form of the curve is a parabola. The parabola for $d(R_{dot})/dt < 0$ is also shown in Figure 40.8, and it applies to the acceleration of the ACC vehicle when the preceding vehicle is traveling at approximately constant speed.

Implicit in this discussion is the idea that the driver takes control of the system when a close preceding vehicle is braking at anything approaching the control authority of the ACC system. Depending upon design characteristics, ACC systems may employ maximum deceleration authorities from 0.1 to 0.3 g approximately. Current commercially available systems tend to utilize the higher levels of control authority in setting system deceleration limits in order to extend the range of utility of the ACC system [6,7]. Acceleration/deceleration factors will be discussed later in connection with ACC systems based upon a desired acceleration/deceleration command structure.

However, braking commands figure into this ACC-using-CCC case. Once conditions reach the point (R and R_{dot} conditions) where throttle modulation is not sufficient to approach the desired dynamics implied by the $T\,R_{dot} + R = R_h$ line, light braking may be used to produce deceleration levels that will intersect the desired dynamics line from the bottom [8]. Constant acceleration lines can be used to intersect the desired dynamics line from the top of the line in the phase plane. In this sense, the desired dynamics line is both a place (in the phase plane) and a dynamics model. More information on phase plane dynamics is reported in Chapter 5. A basic idea here is to switch to the sliding mode rules when the R and R_{dot} conditions are close enough to the sliding surface (more information on sliding mode control is reported in Chapter 6). Although not immediately obvious, one of the aspects of this type of control is that the constant deceleration situations will mean that R falls below R_h in the process of approaching $R = R_h$, the desired following situation. These "undershoots" in range may cause concern and driver braking to avoid short ranges. And the propagation of increasing undershoots from vehicle to vehicle in a string will disrupt the integrity of the performance of the string such that the driver of the last vehicle in the string will need to intervene by braking to avoid crashing into the rear of the preceding vehicle. Nevertheless, systems of this type have been studied in field operational tests and shown to have favorable subjective ratings from lay drivers operating in naturalistic conditions during normal driving [9].

The dynamics of strings of vehicles running on highways is presented in Chapter 39. Ref. [10] treats matters of asymptotic string stability with mathematical rigor. That material addresses highway automation in which the goal is to automatically maintain short headway distances between vehicles regardless of vehicle speed. The following material is aimed at the safety concerns and traffic flow disruptions that may be caused by the dynamics of ACC systems.

From an analytical standpoint, it is interesting to examine the transfer function for the system portrayed in Figure 40.7. For $V_c < V_{set}$, the open-loop transfer function Y_o between R_{dot} and V is given by the following equation:

$$Y_o = \frac{V(s)}{R_{dot}(s)} = \frac{\left[T + \left(1/s\right)\right]}{\left[T_h\left(T_c s + 1\right)\right]} = \frac{\left(Ts + 1\right)}{\left(T_h s\right)\left(T_c s + 1\right)} \tag{40.11}$$

where s represents the Laplace transform variable used in the linear analysis of differential equations.

Examination of Equation 40.11 makes it apparent that $T = T_c$ is a special case in which

$$Y_o = \frac{1}{T_h s} \tag{40.12}$$

The zero/pole cancellation implied by making $T = T_c$ turns a more complicated open-loop transfer function into a simple gain and integrator. This case plays an important role in understanding what various choices of T mean when T_c is a design constraint determined by the CCC system chosen for use in the ACC system.

Based upon Equation 40.11, the closed-loop transfer function for the main loop is as follows:

$$\frac{V(s)}{V_p(s)} = Y_c = \frac{Y_o}{\left(1 + Y_o\right)} = \frac{\left(Ts + 1\right)}{\left(Ts + 1 + T_h s\left(T_c s + 1\right)\right)} \tag{40.13}$$

If

$$T = T_c, \quad Y_c = \frac{1}{\left(T_h s + 1\right)} \tag{40.14}$$

Equation 40.14 implies that if T provided enough lead to cancel the effects of the lag due to T_c, then the system would act like a simple first-order system. And there would be no overshoot or undershoot in response to abrupt changes in V_p (the speed of the preceding vehicle).

For the general case of Equation 40.13, the condition for assuring that the amplitude of disturbances will not increase going back along a string of like vehicles is $|V(s)/V_p(s)|^2 \leq 1.0$ for all s [11]. Upon replacing s by $j\omega$ and performing algebraic operations, the condition can be reduced to the following equivalent inequality for the system of Equation 40.13:

$$1 + T^2\omega^2 \leq (1 - T_c T_h \omega^2)^2 + (T + T_h)^2 \omega^2 \tag{40.15}$$

After simplification of Equation 40.15, it is found that the constraint on the parameters is most stringent at $\omega = 0$ and the result is

$$T > \frac{T_c - T_h}{2} \tag{40.16}$$

The point is that for smooth string behavior we need enough lead (T) to counteract the lag (T_c) associated with the CCC actuator. String behavior issues are critical in the discussions of traffic management and congestion alleviation.

40.4.2 ACC Using Acceleration Control

This case differs from the previous case in that the CCC velocity actuator is replaced by an actuator that accepts acceleration commands. The basic equation for this type of actuator is

$$\tau A_{dot} + A = A_c \tag{40.17}$$

The block diagram for the ACC system using (40.17) is presented in Figure 40.9.

As shown in Figure 40.9, the blocks involving the vehicle and actuator and the ACC command and control unit are different from those shown in Figure 40.7, which pertains to an ACC system using a velocity command structure. Clearly, the traffic kinematics block remains the same. The designer has no control over that. Figure 40.9 indicates explicitly that internal sensors for both the velocity V and the acceleration A, where $A = V_{dot}$, need to be used in the control concept envisioned for this system. The use of A in the design of this control algorithm is an important factor that allows us to unify the components of the system in an advantageous manner.

This unification is implemented through the equations for the acceleration command A_c' shown in the ACC command and control unit block in Figure 40.9. The conceptual reasoning behind that control rule (algorithm) is as follows:

Step 1: A special error function is created. The form of this function contains both the desired headway time gap and an acceleration term. The acceleration term is needed because the chosen actuator is acceleration based as indicated by Equation 40.17. The error function needs to contain a link to

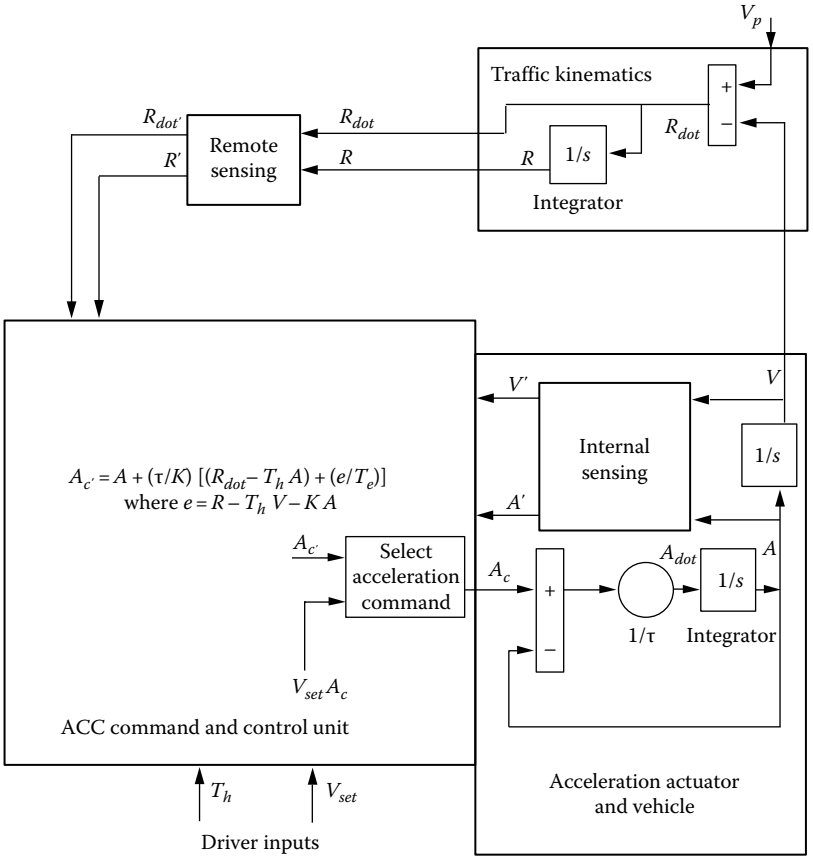

FIGURE 40.9 ACC using acceleration control.

the actuator if the design is to unify the actuator's characteristics into the overall system design. An error function satisfying these concepts is given by the following equation:

$$e = R - T_h V - K\ A \tag{40.18}$$

Step 2: The following equation can be used to define a hypothetical sliding surface that would converge toward $e = 0$ using an exponential approach:

$$Te\frac{de}{dt} + e = 0 \tag{40.19}$$

A point to observe is that *de/dt* contains *dA/dt*, which is A_{dot} in Equation 40.17. This means that we can solve Equations 40.17 through 40.19 simultaneously to determine the desired acceleration command A_c'. By doing this, we cancel the influences of τ and T_e on the open-loop transfer function between R_{dot} and *V*.

Step 3: The operations in step 2 given earlier are purely algebraic, although we are discussing differential equations. This is because we plan to use the integrators already existing in the traffic kinematics and the vehicle actuator and dynamics blocks to design a system that performs the desired ACC function for us. This way we avoid adding integrators, thereby keeping our conceptual design simpler and unifying the design. In this case, the state variables (which result from integrating) are *R, V,* and *A*. When the error *e* is approximately zero for an extended period of time, *R* is approximately equal to $T_h V$ as desired, and R_{dot} is approximately zero. By designing the ACC command and control unit in this manner, we have utilized the parts of the system so that the following relationship applies:

$$A_c' = A + \left(\frac{\tau}{K}\right)\left[R_{dot} - T_h A + \left(\frac{e}{T_e}\right)\right] \tag{40.20}$$

And the open-loop transfer function is as follows:

$$Y_o = \frac{V(s)}{R_{dot}(s)} = \frac{(T_e s + 1)}{\left[T_e K s^3 + (T_e T_h + K)s^2 + T_h s\right]} = \frac{1}{(Ks^2 + T_h s)} \tag{40.21}$$

Step 4: Due to the form of the equation for A_c', the parameter τ does not appear in the open-loop transfer function. And there is a pole/zero cancellation in Equation 40.21, which results from the form of the error dynamics specified by Equation 40.19. The result of this cancellation is that T_e does not appear in the final expression for the open-loop transfer function. Using this expression for Y_o, the closed-loop transfer function between V_p and *V* is as follows:

$$Y_c = \frac{V(s)}{V_p(s)} = \frac{1}{(Ks^2 + T_h s + 1)} \tag{40.22}$$

For a given value of T_h, the condition for the damping ratio to be greater than or equal to 1 is as follows:

$$K \le \left(\frac{T_h}{2}\right)^2 \tag{40.23}$$

Through this design process, we have theoretically arranged an ACC system that will meet our goals and will be free of overshoot as well. And furthermore, the parameter T_e is available for use in meeting other design challenges such as those related to driver ride-comfort issues [12] involving acceleration/deceleration adjustments.

For the magnitude of the transfer function (40.22) to be less than or equal to unity, the string stability condition is $K \leq T_h^2/2$, which is a less stringent restriction on K than that imposed by Equation 40.23. Equation 40.23 is based on eliminating overshoot in the time domain.

40.4.3 Unification Approach Applied to ACC with a Velocity Actuator

This case is similar to the one discussed for ACC using CCC (see Figure 40.7). Unification steps 1 through 4, which were discussed in the previous subsection, are outlined as follows for this case.

Step 1: The state variables are R and V. The functional purpose of this ACC system is to make $R = T_h V$. Hence, let $e = R - T_h V$. This form for e satisfies the functional purpose when it equals zero, and it contains all of the state variables as well.

Step 2: Then, consider $Te\ de/dt + e = 0$ as the desired approach to the sliding surface. This means that we want $V_{dot} = (1/T_h)\ [R_{dot} + (e/Te)]$. For an actuator and vehicle dynamics approximated by $\tau\ V_{dot} + V = V_c$, we want $V_c = V + (\tau/T_h)\ [R_{dot} + (e/Te)]$.

Step 3: Based upon the earlier expression for V_c, the open-loop transfer function is $Y_o = (1/T_h\ \mathrm{s})$. (This is the special case observed in the previous discussion of ACC using CCC.)

Step 4: The closed-loop transfer function is $(V_p(s)/V(s)) = Y_c = 1/(T_h\ s + 1)$. Clearly, this first-order system has no overshoot and it is string stable.

In summary, we have compensated for the actuator and vehicle dynamics while achieving constant time headway as the functional purpose that we chose. Interestingly, the value of the parameter T_e is available to use in tuning the system to have characteristics that are compatible with driver preferences and smoothing the ride performance of the ACC-equipped vehicle. However, the design depends upon having a good understanding of the value of τ and a pole/zero cancellation to remove T_e from the open- and closed-loop transfer functions. Also limits upon maximum acceleration and deceleration performance need to be considered in completing the overall design of the system.

40.4.4 ACC Systems with an Acceleration Actuator and No Available Acceleration Sensor

Although it is conceptually desirable to measure all of the state variables, there may be practical constraints on sensor availability or use such that the host vehicle's acceleration is not available for the ACC designer to use. In that case, the system is similar to that in Figure 40.9 except that A is not measured and the algorithm in the ACC command and control unit needs to be modified. For example, let $e = R - T_h V$ be the deviation from the desired sliding surface, where $e = 0$ if the system were on the sliding surface. Use $T_e\ de/dt + e = 0$ to solve for the desired value of acceleration command A_c. (Formally set V_{dot} equal to A_c.) The result is as follows:

$$A_c = \left(\frac{1}{T_h}\right)\left[R_{dot} + \left(\frac{R}{T_e}\right)\right]\frac{-V}{T_e} \tag{40.24}$$

Using the actuator equation $\tau\ dA/dt + A = A_c$, the open-loop transfer function is found to be

$$\frac{V(s)}{R_{dot}(s)} = \frac{(T_e s + 1)}{\left[T_e T_h \tau s^3 + T_e T_h s^2 + T_h s\right]} \tag{40.25}$$

And the closed-loop transfer function is as follows:

$$\frac{V(s)}{V_p(s)} = \frac{(T_e s + 1)}{\left[T_e T_h \tau s^3 + T_e T_h s^2 + (T_h + T_e)\, s + 1\right]} \tag{40.26}$$

With regard to string performance, the condition $|V(s)/V_p(s)|^2 \leq 1$ results in the following relationship:

$$\left[-T_e T_h \tau\, \omega^3 + (T_h + T_e)\omega\right]^2 + \left[1 - T_e T_h \omega^2\right]^2 - \left[(T_e \omega)^2 + 1\right] \geq 0 \tag{40.27}$$

As presented in Ref. [13], considerable algebraic effort leads to the conclusion that if $T_h \geq 2\tau$, then string stability can be achieved. From a design standpoint, this result has interesting implications. It means that, if the ACC designer and the actuator designer are not working together, the issue of string stability might be left unresolved as may be the case now for some current ACC systems. The issue is that the constraint $T_h \geq 2\tau$ involves quantities that have been regarded as set by considerations other than those associated with string performance. Given that T_h might be 1 s or less to satisfy driver preferences and $\tau \leq 0.5$ s may be difficult or impossible to achieve, there is a conflict. Perhaps, the actuator design might be modified to supply measured acceleration A to the communications bus, allowing A to be used in the ACC design and thereby avoiding the concern with making τ very small.

40.4.5 Summary of Related ACC Designs

Ref. [13] contains analytical work addressing a set of design cases for ACC systems. These cases cover command and control concepts based upon sliding surfaces (such as those already presented here), proportional control, and those nonautonomous systems that depend upon inter vehicle communication to obtain information on the acceleration $V_{p\,dot}$ (also symbolized as A_p) of the preceding vehicle. In order to summarize a number of similar design possibilities, the following generalized transfer function is introduced:

$$Y = \frac{N}{D} \quad \text{where} \quad N = n_2 s^2 + n_1 s + 1 \quad \text{and} \quad D = k_3 s^3 + k_2 s^2 + k_1 s + 1 \tag{40.28}$$

For systems of the form of Equation 40.28, the condition for string stability ($|Y|^2 \leq 1$), which is equivalent to $|D|^2 - |N|^2 \geq 0$, can be reduced to an expression of the following form:

$$\omega^2 (a + b\,\omega^2 + c\,\omega^4) \geq 0 \tag{40.29}$$

where

$$a = k_1{}^2 - 2k_2 + 2n_2 - n_1{}^2 \tag{40.30}$$

and

$$b = k_2{}^2 - k_1 k_3 - n_2{}^2 \tag{40.31}$$

and

$$c = k_3{}^2 \tag{40.32}$$

Inspection of (40.29) indicates that a sufficient condition for string stability is as follows:

$$a \geq 0 \quad \text{and} \quad b \geq 0 \tag{40.33}$$

(The quantity, c, is greater than or equal to zero as indicated by Equation 40.32.)

Table 40.1 presents four items, the special variables sensed or communicated, the actuator concept, the control command rule, and sufficient conditions for string stability in the sense of controlling overshoot. For all these ACC systems, the variables V, R, and R_{dot} (i.e., dR/dt) need to be sensed, but they are not listed as special variables in Table 40.1.

The last row of Table 40.1 represents a nonautonomous ACC system in which the special variable A_p is the acceleration of the preceding vehicle. In this case, it is presumed that A_p is communicated from the preceding vehicle to the ACC-equipped vehicle. The expressions given here represent a high level of abstraction, which means that component design and development at a lower level of abstraction may involve considerable technical challenge due to delays, noise, and inaccuracies in measuring and transmitting A_p.

The control command rule given in the last row of Table 40.1 is based upon a combination of first-order sliding surfaces that provide a second-order numerator for the transfer function, viz.,

let $e_1 = R - T_h V$, $e = T_1\, de_1/dt + e_1$, and $T_2\, de/dt + e = 0$. Based upon these choices, the combined result is as follows:

$$T_1 T_2 \left(\frac{d^2 e_1}{dt^2} \right) + (T_1 + T_2) de \frac{1}{dt} + e_1 = 0 \tag{40.34}$$

The expression for A_c in the last row of Table 40.1 is the result of employing the actuator equation and $e_1 = R - T_h V$ and Equation 40.34 to algebraically solve for A_c where τ_d has been included in case the value of τ is not accurately known. For $\tau/\tau_d = 1$ so that numerator terms cancel denominator terms, the open-loop transfer function Y_o becomes

$$Y_o = \frac{1}{T_h s} \quad \text{and} \quad Y = \frac{1}{(T_h s + 1)} \tag{40.35}$$

The string stability condition, $\tau/\tau_d \leq 1$, given in the last row of Table 40.1 is sufficient. Further treatment of this type of ACC system is given in [13,14]. Clearly, the values of the parameters T_1 and T_2 can be used to adjust for design objectives, uncertainties, and constraints in addition to those

TABLE 40.1
Summary of Related ACC Designs

Special Variables	Actuator Concept	Control Command Rule	For Overshoot Control
None	$T_c\, V_{dot} + V = V_c$	$V_c = (1/T_h)\,(R + T\, R_{dot})$	$T > T_c - T_h/2$
A	$\tau\, A_{dot} + A = A_c$	$Ac = (\tau_d/K)\,(e_{dot} + e/T_e) + A$ where $e_{dot} = de/dt$ and $e = R - T_h V - A$	$\tau/\tau_d \leq 1$ $K \leq T_h^2/2$
A, A_p	$\tau\, A_{dot} + A = A_c$	$Ac = [(\tau_d/T_1\, T_2\, T_h)\,(T_2\, T_1\, d^2R/dt^2) + (T_1 + T_2)\,(R_{dot} - T_h A) + R - T_h V)] + A$	$\tau/\tau_d \leq 1$

Note: R, R_{dot}, and V are sensed on board the vehicle. Also, $d^2R/dt^2 = A_p - A$.

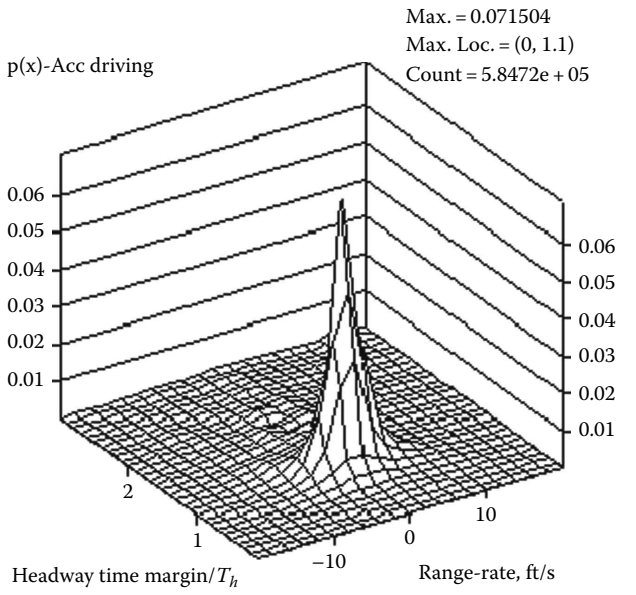
discussed here. Systems of this type are being proposed as candidates for cooperative ACC systems and as steps toward automated highway systems (AHS) [13,14].

40.4.6 Evaluation of ACC Systems

As indicated in Figure 40.3, the same levels of abstraction as used in design may be applied in the evaluation of an existing system. Frequently, when evaluation is a trouble-shooting activity or purchasing related, one starts at the lowest level of abstraction by making sure that the system is packaged nicely, that it is installed well, and that there are no observable defects in any of the components. Tests may be specified to ensure that the components are functioning as designed and in accordance with acceptable performance objectives. International standards and technical-society standards frequently contain requirements concerning component performance. For example, [4,5] have provisions concerning sensors and command and control characteristics.

At the higher levels of abstraction, a limited amount of published work is available on evaluating how well an ACC system meets its functional purpose and the nature of the concepts employed in the system. With regard to functional purpose, a figure similar to Figure 40.10 has been used in [8,9] to compare driver-controlled following and ACC-controlled following. Figure 40.10 is based upon results from an ACC system using CCC as illustrated in Figure 40.6 and as described by Equations 40.8 through 40.10.

The results show that the ACC system achieved its purpose of reaching and holding $R_{dot} = 0$ and $R = T_h V$ very frequently when the system was operated by lay drivers in normal driving situations. In this sense, the system was shown to be robust in the face of the idiosyncrasies of normal traffic situations. And, as shown in Figure 40.10, the ACC system is clearly more predictable than the behavior of human drivers operating under the same types of road and driving conditions.



With regard to determining driver-centered ACC parameters that match the performance of drivers, the data used in constructing Figure 40.10 have been processed to indicate that the value of T used in Table 40.1 and Equation 40.9 should be chosen to be equal to approximately 10 s. This result of 10 s provides a good starting point for tuning the parameters T_e and $(T_1 + T_2)$ as listed in Table 40.1 and as used in Equations 40.19 and 40.34, respectively.

A noninvasive system-identification procedure has been devised for evaluating the operating characteristics of ACC systems in general [15]. In this procedure, the ACC-equipped vehicle and a confederate preceding vehicle are equipped with differential GPSs. Desired speeds and speed changes can be readily controlled if the preceding vehicle is equipped with CCC.

A series of evaluation test maneuvers are prescribed, and linear approximations to the command and control functions are determined in the neighborhood of various steady speed equilibrium points. The GPS data recorded are the positions and velocities of both vehicles and the GPS time at every 0.1 s during the test. The data recorded on board the preceding vehicle is synchronized with that recorded on the ACC vehicle using GPS time as recorded on both vehicles. The difference between the positions of the vehicles represents range R and the difference between velocities represents R_{dot}. The measurement system is noninvasive in the sense that no signals used in the ACC system are needed for the evaluation process.

For current ACC systems with $T_h \geq 1$ s, the accuracy requirements are not large with 1 m resolution in R being adequate for concept evaluation purposes. A time resolution of 0.1 s is achievable with readily available GPS equipment and this has been adequate.

The system-identification results for three current ACC systems indicate that a second-order linear system with R and V as state variables is adequate to represent perturbed performance. The input to the model is V_p, the velocity of the confederate leading vehicle. The identified values of the system parameters (the fitted parameters) are such that strings of these types of systems appear to be moderately unstable in the sense that a small change in speed of the lead vehicle will lead to a nonlinear disruption of string performance for a vehicle far enough back in the string. There would

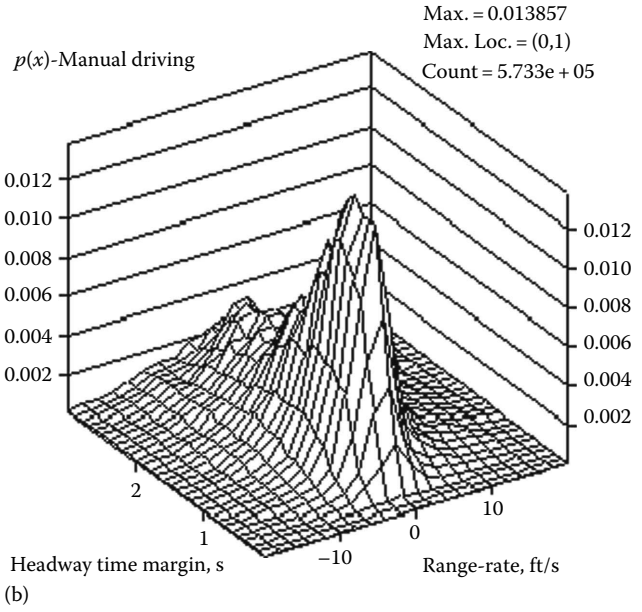


FIGURE 40.10 Evaluation of ACC functional purpose. Histograms of data for (a) ACC driving and (b) manual driving.

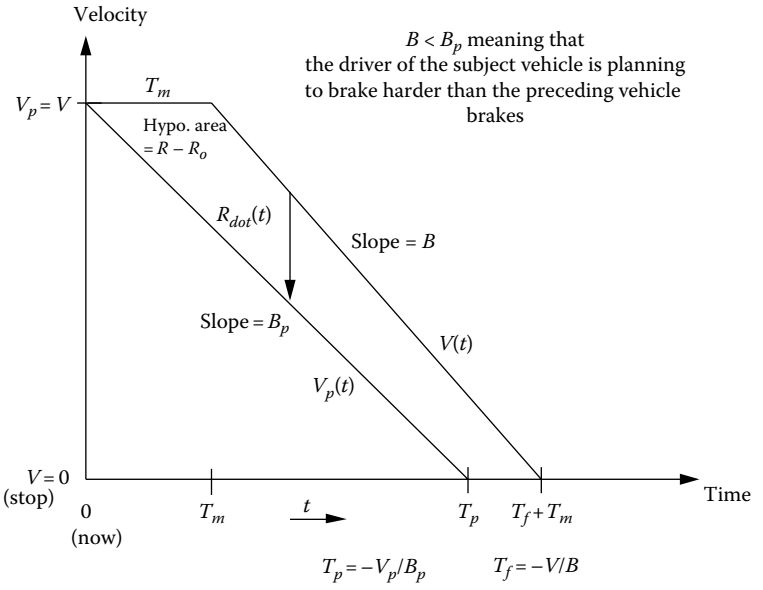
be a vehicle back in the string that needed to apply braking to avoid colliding with its preceding vehicle. This vehicle would need to break away from its control rule for following and adopt a modified rule for stopping or slowing if crashes are to be avoided. In this sense, the basic control structure of long strings of these types of vehicles breaks down due to safety concerns. The vehicles behind the stopped vehicle would need to stop, thereby leading to the possibility of stop-and-go driving. For example, predictions based on exercising the model indicate that the occurrence of four or more of these vehicles in a row would be likely to exhibit considerable overshoot for the last vehicle in response to moderate speed changes of the leading vehicle. Braking intervention by



the driver of the last vehicle would appear to be likely [16] if the lead vehicle reduced speed by approximately 4 m/s in 10 s. More quantitative evaluations of this type are needed to generalize on the state of the art and the adequacy of current designs, particularly with regard to traffic flow implications and the practical importance of string stability issues as related to design concepts.

40.5 EMULATION OF THE LONGITUDINAL CONTROL PROPERTIES OF HUMAN DRIVING

There is a wealth of published material on models of manual driving, for example, see Refs. [17–19] and the papers referenced under driver-related topics in Section 40.9. (The driver's behavior while cornering is dealt with in Chapter 38.) The forms of these models depend upon the applications of the models as well as the concepts and theories that are familiar to the creators of the models. The data collected in recent operational test programs have included measurements of manual driving to use as a basis for comparison between driving with and without driver assistance systems [8,9]. This type of work appears to be in an exploratory phase. However, there is disagreement on the quality of the information available for predicting driver behavior. We are not going to classify driver models here. (See [17] for that.) Instead, we will discuss some recent work aimed at providing driver models to use in microscopic simulations of traffic flow including both manually driven and ACC-equipped vehicles.

The model presented here is based on ideas from Gipps [18] combined with the use of velocity time diagrams such as Figure 40.11 and parametric values chosen to match measured results from field tests involving manual driving [8,9]. Gipps's ideas involve the premise that drivers decide on a steady following distance based upon allowing a time (and/or a distance) margin that depends upon a safety-related estimate of what the preceding driver might do. Figure 40.11 has been created to aid in visualizing how ideas of this type might be viewed and analyzed.

Figure 40.11 shows a hypothetical situation in which the preceding vehicle decelerates at B_p m/s^2 and its velocity would reach zero at a time T_p. The conceptual idea behind Figure 40.11 is that

Hypo. area $= R - R_o = T_m V + T_f\ V/2 - T_p V_p/2$ or
$R = R_o + T_m V + G V^2$ where $G = ((1/2B_p) - (1/2B)) < 0$

FIGURE 40.11 Driver modeling concepts illustrated in a velocity–time diagram.

drivers base their future-driving behavior on the possibility that the hypothetical situation shown there might happen now. What the driver does amounts to allowing for holding the current speed V for T_m seconds and then decelerating at B m/s^2, which would lead to a stop at time $(T_m + T_f)$. The resulting range rate R_{dot} is the difference between V and V_p as indicated in Figure 40.11. The "hypo area" between the V and V_p curves is the integral of R_{dot}, which is the change in range R needed to conform to the hypothetical situation in the driver's mind.

The quantity "R_o" in the equations given in Figure 40.11 represents the clearance distance the driver chooses when both vehicles are stopped. The other terms in the equations result from applying kinematic relationships pertaining to constant deceleration stops. The point is that the driver's objective for steady following is as follows:

$$R = R_o + T_m V + G V^2 \text{ (as shown in Figure 40.11)} \tag{40.36}$$

Figure 40.11 was constructed for $V_p = V$, but similar figures could be constructed for V not equal to V_p. This would represent a transient situation such as closing or separating. Research on this modeling approach has not produced evidence indicating how drivers choose to approach steady following when (40.36) is used. However, there is information indicating that (40.36) is a better approximation to driver behavior in traffic than a constant time headway model [19]. Plots (two-dimensional histograms) of the frequency of various V and R combinations show that there is a well-defined ridge that approximately conforms to Equation 40.36. Attempts to use a number of currently popular microscopic models of traffic flow indicate that the Gipps type of model provides a better fit than several others that were tried [19].

Examination of driving behavior from field operational tests indicates that drivers have a wide range of proclivities for T_m. See, for example, Figure 40.12.

In addition, the parameter G varies considerably from driver to driver, but the values of G may be approximated from those for T_m by the following equation [20]:

$$G = -0.025 T_m + 0.013 \tag{40.37}$$

The implication of Equations 40.36 and 40.37 is that the time gap between vehicles will get smaller as speed increases. This may not be reassuring to safety advocates, but it may be viewed as positive regarding traffic flow on freeways.

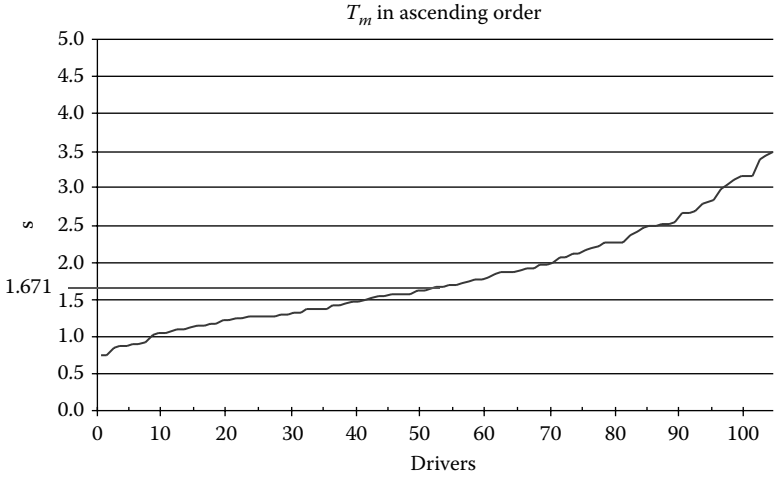


FIGURE 40.12 Linear coefficient in a nonlinear time gap relationship.

40.5.1 Nonlinear Time Gap ACC Systems

In the interest of reducing congestion and improving traffic volume, researchers are considering nonlinear time gap rules such as (40.36) and (40.37) for driver assistance systems. These could be seen as human centered for steady following, but since the transient aspects of human behavior may not be well enough understood, there does not appear to be a good grasp of how driver performance relates to string stability. The ability to emulate stop-and-go driving with microscopic driver models is still under development. Empirical fits to relatively few observations have been used to obtain models that have macroscopic verifications in selected circumstances described by fluid flow analogies.

Nevertheless, it is of interest to discuss the implications of choosing Equation 40.36 as the basis for an ACC system whose functional purpose is to operate in a human-centered manner as indicated by Equation 40.36. Although Equation 40.36 is nonlinear, the concepts and steps used in designing linear systems can be used. Example results for an ACC using CCC may be developed using $e = R - (R_o + T_m V + G V^2)$ as a starting point. Let $T_e\, e_{dot} + e = 0$ and $T_c\, V_{dot} + V = V_c$ for this case. Further, after developing the system equations as before and then obtaining the linear approximation to them at an equilibrium solution with $R = R_e$ and $V = V_e$, the open-loop transfer function is

$$Y_o = \frac{\Delta V}{\Delta R_{dot}} = \frac{(T_e s + 1)}{(ps)(T_e s\ +\ 1)} = \frac{1}{ps} \quad \left(\text{where } p = T_m + 2GV_e\right) \tag{40.38}$$

And the closed-loop transfer function is

$$Y_c = \frac{1}{(ps+1)} \tag{40.39}$$

This system will have string stability in the neighborhood of the equilibrium point at velocity V_e as long as $p = T_m + 2G\, V_e \geq 0$. To shorten the time gap as V_e increases, G needs to be negative, but this will lead to instability of the string structure when p becomes negative as speed is increased. The condition for $p = 0$ is $V_e = T_m/(-2\, G)$. For example, based upon the data discussed in the previous section, consider $T_m = 1.6$ s such that $G = -0.027$ and $V_e = 29.6$ m/s (66 mph). The point of this example is that instability of the string structure can start at a modest highway speed unless care is taken in selecting values for T and G. Suitable values of T and G that will be comfortable for drivers in ACC-equipped vehicles have not been determined as yet. And it appears that deviations from human-centered values might be acceptable for enhancing traffic flow.

The same type of finding applies when ACC using an acceleration-based actuator is employed. Perhaps, specially shaped nonlinear expressions for time gap, as a function of velocity, will be forthcoming. Perhaps switching rules can be employed to meet the special demands associated with both safety-related considerations and traffic flow requirements.

Another example of a nonlinear approach to ACC comes from considering a quantity known as "headway time margin (H_{tm})" where $H_{tm} = R/V$. As its name implies, H_{tm} provides an indication of the instantaneous time margin available to the driver or the controller in adjusting speed to achieve a desired range under the prevailing driving conditions. The original linear expression using $e = R - T_h\, V$ can be restated as follows using H_{tm}:

$$e = \left(\frac{R}{V}\right) - T_h \quad \text{where } H_{tm} = \frac{R}{V} \tag{40.40}$$

Although Equation 40.40 implies the same headway time relationship as $e = R - T_h V$, it represents a different form of algorithm for achieving steady following when we use $T_e\ de/dt + e = 0$ in formulating the control command for an ACC system. The result is as follows:

$$V_{dot} = \frac{V}{R}\left(R_{dot} + \frac{\left(R - T_h V\right)}{T_e} \right) \tag{40.41}$$

For a velocity actuator ($\tau\ V_{dot} + V = V_c$), Equation 40.41 would be substituted into the actuator equation to formulate the command control rule for evaluating V_c. Then (40.41) would be the differential equation describing the dynamic characteristics of the system. This description is similar to the one applying to the linear version except that $H_{tm} = R/V$ replaces T_h. This means that for situations in which H_{tm} is approximately equal to T_h, the nonlinear ACC system may perform much like the linear system listed in the first row of Table 40.1. The system will react aggressively when H_{tm} (i.e., R/V) is smaller than T_h and less aggressively when H_{tm} is larger than T_h. The idea is that the nonlinear system would be more aggressive in ensuring the desired time gap when the situation is more critical because H_{tm} is small.

40.6 FORWARD COLLISION WARNING

Although ACC has been developed commercially for a few years, forward collision warning (FCW) systems are emerging as a consumer product for the general public. Basic issues involve the reliability of these warnings as well as the number of false alarms that may be generated. There are a variety of concepts that have been proposed for implementing FCW systems. To a certain extent, the differences involve basic concepts concerning when and how to warn the driver. The following material provides conceptual examples of three types of warning systems that have slightly different functional purposes.

The first example is a human-centered system that is aimed at providing a warning of the possibility of a collision with a preceding vehicle or object when the driver enters a situation in which the driver is not braking but would be expected to be braking. This system is based on the idea of "time to impact, T_{ti}" where $T_{ti} = -(R/R_{dot})$ for $R_{dot} < 0$. The decision to warn the driver is based upon whether T_{ti} is less than a driver-selected threshold that is chosen by that driver to satisfy personal comfort limits. A typical value of this threshold is approximately 10 s, but drivers vary considerably in their preferences. This is a simple system to implement if the vehicle is already equipped for ACC and has sensors for measuring R and R_{dot}. The system may give frequent alarms [8], but the driver is expected to select a threshold that will meet that driver's comfort and acceptance tolerances. This type of system has been found to have promise in a limited number of trials, but the state of the art is such that researchers have not reported broadly based assessments of how effective this type of system would be.

A second example is based upon using a warning based upon anticipated deceleration needs. In this case, a threshold for the level of the deceleration generated in an ACC command controller could be used to command a warning signal to the driver. Since many ACC systems have a limit on the control authority allocated to the ACC functionality, the warning threshold might be set close to the control limit for the ACC system. For example, Equation 40.41 could be used with a threshold of −0.4 g. Analysis of identical braking situations has shown that this deceleration scheme may produce approximately one-third as many warnings as a time to impact system with $T_{ti} = 10$ s [8].

A third type of warning system can be based upon the range available as compared to the distance needed to stop before colliding. An idea of this type is currently being investigated in a field operational test. The alert algorithm employs a calculated miss distance to decide whether to warn [21].

Figure 40.13 has been constructed to illustrate ideas associated with the calculation of a desired range margin. This figure is like Figure 40.11 except that V_p is not equal to V. As shown in Figure 40.13, $R_{dot} = V_p - V$ has a negative value, which could indicate a crucial situation. The most demanding case is for $V_p(0) = 0$, i.e., a stopped preceding vehicle.

The situation shown in Figure 40.13 can provide the basis for several functional concepts for collision warning. For example, consider a design based upon the idea that the warned driver will decelerate at the same rate as the preceding vehicle in an emergency situation, that is, $B = B_w = B_p$ unless B_p is equal to zero. A warning is to be given if

$$R \le R_m + R_o \tag{40.42}$$

where R_o is the desired clearance at $V = 0$, and where

$$R_m = T_w V + \frac{\left(V_p^2 - V^2\right)}{2B_w} \tag{40.43}$$

If $B_p = 0$, a warning is to be given if the actual deceleration V_{dot} is not less than the value of B needed to stop in $R_m = R - R_o$, that is, $B = -V^2/2\,(R - R_o - T_w\,V)$.

The values of T_w and B_w are design choices. T_w corresponds to the time allowance provided to the driver, and B_w corresponds to the deceleration threshold at which an attentive driver is expected to have been braking already. A starting point for the designer to use in determining a suitable value for T_w might be 1.5 s, which is approximately the median value of T_m in Figure 40.12. Approximately −0.5 g could be a starting point for the designer to use in iterating through analyses, simulations, and experiments to find a suitable choice for the value of B_w.

Current issues involve finding values of T_w and B_w that provide a safety margin without too many false warnings. Experimental work [22] provides data indicating typical deceleration levels that drivers tend to use in situations requiring hard braking.

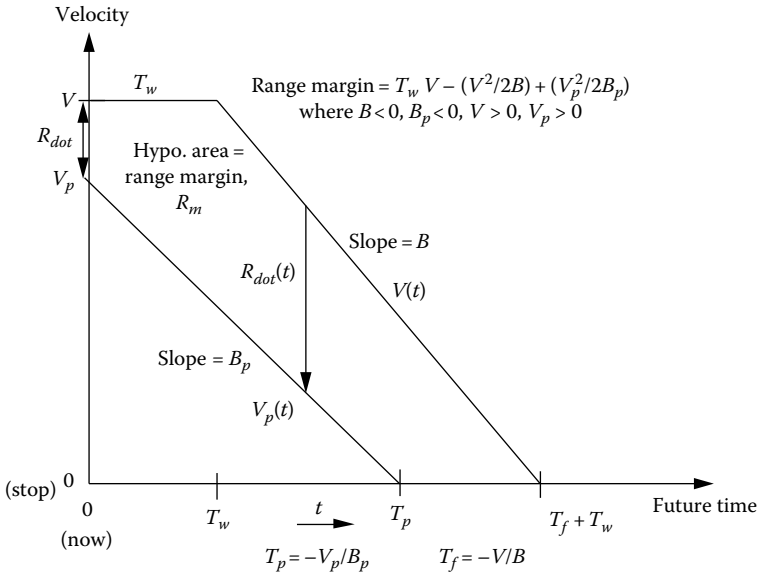

FIGURE 40.13 Range margin as used in FCW.

Another variation of the general theme portrayed by Figure 40.13 involves differentiating R_{dot} to obtain V_{pdot}, viz.,

$$V_{p\,dot} = V_{dot} + \frac{d\left(R_{dot}\right)}{dt} = B_p \tag{40.44}$$

Previously, we introduced a nonautonomous ACC system in which $V_{p\,dot}$ was communicated from the lead vehicle to the following vehicle. However, if R_{dot} could be differentiated practically and accurately enough, the vehicle-to-vehicle communication feature would not be needed and the ACC system could be autonomous. The use of Equation 40.44 for ACC systems has received little public attention, but in the case of FCW, the use of (40.44) to estimate B_p is being evaluated [21]. These possibilities open the way for unifying the design of new systems that combine the functions of both ACC and FCW.

Based on knowing B_p, Figure 40.13 could be interpreted differently. The current deceleration V_{dot} could be compared with a calculated deceleration B_n as needed to make R equal R_o at $V = 0$, viz., by examining Figure 40.13 and defining a quantity ΔR,

$$B_n = \frac{-V^2}{2\Delta R} \tag{40.45}$$

where

$$\left(R - R_o - TwV - \left(\frac{V_p^2}{2B_p}\right)\right) = \Delta R \tag{40.46}$$

If B_n is less than a threshold value for warning, the warning is given. For example, the threshold value might be chosen as −0.5 g. The point is that if the acceleration of the preceding vehicle is known (or estimated accurately enough), the collision warning system may have an advantage over an alert human driver who uses brake lights in sensing changes in the decelerations of preceding vehicles.

Nevertheless, there is a major concern with alarms that appear to be false to alert drivers. Such alarms may occur when the preceding vehicle is beginning to turn out of the path of the vehicle equipped with an FCW system or when an FCW-equipped following vehicle is beginning to pass a preceding vehicle. Perhaps advanced systems will someday use predictions of the path of the preceding vehicle to avoid apparently false alarms, but the meanings of these tactics are not currently clear in terms of tradeoffs between safety goals and driver acceptance.

40.7 AUTOMATED HIGHWAY SYSTEMS

The systems considered previously in this article depend upon the human driver's ability to supervise and interact with the driver assistance system in controlling the vehicle in a relatively continuous manner. In connection with ACC systems, the issue of the influence of ACC control characteristics on the structural performance of strings of vehicles was discussed with the intention of assuring that ACC systems might be designed in a manner that would not contribute to the tendency for stop-and-go driving to develop in congested driving situations. However, the headway time gap is an important factor in determining traffic flow at capacity. In the interest of safety, the time gaps employed in ACC systems may be slightly longer than those typically used by some drivers on congested freeways (see Chapter 39). This might reduce the density of traffic and thereby contribute to a reduction in traffic flow and capacity. Although advanced technology may

provide the impetus to go to shorter time gaps and clearance ranges, the driver may not be able to control the vehicle safely when quick actions are required. The delays in driver response and the bandwidth of driver control preclude the use of very short range clearances, which is the substance of high-capacity flows such as those anticipated for AHS. The behavior of ACC-equipped vehicles may provide insight into desired AHS features, and ACC systems may evolve toward systems using autopilot-like features rather than continuous driver supervision as the braking authority of ACC systems increases.

A literature review by Shladover [23] references and describes many of the ideas generated in early concepts of AHS structures. The use of platoons of closely spaced interacting vehicles is a common theme. The distance between platoons is designed to be long enough to allow the leader of a following platoon to be able to stop before colliding with the last vehicle in the preceding platoon. The goal is to increase traffic flow by having several vehicles at close range clearances in each platoon. The key technical challenge from a vehicle dynamics standpoint is to develop controls that will allow vehicles to travel safely and effectively at close range clearances.

In addition, there are challenges concerned with infrastructure requirements, institutional issues, and social and environmental issues. Nevertheless, congestion is sufficiently prevalent in certain locations around the world that considerable research effort has been supported by governmental transportation organizations.

Figure 40.14 is introduced to provide a simplified microscopic overview of steady traffic flow for vehicles whose speed V_{set} and steady-state time gap T_h are controlled automatically. In this example, all of the vehicles have the same control settings for V_{set} and T_h. In real traffic flows with driver-controlled vehicles, different drivers have different characteristics, which can be represented by distributions of V_{set} and T_h in microscopic models of traffic flow. These distributions lead to conflicts involving fast drivers wanting to pass slow drivers and whether a small or large gap is available for changing lanes. Clearly, the study of driver-controlled flow [24] is much more complicated than we are going to cover here in presenting basic ideas concerning ACC and AHS possibilities for reducing congestion.

Another point about Figure 40.14 is that it is a steady-state diagram, which means that transient disturbances are not shown. For string-stable ACC systems and AHS designs, the high-density end of the flow-density curve (beyond D_c and after the maximum flow F_c) is string stable such that disturbances may be expected to damp out exponentially. However, human drivers are not able to maintain stable strings in this region except for brief periods of synchronized flow that are disrupted by disturbances, often leading to stop-and-go driving [25].

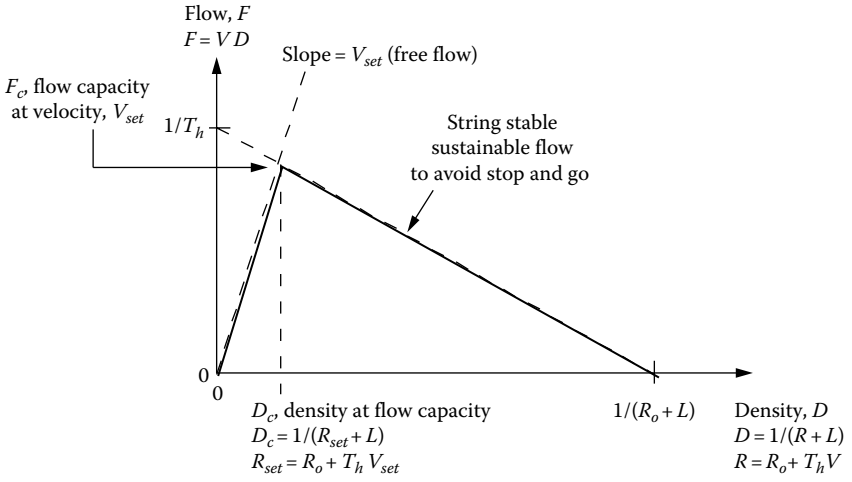

FIGURE 40.14 Steady-state flow with specified V_{set} and T_h.

Figure 40.14 essentially represents the steady-state behavior of identical vehicles equipped with identical string-stable ACC systems. The flow reduces aftercapacity because the ACC system enforces a desire time gap policy defined by $R = R_o + T_h V$. The quantity L represents the length of each vehicle, which is needed to consider density in terms of vehicles per meter and flow in terms of vehicles per second. Although flow may be a dynamic concept, the flow-density diagram is meant to provide insight to the traffic engineer in planning roads that will satisfy transportation needs. In this regard, the capacity F_c is a design goal and L has an important influence on the results.

Figure 40.15 is introduced to illustrate the importance of the platoon concept. For the purposes of this discussion, it is conceptually useful to think of a platoon as consisting of a fairly rigidly held configuration of several vehicles. In a sense, each platoon is like a packet of n vehicles, where n is the number of vehicles in the packet. If the control systems used in the platoon can hold the vehicles together at short clearance ranges, the length of the platoon will be short in terms of its length to number-of-vehicles ratio. The applicable equation for the length (L_p) of the platoon is as follows:

$$L_p = n\,L + (n-1)R_g \tag{40.47}$$

where R_g is the distance gap between vehicles.

Figure 40.15 shows three vehicles per platoon, but the number could be increased. One of the current research and design issues involves the number of vehicles that will perform suitably in a platoon. Nevertheless, the power of this approach concerning traffic flow can be readily demonstrated using three vehicle platoons. For example, consider a numerical example in which $L = 5$ m, $n = 3$, $R_g = 2.5$ m, $V_{set} = 30$ m/s, $R_o = 0$, and $T_h = 1$ s. The idea here is that each platoon leader is equipped with an ACC system that uses $V_{set} = 30$ m/s and $T_h = 1$. Lane A has a string of ACC-equipped vehicles and lane B has ACC vehicles leading three-vehicle platoons. Using the ideas portrayed in Figure 40.14, the flow at capacity for the lane A, with ACC vehicles and no platoons, is 0.857 vehicles/s (3085 vehicles/h). In contrast, the flow in lane B is 1.8 vehicles/s (6480 vehicles/h). These are both extraordinary maximum flow levels compared to what is sustained on freeways today (perhaps 2500 vehicles/h), but these are for idealized cases in which the influences of lane changing and entering and exiting are not considered. Nevertheless, the power of the platoon structure is evident.

If not already evident, the reason for the flow benefit of the platoon structure can be understood by considering packets. Each packet moves as a single entity with the length of the packet depending upon the number of vehicles in the packet. For the earlier example, the number of packets per meter in lane B is 1/(20 + 30) = 0.02 and the packet flow at capacity is (30)(0.02) = 0.6 packets/s. However, because there are three vehicles per packet, the vehicle flow is 1.8 vehicles/s. The point is that the packet structure effectively increases the density of the flow without consuming much additional space.

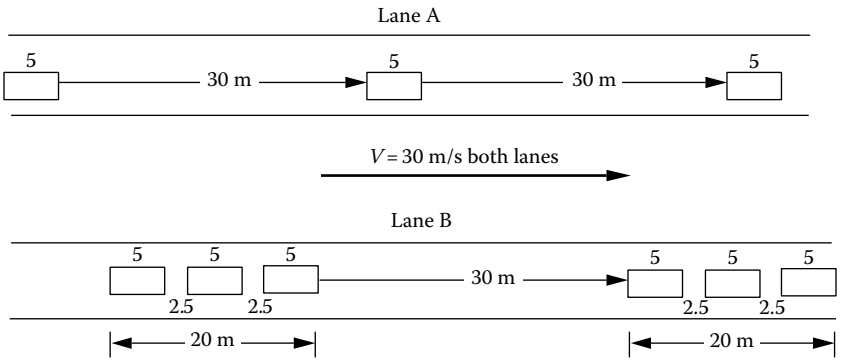

FIGURE 40.15 Example with three-vehicle platoons in lane B.

This density consideration is important in situations where current freeways are operated at over their capacity. Operating over capacity is brought about by the demand to get more cars on the freeway than the density at capacity provides. If the additional capacity brought about by platooning is not enough in an extreme situation, then the ACC lead vehicle could operate at a lower set speed (V_{set}) to accommodate the increased demand for density. This would reduce the flow, but it would increase the number of vehicles that could get onto the freeway and away from the congested area at times of peak congestion.

This same reasoning applies in the case of all ACC vehicles (lane A provided earlier). In the ACC case, the demand for flow is more likely to exceed the flow capacity required to meet the demand for density, that is, the demand for vehicles to get on the road. At periods of peak demand to get on the road, V_{set} may need to be reduced substantially to accommodate that demand. Nevertheless, the proposition is that, if the ACC systems are string stable in a structural sense, a steady flow may be sustained at a level beyond that achievable by manual driving under these high-density conditions. Research experiments are needed to demonstrate this in practice.

Up to this point in this discussion, the matter of the dynamics within a platoon has not been addressed. It has been presumed that the vehicles in the platoon can be controlled to maintain a relatively small distance between each other. The subject of string stability for platoons has been the subject of research concerning AHS. Currently, the work of Swaroop and Hedrick [26] is frequently referenced. This paper contains an elegantly presented mathematical set of theorems and methods indicating sufficient conditions for designing controllers that can achieve string stability for systems that maintain fixed distances between vehicles. A practical implication of implementing this approach is that it is necessary to measure and communicate the acceleration and speed of the lead vehicle to each following vehicle. For example, the third vehicle in a platoon would receive velocity and acceleration information from the lead vehicle in the platoon.

Although there are significant challenges in component and infrastructure design to be met, the existence of these theoretical results has provided the basis for justifying research and development of prototypes of these types of systems. Predictions involving even minimum two-vehicle platoons show significant contributions to increasing traffic flow and reducing congestion. For example, using the parametric choices for lane B as before except with $n = 2$, the maximum flow would be predicted to be 1.41 vehicles/s (5080 vehicles/h) with a density of 0.047 vehicles/m (47 vehicles/km). If the demand to get on the road implied a density of 60 vehicles/ km, V_{set} would need to be reduced to 20.8 m/s and the maximum flow would be 1.25 vehicles/s (4500 vehicles/h).

40.8 CLOSURE TO THE OVERVIEW OF BASIC CONCEPTS

The overview has used a design-oriented approach in describing functional features and performance possibilities for technologically advanced LC systems. The discussions have emphasized ACC, FCW, and AHS systems at the level of functional concepts and basic ideas. For the most part in this chapter, component design has been mentioned but not treated extensively. Rather, component properties have been treated as constraints on design possibilities for LC systems.

The success of these types of systems as consumer products is not currently known, but they are beginning to be offered in the marketplace. There will undoubtedly be many unanticipated issues to be understood and resolved as these systems are developed and introduced. Some of these issues may not have technological solutions. Changing the basic nature of the driving process is certain to have social, legal, and institutional ramifications.

The material that follows provides references to advanced treatments of topics pertaining to the dynamics of LC systems.

40.9 ADVANCED TOPICS

This section identifies a number of miscellaneous advanced topics related to the broad field of LC. The reader is referred to the indicated citations in the reference list for further detail and more in-depth discussions of each particular topic. By and large, the vast majority of these references are from the last 15 years or so. More seasoned works have been selected to help address some of the more traditional LC topics. Many of these topics have had a waning research interest in recent years or have been more competently examined, in large measure, by those earlier studies.

40.9.1 Driver Closed-Loop Braking Performance under Limit Conditions

Examples of driver closed-loop braking performance in emergency-like or hard-braking scenarios are provided in such studies as Rompe [27,28], McLean [29], Newcomb [30], and more recently by Fambro [31]. Rompe and Fambro provide experimental measurements of drivers in passenger cars and light trucks. McLean and Newcomb provide not only similar experimental measurements of passenger car and commercial vehicle drivers during heavy braking but also a fairly comprehensive and validated model of the human driver engaged in such stopping maneuvers. Hisaoka [32] provides a more recent study of measuring and modeling driver behavior under braking-in-a-turn conditions. Various aspects of understanding and modeling basic human control behavior over a range of operating conditions are also discussed in MacAdam [17].

40.9.2 Driver Headway Control Behavior

The difficult task of studying and characterizing driver LC behavior under more routine or less demanding longitudinal conditions, such as headway control, is also examined in a number of other works. In many of these cases, driver LC is often intermittent, due to competing distractions or low attention demands imposed on the driver by the control task. Examples would include the works of Fancher [33,34], Eyre [35], Gerdes [36], Girault [37], Lee [38], Lu [39], Mayr [40], Peng [24], Stankovic [41], and MacAdam [42]. Most of these works include measurements of driver behavior as well as efforts to model such behavior. In some cases, interaction with driver-assist systems is also a major component of the study such as in Bengtsson [43] or Fancher [33].

40.9.3 Sliding Control

Example studies that have employed sliding control techniques to represent longitudinal controllers or driver assists are provided in such works as Gerdes [44], Hedrick [45], Lee [38,46], Lim [47], Lu [39], and No [48].

40.9.4 Driver Longitudinal Control Behavior When Entering Curves

The braking behavior of drivers, when approaching or entering curves, is examined in a number of studies. Example works that have measured and modeled this behavior are provided by Levison [49,50], Savkoor [51], and Yoshimoto [52].

40.9.5 Nonlinear Control

Examples of nonlinear LC applications include Fritz [53], Gerdes [44], Hedrick [45], Kalkkuhl [54], Lee [46], Lim [47], Omae [55], Schiehlen [56], Seshagiri [57], Warnick [58], and Yanakiev [59].

40.9.6 Control Hysteresis and Saturation

Issues related to the nonlinear topics of control hysteresis and control saturation are addressed in such studies as Gerdes [44], Girault [37], and Warnick [58].

40.9.7 Control Delays

The importance of transport delays on the performance of LC systems is given in such works as Huang [60,61], Liu [62], Wang [63], and Yanakiev [59].

40.9.8 Platoons and String Stability

Papers related to the topics of platoons or longitudinal string stability are found in works such as Eyre [35], Girault [37], Hedrick [10], Huang [61], Lee [38,46], Liu [62], Lu [64], No [48], Nobe [65], Omae [55], Rajamani [66], Schiehlen [56], Seshagiri [57], Stankovic [41], Swaroop [67], Tsugawa [68], Wang [69], Warnick [58], and Yanakiev [59].

40.9.9 Artificial Intelligence Methods Applied to Longitudinal Control

Neural network and fuzzy logic approaches to analyzing and modeling the LC behavior of both drivers and advanced vehicle control systems are seen in such works as Kalkkuhl [54], Lee [38,46], MacAdam [42,70], Nobe [65], and Wang [63].

41.1 INTRODUCTION

The story of the evolution of motorized vehicles is also the story of vehicle accidents. Nicolas Cugnot, a French military engineer, designed the very first self-propelled car, a steam-powered road vehicle, in 1769. In the following year, he built another steam-powered tricycle that carried four passengers. Only a year later, Cugnot drove one of his road vehicles into a stone wall, which would make him the first known person to get in a motor vehicle accident. Although it is disputed whether this accident ever happened, it is quite likely that developing new technology at this time would cause some unforeseen events and accidents.

According to [1], the first recorded automobile fatality occurred in a small town in the Irish Midlands in 1869. Mary Ward, a celebrated microscopist, artist, astronomer, and naturalist, fell from a steam carriage and died of severe injuries from its heavy iron wheels.

If the accident mentioned earlier actually happened to Mr. Cugnot, then the claim [2] that the world's first automobile accident occurred in Ohio City/Ohio in 1891 must probably be confined to gasoline-powered vehicles in the United States. James W. Lambert, a very successful inventor holding more than 600 patents mostly affiliated with the automobile industry, was driving in his vehicle. When a wheel hit a tree root, the car careened out of control and smashed into a hitching post. Luckily, injuries from this accident were minor.

A more severe accident with less luck for the vehicle occupants happened a few years later, on February 25, 1899, in Great Britain. Edwin Sewell and Major Richer are the first recorded driver and passenger fatalities, respectively. They were thrown from their vehicle on Grove Hill Road in Harrow on the Hill, Middlesex, London. In remembrance of this tragic event, a roadside plaque was unveiled at the accident scene seventy years later [3].

Since these early days, road traffic has grown immensely all over the world. Along with this growth, also traffic accidents have reached a frequency that is hard to believe and has dramatic consequences. According to a study by the WHO for Europe, every year, road traffic accidents kill about 127,000 people, injure at least some 2.4 million, and kill more children and young people aged 5–29 than any other causes of death. Worldwide, road incidents result in the death of an estimated 1.3 million people each year and between 20 and 50 million sustain nonfatal injuries [4].

Although such numbers should shock people, they are too difficult to imagine, too surreal, and therefore don't really impress the public. A traffic accident moves people if they bear relation to the location, the vehicles, or the victims. If a relative, a friend, or a celebrity is involved in an incident, then people are willing to focus on what is happening every day, every minute, somewhere on streets and roads.

Vehicle accidents involving celebrities also put the work of accident reconstructionists in the center of focus. Movie hero James Dean was killed in 1955 in a Porsche 550 Spyder in an almost head-on collision with a 1950 Ford Tudor. Millions of fans of the actor mourned, but also the cause of the accident was debated and investigated several times. More recently, the tragic vehicle accident on August 31, 1997, in Paris that caused the death of Lady Diana, Princess of Wales, moved even more people all around the world. Since the circumstances of this fatal crash have been quite unclear, accident reconstruction did play a major role in this case [5] and probably made this car accident the most thoroughly and comprehensively investigated one so far.

41.1.1 Accident Analysis: Who and Why

The analysis and reconstruction of road vehicle accidents are conducted by various institutions within a country and also differently organized in different countries. Most often, police traffic units are the first to be involved in the process. Typically, they will secure the accident scene, collect and document evidence, take vehicles into custody, etc. Sometimes accident reconstruction experts are involved at this early stage, and sometimes they act at a later stage. These experts may be specially trained officers within police units, and they may be employed by other government

organizations or by law offices, professors within academic institutions, or members of forensic offices specializing in accident reconstruction. Vehicle manufacturers also have their own departments with specialists in the field of accident analysis and reconstruction.

The obvious reason for analyzing a vehicle traffic accident is to determine the cause of the accident. If a criminal act was the cause, a criminal procedure will be started against the individual(s) involved, and if held criminally liable, those individuals may be subject to criminal penalties. Even if no crime occurred, lawsuits frequently result from vehicle accidents. This can be true whether the accident was caused by human error, defective design, or construction of the vehicles involved or even defects in the design or construction of the road or the signage in the vicinity of the accident location.

At least since the publication of the famous book "Unsafe at Any Speed" [6], product liability has become an important issue in the automotive industry. Manufacturers are often accused of having produced defective products that either caused or significantly contributed to accidents. Defective design cases can be especially challenging for the accident reconstructionist.

41.1.2 Information Sources

Before the topic of this chapter is discussed in detail, a brief overview of major literature resources is given. During the last decades, significant research efforts were made at various institutions and in different countries, and meanwhile a wealth of information is available. Comprehensive material on vehicle accident reconstruction and numerous of references can be found in these up-to-date books [7–11] and the following journals:

- *Accident Analysis & Prevention*, Elsevier, ISSN: 0001-4575
- *The Accident Reconstruction Journal* (*AR Journal*), ISSN 1057-8153
- *VKU Verkehrsunfall und Fahrzeugtechnik*, Vieweg+Teubner, ISSN: 0724-2050

Note that these are by no means complete lists and shall serve only as a base to start from.

41.2 ACCIDENT SCENARIOS

It is impossible to develop and present a unified approach to the analysis of vehicle accidents. The reason for this is the fact that too many different scenarios of accidents are possible and do actually occur in daily life. Let us start with a list of different motorized vehicles, which populate roads and highways:

- Four-wheeled vehicles (cars, ATVs, light trucks, etc.)
- Powered two-wheelers (PWTs) (motorcycles, mopeds, etc.)
- Multiwheeled vehicles (trucks, busses, etc.)
- Multivehicle combinations (tractor–trailer, RV with trailing car, etc.)
- Special vehicles (trikes, articulated vehicles, off-road vehicles, etc.)

Although the laws of physics hold for all these vehicles, an accident may appear very different if, for example, either a passenger car or a motorcycle is involved. Since each group of vehicles has its own specific properties, accident analysis needs to consider such particular features. Consequently, there are comprehensive publications on accident reconstruction devoted to certain groups of vehicles like motorcycles [12], trucks [13], or busses [14].

Not only do we have to consider the various aforementioned motorized vehicles, but collisions may also occur in any combination with

- Other motorized vehicles
- Nonmotorized vehicles (bicycle, tricycle, etc.)
- Pedestrians

- Animals
- Nonmoving objects (tree, mast, building, guardrails, etc.)
- The road or a part of the environment (curb, slope, river, lake, ditch, etc.)

From this compilation, it is easy to imagine that there are many combinations possible and almost each of them has its subtle peculiarity. There are, of course, standard situations like a pedestrian hit by a car on the crosswalk, a car versus car collision at an intersection, or a motorcycle going off the road in a turn that can be analyzed by routine. But quite often, special details have to be taken into account that make an accident unique and difficult to analyze.

41.3 SEQUENCE OF ACCIDENT PHASES

There is a distinctive pattern that is common to practically all accidents. The event can be subdivided into three different phases: precrash, collision(s), and postcrash. Depending on the type of accident, the kind of vehicles, or nonvehicles involved, each individual phase may be different, but the sequence will be the same and can be used to structure the entire event.

In the following sections, the characteristics of all three phases will be discussed. To illustrate and underline the principle issues of each phase, the simple case of a straight-line rear end collision is used as an example. More complex scenarios will be discussed later in this chapter.

41.3.1 Precrash Phase

The precrash phase is defined as the period of time before the first and unintended contact with another vehicle, human being, animal, or object. In general, this phase starts with a stimulus for the driver of a vehicle, which triggers a sequence of visual information processing. This process involves the perception of a hazard or threat, the decision-making, and the response to avoid the accident. The beginning of this sequence is largely dominated by the cognitive abilities of the driver [15,16]. To analyze an accident, especially when environmental factors (like darkness and rain) do play an important role, a profound knowledge in cognitive science is needed [17]. The task for the reconstructionist is to determine how much time passed between the first possible moment for the driver to realize the hazard and the beginning of the evasive maneuver.

In [7], the triplet "perception–decision–reaction/response" is abbreviated by the acronym PDR, and the time needed to perform these tasks is termed PDR time. PDR times may vary widely and depend on numerous factors including weather and traffic environment, day- or nighttime, type of vehicle, and mental and physical condition of the driver (alcohol, drugs, medication). The perceptibility of what constitutes a hazard for the driver is of utmost importance. A car entering an intersection on a sunny day is much easier to perceive compared to a pedestrian attempting to cross a road coming from behind a parking car during nighttime. Consequently, the PDR time can range from 0.5 to about 2.5 s. In [11], the authors conclude that, under normal circumstances, it takes a car driver on average between 0.8 and 1.0 s to set an avoidance action. This is the time period from the instant when the phase of perception is finished and the driver is aware of a hazard and the necessity of a reaction, until the brakes or any other avoidance action becomes effective.

During PDR time, the driver also has to make a decision about the action for accident avoidance. Under normal circumstances, a car or truck driver will have no choice other than a braking maneuver. A motorcycle rider, however, may also try an evasive lane-change maneuver to circumnavigate an obstacle blocking his or her way. We will address motorcycle-related issues in a later chapter and assume that the driver initiates an emergency braking maneuver for accident avoidance.

41.3.1.1 Calculation of a Basic Braking Maneuver

It is commonly assumed that within PDR time the dynamic properties of a vehicle play a minor role. Consequently, the vehicle is modeled as a single mass with one degree of freedom (DOF) in

longitudinal direction. This simplification allows to use the formulas listed in the following for all kinds of vehicles. Nevertheless, it is necessary to make sure that this is a valid model for the pre-crash phase. Since there is almost always a lack of information concerning the acceleration during that phase, frequently, a constant value is assumed, making it is easy to calculate unknown parameters for a given set of known or assumed other parameters. In Equations 41.1 through 41.5, as known from textbooks as well as from [8], the following symbols are in use: t for time, d for distance, v_i and v_e for initial and for end velocity, respectively, and a for a constant acceleration. A negative value has to be used for a to become a deceleration.

To calculate the time t to accelerate/decelerate from an initial speed v_i to a final speed v_e at a constant acceleration a,

$$t = \frac{v_e - v_i}{a}. \tag{41.1}$$

To calculate the travelled distance d when accelerating/decelerating from an initial speed v_i to a final speed v_e or within a time period t at a constant acceleration a,

$$d = \frac{v_e^2 - v_i^2}{2a} = v_i t + a\frac{t^2}{2} = \frac{t}{2}(v_i + v_e). \tag{41.2}$$

To calculate the final velocity v_e from an initial speed v_i for a given time t, distance d, or constant acceleration/deceleration a,

$$v_e = v_i + at = \sqrt{v_i^2 + 2ad}. \tag{41.3}$$

To calculate the initial velocity v_i for a constant acceleration/deceleration a from a final speed v_e and/or a given time t and distance d,

$$v_i = v_e - at = \frac{2d - at^2}{2t} = \sqrt{v_e^2 - 2ad}. \tag{41.4}$$

To calculate the constant acceleration a from an initial speed v_i and for a given time t, distance d, or a final speed v_e,

$$a = \frac{v_e - v_i}{t} = \frac{2d - 2v_i t}{t^2} = \frac{v_e^2 - v_i^2}{2d}. \tag{41.5}$$

If the accident can be avoided, in general the final velocity v_e would be zero. Otherwise, v_e is the collision speed and will be needed in the subsequent crash analysis. If the acceleration is not constant for the entire maneuver, suitable formulas need to be derived, or the maneuver may be subdivided into sections of almost constant acceleration, for which the presented equations can be applied. The entire braking maneuver is then composed by assembling the individual results.

41.3.1.2 Estimation of Braking Deceleration

The choice of value used for the acceleration a depends on several factors, such as type of vehicle, braking system, degree of brake application, type of road, and road condition. Only for a full braking maneuver with all wheels locked or operating near the optimum slip (see Chapters 17–19), the deceleration can be related directly to the friction parameter of the combination of road and tire. Nowadays, practically all new passenger cars are equipped with an antilock braking system (ABS), which guarantees almost optimal deceleration, if engaged by the driver for the entire braking maneuver. The prevalence of ABS is not nearly as high, however, for other vehicles like trucks

and powered two-wheelers (PTWs) and makes estimating the deceleration more difficult. In principle, there are three approaches available to put such estimated values on a solid base:

1. Using measured longitudinal forces and friction parameters for tires on the kind of surface and for conditions equivalent to that at the accident scene
2. Using measured deceleration values from vehicle manufacturers, consumer reports, or specific references
3. Making individual measurements at the accident scene, preferably with a vehicle of the same make and year under similar road conditions

Approach (1) has the advantage of not being restricted to a specific vehicle or braking equipment. Based on more elaborate vehicle models, as presented in other parts of this book, for example, the brake force distribution between axles can be taken into account, and quite realistic results can be obtained. Although there are numerous references of measurements in the tire literature, they are mostly valid for artificial surfaces, as used in tire testing machines. One will hardly find data for realistic surfaces, like a used and wet asphalt pavement or for icy road conditions.

The second approach (2) is the most common method to estimate the achievable braking deceleration. Measured data from vehicle tests can be found in various comprehensive sources like [8,10,11,18] but also in journal articles and vehicle reports. Note that parameters of the testing method and the method of data analysis have an influence on the results. Therefore, it is necessary to closely examine such data in order to avoid a misinterpretation. For instance, in [8], the range for nondimensional deceleration under various conditions is given for different initial speeds (below and above 30 mph) of the braking maneuver. On the other hand, in [11], it is pointed out that 50% of the brake response time is included in the results. Table 41.1 is a compilation from several references listing maximum braking deceleration achieved with passenger cars on various road surfaces and road conditions. Differences within testing methods and parameters are accounted for by listing ranges for the results. Note also that results from different sources vary widely, especially for low friction surfaces, and original references need to be consulted when data are used at court.

Occasionally, approach (3) is chosen, especially in difficult cases. Although this seems to be the most reliable method, there are still uncertainties that are hard to overcome. Road and tire temperature and tire age and road condition have a significant influence on the generation of braking forces. Since these parameters are rarely known, it is virtually impossible to reproduce exactly a braking

TABLE 41.1
Maximum Nondimensional Braking Deceleration[a] Achieved with Passenger Cars

Road Surface and Condition	Dry	Wet
Concrete new	0.60–1.00	0.50–0.75
Concrete used	0.50–0.75	0.45–0.65
Asphalt new	0.60–1.00	0.50–0.75
Asphalt used	0.50–0.70	0.45–0.65
Gravel packed	0.35–0.70	0.40–0.70
Gravel loose	0.30–0.70	0.45–0.60
Grassy ground	0.30–0.60	0.10–0.40
Snow packed	0.30–0.55	0.30–0.60
Snow loose	0.10–0.25	0.05–0.25
Ice	0.10–0.20	0.02–0.10

[a] a/g with g being the acceleration due to gravity.

maneuver that has happened in the past. However, chances are good to be as close to reality as possible, and valuable insight into the accident may be gained from on-site testing. On the other hand, application of this approach is also limited because it might be impossible to carry out such tests for various reasons.

41.3.1.3 Analysis of Evidence at the Accident Scene

Aside from the uncertainty of the technically achievable braking deceleration, there is also the question of brake application by the driver. Unless skid marks are found, there is no evidence how heavy, or if at all, the brakes have been operated. Skid marks are an important piece of evidence, and therefore reconstruction of the precrash phase relies heavily on them. With recent cars and ABS, however, skid marks become rare, since wheel locking is prohibited by the braking system. Although a braking wheel at optimum longitudinal slip may leave some traces on the road surface, such tire marks, if present at all, are difficult to recognize and easily overlooked when the scene of the accident is examined. The resulting lack of evidence of a braking maneuver with ABS-equipped vehicles is an additional difficulty in an accident analysis. Therefore, event data recording devices (EDS) that record and store vehicle data like speed and brake application prior to an accident will be the only reliable solution to this problem for the future [19].

In the discussion of the precrash phase, it was assumed that the driver has the vehicle under control until the crash occurs. The only input assumed for the driver was the application of the brakes. There are, however, accidents where the driver loses control over his or her vehicle before it collides with other vehicles or objects. Typical cases are rollover accidents and accidents where the vehicle unintentionally goes off the road. Evidence is mostly found as curved and diverging tire marks resulting from tires operating at large slip angles. Such accidents need to be analyzed differently already in the precrash phase, and a more elaborate model must be employed to capture the precrash dynamics of the vehicle.

41.3.2 Crash Phase

Compared to the pre- and the postcrash phase, the crash phase itself is very short lived. Nevertheless, it is the phase that makes the incident an accident, with consequences for the concerned persons and involved real assets, ranging from minor to dramatic. The crash phase is characterized by the action and exchange of mostly very high contact forces within a short period of time. It starts with the first contact of the colliding bodies and ends when the contact is terminated. A typical collision of a car with another car or a road barrier lasts for only about 100–200 ms and is also called *impact*. During this short interval of time, the contact forces cause deformations of the impacting bodies. These deformations can be nonpermanent or permanent, that is, *elastic* and *plastic*, respectively. While for an elastic impact of two bodies, both momentum and kinetic energies are conserved, in the case of a nonelastic (plastic) impact, some kinetic energy is transformed into deformation.

There are several excellent literary sources that treat impact dynamics of bodies comprehensively and in a general manner (see, e.g., [20,21]). Sources that are focused on the impact and collision of vehicles are the books [7,22,23]. But practically all sources on accident reconstruction comprise parts that deal with the mechanics of impacting and colliding vehicles.

To outline basic impact mechanics of colliding vehicles, one of the most simple accidents, a straight-line rear end collision (see Figure 41.1), will be discussed now. We assume that two vehicles of masses m_1 and m_2 are moving at velocities v_1 and v_2 in the same direction, with vehicle m_2 being ahead and $v_1 > v_2$. Centers of gravity of the vehicle masses and velocity vectors are aligned, and so a 1D impact can be considered. At time $t = t_b$, contact and compression and deformation of the vehicle structures start. This first phase, called compression phase, ends at $t = t_m$ when the minimum distance between the centers of gravity is reached. Both vehicles now move with identical velocity v_m.

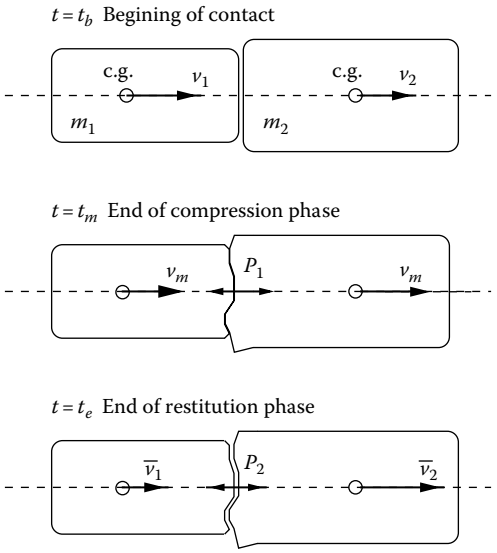

FIGURE 41.1 Definition of phases of a 1D impact.

From the conservation of momentum, it follows that at the end of the compression phase, an exchange of impulse P_1 has taken place between vehicle m_1 and m_2:

$$m_1(v_m - v_1) = -P_1 \quad \text{and} \quad m_2(v_m - v_2) = P_1. \tag{41.6}$$

A second phase, the restitution phase, follows, where deformation back-forming to some degree may take place and the vehicles move apart until the contact ends at $t = t_e$. At t_e, vehicle m_1 moves with velocity $\overline{v}_1$, and vehicle m_2 with $\overline{v}_2$ and $\overline{v}_2 \geq \overline{v}_1$ holds. Again, an exchange of an unknown impulse P_2 has taken place:

$$m_1(\overline{v}_1 - v_m) = -P_2 \quad \text{and} \quad m_2(\overline{v}_2 - v_m) = P_2. \tag{41.7}$$

Merely four equations (41.6 and 41.7) are available for the five unknown quantities v_m, $\overline{v}_1$, $\overline{v}_2$, P_1, and P_2. This dilemma can only be solved by an additional equation, that is, obtained from Newton's hypothesis, suggesting that a restitution coefficient k exists that relates P_1 to P_2:

$$P_2 = kP_1 \quad \text{or} \quad (\overline{v}_2 - \overline{v}_1) = k(v_1 - v_2). \tag{41.8}$$

Now, the final velocities $\overline{v}_1$, $\overline{v}_2$ after the impact can be calculated from

$$\overline{v}_1 = v_1 - \frac{(v_1 - v_2)(1+k)}{1 + m_1/m_2} \quad \text{and} \quad \overline{v}_2 = v_2 - \frac{(v_2 - v_1)(1+k)}{1 + m_2/m_1}. \tag{41.9}$$

Introducing a restitution coefficient k is a simple trick to overcome the mathematical problem of a missing equation but raises another difficulty: what value shall be inserted for k? When $k = 1$, a fully elastic impact is assumed. This may be valid in real accidents for collisions at very low speeds where only the bumpers are elastically deformed and fully restitute. The other extreme $k = 0$ (fully plastic impact) may hold for a high-speed collision with vehicles deformed and crushed beyond recognition. Obviously, k can be related to the relative velocity of the colliding vehicles (see [24]). Another possibility for the reconstructionist is to make a good guess, mainly based on the

deformations of the vehicles. Well-documented vehicle crash tests are probably the only way to gain sufficient experience and a solid base to make an educated guess when the coefficient of restitution needs to be determined. Some sources that may be helpful are [24] (www.crashtest-service.com) for the Old World and [18] for the New World. This differentiation is indicated, since vehicle models are still different in Europe and in the Americas.

While the total momentum is unchanged for the system of two colliding bodies and does not depend on the restitution coefficient, there is an energy loss for $k < 1$. This energy loss E_C of a partly inelastic impact can be calculated from

$$E_C = \frac{1}{2}[(m_1 v_1^2) + (m_2 v_2^2)] - \frac{1}{2}[(m_1 \overline{v}_1^2) + (m_2 \overline{v}_2^2)], \tag{41.10}$$

and with the solutions Equation 41.9, it follows

$$E_C = \frac{1}{2}(1-k^2)\frac{m_1 m_2}{m_1 + m_2}(v_1 - v_2)^2. \tag{41.11}$$

As one can see, this equation relates the dissipated energy to the coefficient of restitution. Therefore, one can also try to estimate the deformation energy, instead of guessing k, and solve the missing equation problem. In fact, this is another approach that became popular at the time when an almost linear relationship between residual deformation and impact speed [25] was found. Since then, large efforts have been made to analyze crash tests against barriers, obstacles, and other vehicles in order to determine the deformation (crush) energy and to transfer the results to other collisions of the same vehicle with similar deformations (see [26] and many other papers of this kind in [18]). Also, we will come back to this topic in Section 41.4.3.2.

The straight-line rear end collision was also used as the example to discuss the crash phase since it is an accident scenario that is frequently associated with whiplash injuries of the passengers in the vehicle in front. This kind of injuries has become very common in the past, partly because there is practically no visible evidence of this cervical spine trauma, making it very hard to prove or disprove the existence [27]. In particular, the accusation of fraud is associated with this injury. The accident reconstructionist is challenged since the probability of a whiplash injury of the passengers in a vehicle is linked to the velocity change $\Delta v = \overline{v} - v$. Therefore, the analysis of this seemingly rather simple to analyze accident scenario can become very tricky (see [28,29] for further discussion of biomechanical aspects). On the other hand, the automotive industry has also reacted, and, for example, the seat design is continuously improved to reduce the risk of whiplash injuries in rear accidents (see [30,31]).

41.3.3 Postcrash Phase

This phase starts when the last contact between crash opponents has ended and a vehicle or accident victim moves into its final position. Occasionally, it may be difficult to draw a clear line between the crash and the postcrash phases, especially with secondary and minor impacts after the main collision. The postcrash phase ends when the vehicle or its driver comes to rest. It is important to realize that vehicle and driver may separate during the crash phase and therefore their postcrash phases may be independent from each other. This occurs quite frequently for PTW's and their riders, but this may also happen to drivers of convertible cars. In rare cases, even drivers of regular cars are ejected, mostly when the safety belt was not used and the doors opened during the crash.

The final or end positions of the vehicles involved in an accident are often known, especially when vehicles are not mobile after a severe accident. Additionally, skid marks, scratches, and other traces give evidence of the path the vehicle did follow during this phase. Together with other evidences on the location of the crash, like kinks in skid marks, traces of fluids on the ground, pieces of

glass, or debris, it is quite often possible to identify the beginning, the end, and the path in between of a vehicle's postcrash phase. For pedestrians, drivers, or passengers, mostly, only the final position is known, since significant parts of the postcrash trajectory may be travelled in the air or at least without sufficient contact to the ground to create traces.

Since the postcrash phase generally is the one to offer the most reliable information and also the information suitable for an evaluation, the accident reconstruction frequently starts with the analysis of this part of the accident event. By going backward in time starting from the final position with all velocities being zero, the velocities at the beginning of the postcrash phase are sought. By employing a suitable mathematical model, it may be possible to find a numerical solution for the motion of the vehicle. Ideally, such a solution would reproduce the velocities at the beginning and also match with evidence (skid marks, spilled fluids, location of debris etc.) at the accident site.

In general, the motion of a vehicle in the postcrash phase will be a combination of longitudinal, lateral, yaw, and roll motions. Only in simple accident scenarios like a straight-line rear end collision, or a car hitting a pedestrian or a lightweight object, the longitudinal motion will be predominant. But even in these cases, a significant pitch motion may occur. The point is that other than for the precrash phase, the application of very simple models like the single DOF model as used in Section 41.3.1 is quite restricted, or, if applied nevertheless, the value of the results may be limited. Therefore, more elaborate models are needed that capture the postcrash motion in more details. For accidents with vehicles that do not roll or tip over, a model capable of describing the planar motion by the longitudinal, the lateral, and the yaw motion may be sufficient. If the roll motion is significant or if overturning occurs, then a 6-DOF model will be needed.

Two-wheeled vehicles are especially difficult to model during this phase, since overturning can be an essential part of the postcrash phase. It may occur simultaneously within the crash, immediately thereafter or after travelling some distance in a stable upright position.

Likewise, the postcrash motion of human beings and animals is quite complex. Phases of free flight with full translational and rotational motion of the main body, plus additional motion of extremities, are disrupted by contact with the ground or objects. In addition, possible muscular activity during this phase may affect the postcrash trajectory significantly. Due to the complexity of valid models and also the unknown inputs, in general, the analysis mainly relies on experimental data supplemented by an analysis based on very simple models [32]. There is, however, multibody system software for biomechanical systems available to simulate the complex motion of pedestrians and vehicle occupants to some extent (see Chapter 5). The application of such software may be indicated in special cases of an accident reconstruction.

41.3.4 Reconstruction Strategies

A common and main goal of an accident reconstruction is to determine trajectories and velocities of all participants and involved objects in the accident. This will enable the reconstructionist to answer questions about the speed and path driven by the vehicles involved and may explain the cause of a traffic accident and the liability of the participants.

The strategy to solve the reconstruction problem largely depends on the information and evidence available. First, one will try to determine vehicle positions and velocities at the beginning and at the end of the phase for which most data are accessible. Thereby unknown parameters will become available for an adjacent phase, and so the next phase can be dealt with. Since this approach separately treats each phase, it is possible to use different calculation methods and also different models for each phase. Ultimately, all three phases are solved for all participants in the accident and can be stitched together for a unified solution. This approach has the advantage that methods and models to analyze a phase can be selected according to the specific characteristics of an accident.

A different approach is used with some software tools (see Chapter 5) where numerical simulation is employed to solve the governing differential equations of the vehicle model. Due to the nature of this approach, initial state values and impact parameters have to be determined or assumed, and

then the sequence of phases is computed from beginning to end. The crash phase as the major discontinuity in this process is handled based on data provided initially or interactively. When the end position of a vehicle is reached, computations will be stopped. Now, the results have to be compared with information not used so far, for example, the final position of a vehicle. If the known (documented) final position matches the computational results reasonably well, and if other evidences fit in, then it can be assumed that a valid solution was found. If there are discrepancies, the assumptions need to be changed, and another try can be started as a second step in an iterative procedure that should converge toward the solution satisfying all verified information and evidence.

41.4 MODELS FOR ACCIDENT ANALYSIS

Mathematical vehicle models for the analysis and reconstruction of vehicle accidents are, in principle, not different from the models used in other investigations of vehicle dynamics. There is, however, the need for rather small models for several reasons. First of all, with increasing complexity, also the number of necessary input parameters increases. Often, such data are not available and cannot be investigated. Consequently, assumptions need to be made, which can make a more accurate model less faithful and diminish the original advantage of the detailed model. Secondly, such models must not cause undue computational time on a desktop computer. This aspect is important since calculations need to be carried out numerous times if the solution can be found only by an iterative procedure.

Another issue with accident analysis models is the area of validity with regard to the range of certain parameters. Since the motion of a vehicle can be quite extreme, especially in the postcrash phase, fully linear models cannot be used in most cases. Dynamic parameters of the vehicle like tire slip angles may take on any value between 0 and $\pi/2$ during skidding, and a linear tire characteristic would be inappropriate.

In the following sections, an overview will be given on the modeling of vehicles, particularly with regard to passenger cars. The content focuses on the main modeling issues, the vehicle as a whole, the tire characteristics, and the collision event. Considering other vehicles like motorcycles and semitrailers would go beyond the scope of this chapter, and one may check the listed literature for details on other vehicles.

41.4.1 Vehicle Models

Typically, vehicle models with a low number of DOFs are in use. Either the analytical solution of the differential equations describing the model is employed or the solution of the equations is sought by a numerical time-stepping routine.

41.4.1.1 Kinematic Models

Kinematic models are based on 1-DOF models of a single mass. If the acceleration of mass m is assumed to be a constant parameter a, the governing equation of a linear motion in direction x becomes

$$m\ddot{x} = ma = \text{const.} \tag{41.12}$$

and can be solved analytically on the time interval $t = [t_i, t_e]$. For a given initial distance x_i and initial velocity v_i at initial time $t_i = 0$, one obtains

$$\dot{x}(t_e) = v_e = at_e + v_i \quad \text{and} \quad x(t_e) = d = a\frac{t_e^2}{2} + v_i t_e + x_i. \tag{41.13}$$

These basic equations can be converted, and additional relations can be derived as shown in Equations 41.1 through 41.5. Many fundamental problems in accident analysis can be investigated by applying these equations. This approach can also be used for the motion on a circular path,

lane-change maneuvers, and others. Note that the key point and essential simplification in this example is to assume the acceleration a to be constant within the time interval $t = [t_i, t_e]$. Different assumptions, for example, a linearly increasing acceleration or a constant velocity, can be prescribed as well, and analytical solutions derived.

It is important to realize that the forces needed to bring about a certain enforced motion do not appear in the solution of Equations 41.1 through 41.5 and 41.13. Therefore, one has to verify that implied conditions on, for example, braking or cornering forces do not exceed physical limits.

The advantage of such kinematic models is their simplicity, which makes coding easy and facilitates the usage in spreadsheet programs and other software of that kind. The drawback clearly is that only simple cases of motional behavior can be analyzed and kinetic models must be used for more complex situations.

41.4.1.2 Kinetic Models

Kinetic models, by some authors also termed dynamic models, are represented by differential equations for single- or multibody systems based on Newton's laws. These equations of motion are well known from other chapters and are repeated for completeness in a general matrix notation:

$$\mathbf{M}(\mathbf{q})\ddot{\mathbf{q}} = \mathbf{F}(\dot{\mathbf{q}}, \mathbf{q}, t). \tag{41.14}$$

Vector $\ddot{\mathbf{q}}$ is the second time derivative of the generalized position vector $\mathbf{q}$ of length n, which contains translational and rotational displacements, associated with the n DOFs assumed for the system. Typically, 3-DOF planar systems with $\mathbf{q} = [x,y,\phi]^T$ are used for vehicles models, allowing for longitudinal and transversal motion $\dot{x}$, $\dot{y}$ and the yaw motion $\dot{\phi}$ (see [7,22]). Very few 6-DOF models that account for the full motion of the main vehicle body are employed. Complex multibody models for single vehicles, as frequently applied in vehicle dynamics analysis, are rarely used, due to reasons as outlined before. Vehicle combinations, for example, trailers attached to trucks or cars and articulated vehicles, need, of course, models with additional DOFs.

In Equation 41.14, matrix $\mathbf{M}(\mathbf{q})$ represents the mass matrix of the system, containing the mass and the rotational inertia properties of the system. For a rigid-body vehicle, this matrix is constant $\mathbf{M}(\mathbf{q}) = \mathbf{M}$; however, with multibody models, it may depend on the system states.

The complexity of such models, even for 3-DOF planar systems, lies in the right-hand side of Equation 41.14, which contains all external forces acting on the system and gyroscopic forces as well, if present. Noticeable external forces during the pre- and the postcrash phase result from aerodynamic forces $\mathbf{F}_{aero}(\dot{\mathbf{q}}, \mathbf{q})$ and from tire forces $\mathbf{F}_{tire}(\dot{\mathbf{q}}, \mathbf{q}, t)$. The latter constitute the most dominant forces that determine almost exclusively the motion of the vehicle during the noncrash phases. Tire forces are determined from mathematical models describing the tire behavior under various conditions and will be discussed in the next section.

Aerodynamic forces depend largely on the speed of the vehicle since they increase with the square of the relative velocity to the air mass. For high-speed accidents, they may be important and can be taken into account by respective forces and moments acting along the principal axes of the vehicle body. These forces and moments can be calculated from aerodynamic coefficients like for drag and lift (see [33]).

41.4.2 Tire Force Models

Except during the crash phase, tire forces are the most important forces to operate on the vehicle during a vehicle accident. Therefore, its motion is essentially determined by these forces, and their accurate calculation is of utmost importance. It is the role of a tire force model to calculate the forces and moments acting within the tire–road contact area and provide them for the vehicle model. In the past, numerous tire force models have been developed and reported. A recent compilation of such models is found in [34] and a model performance test in [35]. A suitable tire force model, however,

must be tailored to the particular needs of accident reconstruction. The main requirements are the validity for large values of longitudinal slip and of side slip, scalability to suit different tire sizes, ease of application, and, last but not least, fast numerical calculation.

Generally speaking, the tire force model is a mathematical function that computes the forces and torques needed for the vehicle model from a set of input parameters:

$$\mathbf{F}_{tire} = [F_x, F_y, M_y]^T = \mathbf{f}(F_z, \dot{x}_T, \dot{y}_T, \dot{\phi}_T, \omega_T, p_1(t), t, \ldots, cp_n(t)). \tag{41.15}$$

Equation 41.15 is a generic formulation of such a model, which computes the longitudinal and lateral tire forces F_x and F_y, respectively, as the most important forces needed. To account for the rolling resistance, the moment M_y may also be computed. The other moments M_x and M_z acting on the tire are rarely applied to accident reconstruction models, except for single-track vehicles.

Note that the vertical tire force F_z is an input parameter to the model. Other input parameters are the angular velocity ω_T and the longitudinal and lateral velocities $\dot{x}_T$, $\dot{y}_T$ that determine the actual longitudinal and lateral slip as the characteristic operating parameters of a tire. Some input parameters $p(t)$, like a steering input by the driver, may depend on time t; others may be assumed constant in certain regions of the solution domain, for example, the tire–road friction parameters; and some are simply numerical parameters of the model. Due to the nonlinear behavior of the tire, especially when operated at limit situations, most tire force models cannot be represented by just one universal function **f** as it may appear from Equation 41.15. In fact, the tire force model **f** may consist of a set of s functions $\mathbf{f}_{1,\ldots,s}$ that account for different ranges of the operating parameters.

In regard to the complexity of most tire force models on one hand and the comprehensive discussion of the tire as a vehicle component in Part III of this handbook on the other, a brief overview on current state-of-the-art tire force models is given in the following. It is based on a very detailed treatise [36] on various tire force models as currently used in vehicle accident reconstruction software. Since elaborate tire force models are needed primarily in accident simulation software, there is a strong tie between such software and tire force models.

41.4.2.1 "Magic Formula" Tire Force Model

This tire force model is comprehensively discussed in Chapter 17 and in [37]. In the literature originating from the New World, the model is also referred to as the Bakker–Nyborg–Pacejka (BNP) model, because of Ref. [38]. The *magic formula* described therein is capable of calculating the characteristics of side force, brake force, and self-aligning torque. The mathematical representation is limited to steady-state conditions during either pure cornering or pure braking and forms the basis for a model describing tire behavior during combined braking and cornering. Its versatility can be seen from the fact that it can be not only used for general vehicle dynamic analysis but also adapted and used for vehicle accident reconstruction.

41.4.2.2 VCRware Tire Force Model

This tire force model is based on a subset of the BNP model [38]. For combined longitudinal and lateral forces, the Nicolas–Comstock–Brach (NCB) equations are employed (see [7,39]). A characteristic feature of the model is that it consists of functions for the longitudinal and the lateral tire forces $F_x(\alpha, s)$ and $F_y(\alpha, s)$ that are continuous functions over the entire range of the lateral slip angle ($0 \le \alpha \le \pi/2$) and the longitudinal slip ($0 \le s \le 1$) from a free rolling to a locked wheel. This tire force model is used in the accident simulation software VCRware (vehicle crash reconstruction software) (see Section 41.5).

41.4.2.3 PC Crash Linear Tire Force Model

The accident simulation software PC Crash (see Section 41.5) offers and works with two different tire force models, a "linear" model and the TMEasy tire force model (see the next section). The "linear" model is not an entirely linear model, but it approximates the nonlinear tire characteristics by piecewise linear and almost linear functions and is hence termed "linear model" within PC Crash.

Longitudinal and lateral tire forces are defined within three regions of the lateral slip angle α. The lateral force F_y increases linearly within the first region ($0 \leq \alpha \leq \alpha_{max}$) and remains constant at the friction limit in the second region beyond α_{max}. The longitudinal tire force F_x is at the maximum value in region I and II. Region III begins when F_x and F_y both reach the friction circle. Both forces are linked together in region III by the equations for the friction circle for a fully skidding tire with slip angles $\alpha \leq \pi/2$. See [22] or [36] for a full discussion of the modeling aspects.

With less equations to evaluate and less harmonic functions to compute, this model has the advantage of fast numerical computation. Of course, there is a price to pay. Compared to other models, the approximation of the tire characteristics is of lesser quality in certain regions of the parameter range [36].

41.4.2.4 TMEasy Tire Force Model

The TMEasy tire force model is presented in full details in [40,41]. It is a rather sophisticated semiphysical tire model that is suitable for planar motion as well as for full 3D motion of a vehicle. TMEasy calculates the contact force characteristic in longitudinal and lateral direction from a rather small number of physical parameters. The combined force characteristics are directly generated via a generalized slip approach. With this model, also the tire loads as the third component of the tire contact forces can be computed. In addition, and not available with most other models, self-aligning moment, rolling resistance moment, and also the bore moment (torque) can be determined.

Furthermore, another feature distinguishes the TMEasy model; it includes nonlinear first-order dynamics for longitudinal and lateral forces and for the aligning moment. From the viewpoint of model fidelity, this is a clear advantage of this model, since highly transient vehicle motions regularly occur during postcrash motion.

The integration of TMEasy into other software is facilitated by a standard tire interface (STI). TMEasy and some of its derivatives are used in various simulation software for vehicle dynamics, among them the accident reconstruction program PC Crash. Taking advantage of all features of the tire model only makes sense with an adequate vehicle model and results in comparably slow execution time.

41.4.2.5 Other Tire Force Models

Due to the need of an appropriate tire force model in a vehicle accident simulation program, each of these programs has their own tire model, which is mostly developed as variations of previously existing models. The software SIMON (see Section 41.5.1) uses a semiempirical model based upon the widely used HSRI tire model [42], which is known for quite a long time. Another program, SMAC, uses a tire force model, which has its root in an even older model by Fiala [43] and is discussed in [7].

41.4.2.6 Evaluation and Comparison of Tire Force Models

This list, although incomplete, shows that there are quite a number of different tire force models in use. As pointed out already, the tire forces determine the vehicle motion during the postcrash phase to a great extent. Therefore, tire force models play an important role in the process of analyzing and reconstructing a vehicle accident by numerical methods.

Nevertheless, there is no procedure available to validate such tire models or to check them for correctness. Crash tests have been used in the past to test and benchmark simulation programs, but such comparisons involve the entire vehicle model including the tire model. In [36], a first attempt was made to highlight the influence of tire models. The use of simulation models with different tire models but identical initial conditions led to quite different final positions after postcrash motions under various conditions of locked wheels and brake application. In the interest of comparable and reproducible results, establishing benchmarks for tire models and standards for the definition of tire parameters should be a goal for the future.

41.4.3 Crash Models

During a vehicle-to-vehicle collision, forces that are several magnitudes higher than during the pre- or the postcrash phase act in the contact area. Moreover, this happens typically within a few tenth of a second. Therefore, compared to the other phases, the crash phase needs to be treated differently.

The goal of a crash model is to calculate the states of the vehicle(s) immediately after the crash, based on the states when the crash phase starts. There are two major and quite distinct approaches possible:

- Models based on the mechanics of impacting rigid bodies, which implies an infinitely short contact time with infinitely high forces acting in the contact interface
- Models that resolve the contact in the time domain, calculate the contact forces, and apply them to the colliding objects

The first approach has the clear advantage that only a few algebraic equations need to be solved. Modeling the collision of vehicles by impacting rigid bodies, however, implies stringent conditions, which either limit the applicability considerably or are ignored in an undue manner. The second approach certainly captures the actual mechanical processes much better and gives more realistic results. The drawback is the enormous computational time for really detailed models. In addition, all but the manufacturer of a vehicle will mostly fail with this approach due to the lack of specific data needed, if one wants to take full advantage of the model. However, in recent years, there has been progress made in developing mesh methods that are a compromise between model fidelity and numerical effort (see Section 41.4.3.3).

The topic of modeling the collision of vehicles is covered by extensive literature. Comprehensive references directly related to the reconstruction of vehicle accidents are [7,10,22,23,44] and others. For an in-depth study of the topic, these books will be valuable sources.

41.4.3.1 Planar Impact Mechanics

As a first example of impact mechanics, the 1D impact between vehicles was already discussed in Section 41.3.2. Here, the most widely used governing equations for planar impact mechanics of vehicles are presented, and the basic assumptions are discussed. As outlined, impact models consist of a set of algebraic equations that constitute a relation between the linear and the angular velocities v, ω before the impact and $\overline{v}$, $\overline{\omega}$ afterward. Part of this set of equations are the well-known planar impulse–momentum equations with the change of momentum on the left-hand side and the contact impulse components P_n and P_t on the opposite side:

$$m_1(\overline{v}_{1n} - v_{1n}) = P_n, \quad m_1(\overline{v}_{1t} - v_{1t}) = P_t, \tag{41.16}$$

$$m_2(\overline{v}_{2n} - v_{2n}) = -P_n, \quad m_2(\overline{v}_{2t} - v_{2t}) = -P_t. \tag{41.17}$$

For a general planar motion (see Figure 41.2), where the rotational motion of the colliding bodies is also considered, additional equations can be derived for the change in angular momentum for each vehicle that must be equal to the moment of the contact impulse:

$$I_1(\overline{\omega}_1 - \omega_1) = P_t n_1 - P_n t_1, \tag{41.18}$$

$$I_2(\overline{\omega}_2 - \omega_2) = -P_t n_2 + P_n t_2. \tag{41.19}$$

With six equations for eight unknown quantities $(\overline{v}_{1n}, \overline{v}_{1t}, \overline{v}_{2n}, \overline{v}_{2t}, \overline{\omega}_1, \overline{\omega}_2, P_n, P_t)$ in the general planar case, now two equations are missing (one more compared to the 1D case) to solve the problem.

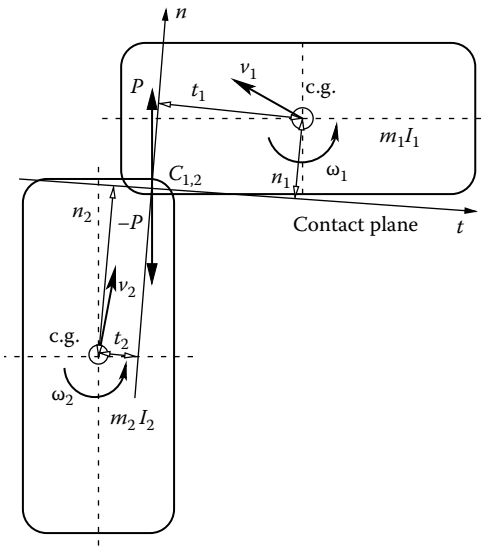

FIGURE 41.2 Planar impact mechanics of two colliding vehicles.

With the contact impulse vector $\mathbf{P} = [P_n, P_t]^T = \mathbf{P_1} + \mathbf{P_2}$, we can again relate the restitution impulse $\mathbf{P_2}$ to the impulse during the compression phase by a coefficient of restitution k and obtain

$$\mathbf{P_2} = k\mathbf{P_1}. \tag{41.20}$$

By eliminating the restitution impulse, we get components in normal and tangential direction to the contact plane for the contact impulse:

$$P_n = P_{1-n}(1+k), \tag{41.21}$$

$$P_t = P_{1-t}(1+k). \tag{41.22}$$

Obviously, there are still too many unknowns, and a second hypothesis is needed. It will be a kinematic assumption concerning the relative velocity $\Delta\mathbf{v_c} = [\Delta v_{c-n}, \Delta v_{c-t}]^T$ of the congruent contact points C_1,C_2 on the vehicles 1 and 2. This relative velocity is

$$\Delta v_{c-n} = v_{1n} - \omega_1 t_1 - (v_{2n} + \omega_2 t_2), \tag{41.23}$$

$$\Delta v_{c-t} = v_{1t} + \omega_1 n_1 - (v_{2t} + \omega_2 n_2). \tag{41.24}$$

We will assume that the direction of this relative velocity at the beginning of contact will be constant within the compression phase:

$$\frac{\Delta v_{c-t}}{\Delta v_{c-n}} = \text{const.} \tag{41.25}$$

This is the essential assumption of the frequently so-called *Kudlich–Slibar impact model* [45]. It is important to realize that the direction of $\Delta\mathbf{v_c}$ is not the direction of the impulse $\mathbf{P}$. Nevertheless, based on Equation 41.25, one can derive the appropriate contact impulse components (see [45]):

$$\Delta v_{c-n} = hP_{1-t} - c_n P_{1-n}, \tag{41.26}$$

$$-\Delta v_{c-t} = c_t P_{1-t} - h P_{1-n}, \tag{41.27}$$

with constants

$$\begin{aligned} c_n &= \frac{1}{m_1} + \frac{1}{m_2} + \frac{n_1^2}{I_1} + \frac{n_2^2}{I_2} \\ c_t &= \frac{1}{m_1} + \frac{1}{m_2} + \frac{t_1^2}{I_1} + \frac{t_2^2}{I_2} \\ h &= \frac{t_1 n_1}{I_1} + \frac{t_2 n_2}{I_2}. \end{aligned} \tag{41.28}$$

By rearranging the equations and inserting Equation 41.21, we get the final result:

$$P_n = (1+k)\frac{\Delta v_{c-n} c_n + \Delta v_{c-t} h}{h^2 - c_n c_t}, \tag{41.29}$$

$$P_t = (1+k)\frac{\Delta v_{c-n} h + \Delta v_{c-t} c_t}{h^2 - c_n c_t}. \tag{41.30}$$

With Equations 41.16 through 41.19, 41.23, 41.24, 41.29, and 41.30, the problem is solvable and the unknown quantities can be calculated.

Most impact models for vehicle collisions are either identical to this model or very similar (see, e.g., [7,22,44]), although the explanation of the underlying ideas may read somewhat different.

As with every model, it is important to be aware of its limitations. Note the resultant impulse ratio:

$$\frac{P_t}{P_n} = \frac{\Delta v_{c-n} h + \Delta v_{c-t} c_t}{\Delta v_{c-n} c_n + \Delta v_{c-t} h} = f \quad \text{hence } P_t = f P_n, \tag{41.31}$$

which relates the tangential impulse to the normal impulse. The assumption Equation 41.25 implies that this ratio can be achieved in the contact area. However, this is only possible if the friction condition is such that the local friction coefficient μ exceeds the impulse ratio $f \leq \mu$. Only then, tangential forces of the necessary amount can be developed in the contact area, and Equation 41.25 is a valid assumption. If this is not the case, a sliding contact may have occurred, and the tangential forces (and hence impulses) are limited by the friction coefficient. Strictly speaking, Equation 41.25 is violated and other assumptions must be made. To get around this difficulty, various strategies have been proposed (see again the literature as mentioned so far).

Another crucial question is the location of the contact point. Ideally, the impact model holds for very small deformations. In practice, the deformations are quite often rather large, and therefore it may be difficult to define the contact "point." Its location, however, defines the distances and arms n_1, n_2, t_1, and t_2 and has a direct and decisive influence on the calculation and the results. This becomes especially important in head-on accidents with a small offset of the colliding vehicles. Such accident scenarios are extremely sensitive to the mentioned geometric parameters and need careful analysis. The model is also not suited well for very large offsets either, because then a sliding collision will occur with no distinct restitution phase at all.

Despite all drawbacks and pitfalls, this crash model or one of its varieties is very popular and used in many software packages for accident reconstruction (see Section 41.5).

41.4.3.2 Energy-Based Methods

The crash model presented in the previous section only accounts for the deformation of the vehicles by the coefficient of restitution. All the information about the permanent deformation of the vehicle and the energy dissipation is condensed in this parameter. It suggests itself to analyze these deformations thoroughly and extract additional information about the collision. Car manufacturers do this regularly during the design process of a new vehicle model, when crash tests are carried out and at the same time large finite element (FE) models of the vehicle are used to simulate the crash test on the computer and bring both results in agreement. For an accident reconstruction, it is almost never an option to do a full scale FE analysis of the crash, since such FE models are not available to the reconstructionist in general and creating them would be very difficult, too time-consuming, and expensive.

In the past, there have been attempts, however, to drastically reduce the complexity of the problem and relate the shape of the deformed vehicle to the energy consumed to produce the residual deformations. Starting out from the fixed rigid-barrier tests carried out with passenger cars at various speeds, the test results suggested an almost linear relationship between residual deformation and impact speed [46]. The studies finally led to a well-known relation [47]:

$$\sqrt{\frac{2E_C}{L}} = c_0 + c_1 D, \tag{41.32}$$

which relates the deformation (crush) energy E_C per unit length L to the residual deformation dD measured perpendicular to the original and undeformed surface of the vehicle body. Two constants c_0 and c_1 are to be determined experimentally, however, and are different for each vehicle and even different for each location (front, rear, and side) of the deformation.

The adaption of these findings to real-world car to car accidents and with approach directions other than head-on led to a method named CRASH3 [48]. The basic idea of the method is to start out from a contour line (horizontal projection) of the vehicle before and after the crash (see Figure 41.3). Typically, the deformations at six points along the destroyed contour are taken, and from these measurements, the crush energy is computed (see, e.g., [47]), from

$$E_C = c_0^2 K_1 + c_0 c_1 K_2 + c_1^2 K_3, \tag{41.33}$$

where

$$K_1 = \frac{L}{2} \tag{41.34}$$

$$K_2 = \frac{L(D_1 + 2(D_2 + D_3 + D_4 + D_5) + D_6)}{10} \tag{41.35}$$

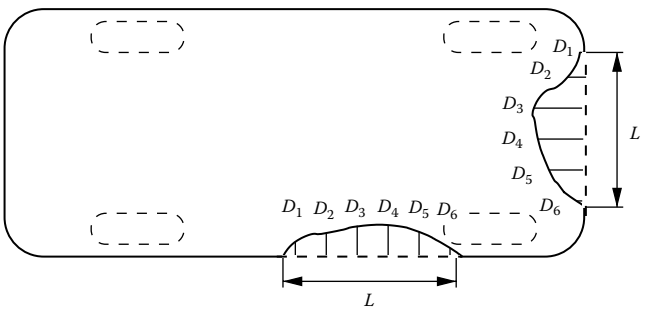

FIGURE 41.3 Estimation of deformation energy from vehicle deformations.

$$K_3 = \frac{L(D_1^2 + 2(D_2^2 + D_3^2 + D_4^2 + D_5^2) + D_6^2)}{30} + \frac{L(D_1D_2 + D_2D_3 + D_3D_4 + D_4D_5 + D_5D_6)}{30}. \quad (41.36)$$

Note that still two parameters c_0 and c_1 need to be known or estimated for a specific vehicle to make use of this method.

Once the deformation energy E_C is calculated, it depends on the kind of impact configuration how to proceed. For a 1D collision with both vehicles moving in the same or opposite direction, the impact problem can be solved immediately (see Section 41.3.2). The deformation energy substitutes for the coefficient of restitution, as introduced in Equations 41.8 and 41.10, can be used as the additional equation needed to complete the momentum equations and to get a solvable system of algebraic equations.

In the case of a general planar impact (2D) or a 3D-impact configuration, the information about the deformation energy is not sufficient to solve the respective impact problem. The equations for the conservation of the linear and the angular momentum need to be supplemented by additional assumptions as this was the case in the previous section. In crash models, frequently, such assumptions are part of the algorithm and not always obvious to the user. A typical example and a general weakness of this approach is the assumption that the entire dissipated energy is equal to the deformation energy. This is especially not true in cases with large frictional forces in the contact area during the collision, like in head-on collisions with a large offset and substantial sliding contact between the vehicles. The CRASH3 model also assumes a perfectly inelastic collision with no restitution of the vehicles perpendicular to the deformed surface. This assumption is also known as the so-called common-velocity condition, since the velocities will be identical at the contact zone after contact for a fully inelastic impact.

Therefore, the velocity changes of the vehicles can be computed in different ways, depending on the details of the crash model (see Ref. [7] for a discussion of this issue). Several such models that calculate the deformation energy are based on the CRASH3 model, which was the first fully developed model of this kind. In the past, modifications and extensions had to be made to make the model more versatile, especially for 3D applications. This aspect will again appear in Section 41.5.

The rather simple method of calculating the deformation energy from measurements at six points along the deformation zone has, of course, called for more sophisticated methods. To mention one of them, in [49], the authors divide the projected deformation area into cells, which they associate with a certain amount of energy necessary to crush this cell. The cell energy data need to be known in advance from crash tests and can be used to estimate the total energy dissipated during the collision for this vehicle. Improved results for the calculated deformation energy can be only expected if the vehicle crash data are adequate.

From these two examples, it already becomes quite clear that evaluating the deformation of vehicles with the goal to calculate the dissipated energy is not a trivial task either. For the most simple model, two vehicle-specific parameters are needed, and more sophisticated models need a lot more data, in addition to the measurements of the deformation area. Therefore, it largely depends on the information available which approach suits best for a certain problem.

41.4.3.3 Alternative Methods

In the two previous sections, two principle approaches of modeling the collision of vehicles were discussed. Both approaches have in common that the collision is treated as an impact, which implies several assumptions. Among them is the presumption that the contact duration is negligible and can be assumed to be zero, which has the consequence that the contact forces become infinite and cannot be calculated directly. For certain accident configurations, this presumption and others involved with the impact model do not hold completely. For example, head-on collisions with a large offset lead to prolonged contact times and significant frictional sliding contact between the colliding vehicles and are basically unsuitable for the impact model.

To overcome the typical deficiencies of the impact model, the only loophole is to resolve the collision in the time domain. As a consequence, rigid bodies cannot be used anymore, and rather than that deformable bodies with appropriate material properties must be introduced. Commonly, this is achieved by some kind of FE approach where the vehicle body or at least the contact area is discretized by deformable structural elements. Another necessity of such models are contact elements on both contacting surfaces to generate the respective contact forces.

The advantage of a more appropriate and reliable model is bought with much more time-consuming numerical calculations. Not only the computational speed is an issue, but also data acquisition and FE-mesh generation add to the additional time needed for an accident analysis. This has led to the development of so-called mesh methods that shall avoid the disadvantages of full FE models but shall be more versatile than simple spring–damper models. An example for this approach is the "DyMESH method" (see [50,51]). It is based on a collision algorithm that uses a triangular mesh defined by the discretized exterior of a vehicle. A possible contact between two meshes is detected by monitoring the positions of nodes of one mesh with respect to the nodes and surface elements of the other mesh. On contact, the interacting 3D forces are generated from vehicle material properties.

Due to the complexity of such mesh models, they can only be used in combination with an elaborate vehicle simulation model (see Sections 41.5.1 and 41.5.2).

41.5 SOFTWARE TOOLS FOR ACCIDENT ANALYSIS

Graphical methods have been in use for a long time in accident reconstruction. But since powerful computers have become available for the reconstructionist, more and more work during an actual accident analysis and reconstruction is performed with the help of computers and software.

The process of an accident analysis and reconstruction involves a number of tasks, starting from the evaluation of evidence including extraction of information from photographs, inspection of vehicles, and data acquisition to the point of the reconstruction of the motion of the vehicles and, where applicable, the accident victims. During almost all of the necessary steps, computers can be helpful in some ways. Therefore, quite a large number of software products are available to the reconstructionist for various tasks [8], covering vehicle dynamics and crash analysis in the first place, but also other important tasks like photogrammetry, image restitution, and calculation of repair costs, to mention a few.

In the following, only software to analyze the motion of vehicles or the collision will be briefly introduced. The primary purpose is to direct the interested reader to some of the most popular software tools. But one might also benefit from this compilation in that it shows the variety of aspects relevant in accident reconstruction. This list of software, however, is incomplete and does not relieve the reader from thoroughly checking what software is available for his or her specific needs. Also, the sequence of the software listed has no special relevance and is simply in alphabetic order.

41.5.1 HVE AND HVE-2D

HVE (human–vehicle–environment) and its constricted version HVE-2D are both products of Engineering Dynamics Corporation (EDC), located in Beaverton, Oregon. The following overview and product description reflect the product's development status when this book was published and is largely based on information and material available from the company's website [52].

Rather than a single simulation program, HVE is a complete 3D simulation environment for setting up and executing simulation modules to study a variety of safety issues related to passenger and commercial motor vehicles, such as dynamic handling behaviors, effects of road conditions, systems failures or driver reactions, and real-world crashes including underrides and rollovers or involving occupants or pedestrians.

By using various program modules specifically designed to take advantage of the capabilities found in HVE, one can perform studies to evaluate the dynamic handling behavior of vehicles, design and test the effectiveness of vehicle braking systems, study driver response to transient effects caused by tire blowouts or irregular terrain, simulate vehicle-to-barrier and vehicle-to-vehicle crash tests, simulate real-world crashes, and identify potential sources of occupant injury resulting from those same crashes.

A number of the so-called editors within HVE allow to move freely between model setup (human, vehicle, and environment), event management, and results. Additionally, HVE offers an extensive feature set available in several HVE-compatible simulation programs. These features allow for advanced simulation of vehicle control systems, driver reactions, tire or brake system failures, and 3D collision modeling. Each HVE-compatible physics program is an independent program running inside the HVE simulation environment.

41.5.1.1 Program Modules Compatible with HVE

The most important models for accident analysis in the HVE environment are listed in the succeeding text. Note that the program modules EDVSM, EDVSD, and SIMON use 3D features and are therefore not compatible with HVE-2D, which is basically a version of HVE that allows only to use planar vehicle models and is restricted to three DOFs for each vehicle:

- *EDCRASH* is a reconstruction program module for single- or two-vehicle accidents, including collisions. The main purpose is to determine the impact speeds and delta-V velocities based on accident site evidence and vehicle damage measurements. This module is also usable for collisions with immovable barriers, such as bridge abutments and large trees. While EDCRASH has been extended and revalidated for use in HVE to account for 3D terrain, it is essentially a 2D reconstruction program.
- *EDSMAC4* is a simulation program module for vehicle collisions. Based on EDSMAC, EDSMAC4 includes numerous extensions developed by EDC. Any number of vehicles, trailers, and/or barriers may be included. Simultaneous collisions between any numbers of objects are allowed. The original SMAC collision model has also been extended significantly and now includes different stiffness parameters for each side of the vehicle, as well as direct support for barrier collisions. It also provides features for occupant crash simulations (see EDHIS and Articulated Total Body (GATB) in the succeeding text). While EDSMAC4 has been extended and revalidated for use in HVE to account for 3D terrain, EDSMAC4 is essentially a 2D reconstruction program.
- *EDVSM* is a simulation program module for the true 3D dynamic response of a motor vehicle to driver inputs and 3D road conditions. Based on the HVOSM-VD2 model developed at Calspan, EDVSM incorporates enhancements, including a tire–terrain interaction model and a tire blowout model. The user has to enter initial position, velocity, and driver controls. The program will calculate the 3D vehicle kinematics, the tire forces and moments, the suspension forces and deflections, the aerodynamic forces, and the drive and brake system torques. Vehicle body versus terrain interaction is also modeled by calculating the force between the vehicles 3D mesh (see Section 41.5.1.2) and the terrain mesh. With EDVSM, a vehicle may be simulated driving on virtually any surface under any conditions, including airborne vehicles and complete vehicle rollover.
- *EDVDS* is a simulation program module for the 3D dynamic response of a commercial vehicle to driver inputs and 3D road conditions. A tow vehicle and up to three trailers may be simulated. EDVDS is an extended version of the phase 4 program developed at UMTRI, and its features are comparable to those of EDVSM.
- *SIMON* is another simulation program module for the 3D dynamic response of one or more vehicles to driver inputs, intervehicle collision(s), and factors related to the environment. SIMON is a newly developed simulation module, using a new, general purpose 3D vehicle

dynamics engine (see [53,54]). The dynamics engine allows a sprung mass with six DOFs and multiple axles with up to five DOFs per axle. The user assigns initial position, velocity, and driver controls for each vehicle. Trailers and dollies are automatically positioned behind a tow vehicle according to connection compatibility and location. SIMON then predicts the motion of each vehicle's sprung mass and the motions of the unsprung masses, suspension dynamics, tire dynamics, and current brake system parameters at each wheel. Vehicle body damage from a collision simulation is also calculated and displayed using HVE's 3D viewers. SIMON was specifically designed to take advantage of the advanced features available in the HVE simulation environment.

- *EDHIS* is a simulation program module for the 3D analysis of the response of a human occupant during a motor vehicle collision. EDHIS is based on the HSRI 3D model developed at UMTRI and includes several extensions and refinements. It employs airbag and belt (torso and lap) models suitable to study issues related to restraint system effectiveness. EDHIS is a 12-DOF analysis, dividing the human body into three masses (head, torso, and lower extremities) and two joints (neck and hips). The body is visualized using the HVE 15-segment/14-joint human model.
- *GATB* is a 3D computer model based on the computer program ATB. The GATB model may be used to study occupants or pedestrians involved in motor vehicle collisions. GATB represents the human body with 15 segments and 14 joints. The GATB model has 48 DOFs for each human. Each of the 15 mass segments can move and interact with the environment. GATB computes human kinematics, joint angles and torques, contact forces between the human and contact panels attached to the vehicle, and contact forces between humans or between a single human's limbs. By using GATB, up to four human models can be placed inside a car during a crash to predict how the humans would move, what part of the interior of a car they would hit, or how an ejection could occur. GATB can also simulate a human body being struck by a vehicle's exterior to study pedestrian impacts.

41.5.1.2 Advanced Features in HVE

- *DyMESH*: A computer model for 3D dynamic simulation of motor vehicle crashes. DyMESH employs methods from FE technology for collision detection and stress–strain relationships for force calculation. DyMESH uses a 3D vehicle mesh with mechanical properties as input and produces vehicle-fixed collision forces and moments as output. The output from DyMESH is then used by the vehicle simulation module along with suspension forces, aerodynamic forces, and intervehicle connection forces to produce the total vehicle-fixed forces and moments acting on the vehicle at each time step. Whereas a full FE analysis requires several hours or even days, a simulation using DyMESH is completed in a few minutes.

  DyMESH is useful for all collision simulations and is especially useful for underride or any crash where 3D collision dynamics are present. Detailed validation results can be found in [50,51].
- *HVE driver model*: This is a closed-loop driver model, allowing users to define an attempted maneuver and have the simulation determine the required steering inputs to make the vehicle follow the defined path. Typical examples include single and double lane-change maneuvers. The HVE driver model may also be used to study the effects of driver fatigue and intoxication.
- *HVE steer* DOF *model*: It allows users to study how hands-off steering affects vehicle trajectory. The steering inputs used in the simulation are calculated from the interaction of the vehicle's tires travelling over and interacting with the 3D terrain model defined by the user. An obvious application of the steer DOF model is the postcollision motion of a vehicle.
- *HVE tire blowout model*: A model that provides detailed information regarding the transient nature of a vehicle's response to a tire blowout that occurs during any maneuver.

- *Other models*: The *ABS model* simulates the ABS system on an actual vehicle. The *Brake Designer* includes the capability to study brake fade characteristics. The *Radial Spring Model* allows for simulating tires mounting curbs and rolling over potholes. The *Sidewall Impact Model* allows for a rigorous modeling of the forces applied to the sidewall of a tire such as occurs in a curb-tripped rollover. The *Soft Soil Model* allows for calculating tire drag for a vehicle that has left the roadway and is travelling through soft dirt.

41.5.2 PC Crash

PC Crash and its constricted version PC Crash 2D are both products of Dr. Steffan Datentechnik (DSD), located in Linz, Austria. The programs are distributed in North America by MEA Forensic Engineers & Scientists, located in Richmond, Canada, and by several distributors in Europe (see the webpage [55]). The following overview and product description reflects the product's development status when this book was published and is based on information and material available from the product websites [55,56].

PC Crash is a MS-Windows-based 3D collision and trajectory simulation tool that enables the analysis of a wide variety of motor vehicle collisions and other incidents. Collisions with up to 32 vehicles can be simulated in 2D and also in 3D. Car-to-car accidents, car-to-motorcycle accidents, car-to-pedestrian accidents, occupant movement, and also rollover can be investigated. Currently, PC Crash is maybe the most popular accident reconstruction program with more than 2700 installations in countries around the world.

The basic models and features of PC Crash are summarized briefly:

- *Impact models*: PC Crash uses the Kudlich–Slibar impact model [22,45] as the primary tool for collision analysis. Primary and secondary impacts are detected automatically. Secondary impacts can have different properties than specified for the primary impact. A very useful feature is the collision optimizer. One may define an objective function to quantify the quality of any given solution. PC Crash will then vary the quantities specified, including vehicle speeds, impact properties, and vehicle positions. The collision optimizer will find a solution that minimizes the objective function.

  Another impact model available, and especially useful with 3D models, is a deformable mesh model. By specifying the mesh force/deflection characteristics, PC Crash will determine contact forces and deformations over time, modifying the vehicle trajectory accordingly. Meshes can interact with other deformable meshes, rigid objects, or the ground. This model is useful when vehicle deformations may significantly affect subsequent vehicle interactions.

  For impacts with sustained, low-level contact or impacts with a significant vertical component, a so-called ellipsoid model is available. The vehicle is modeled as a set of compressible ellipsoidal elements. This is the default rollover model and can be used for vehicle-to-vehicle collisions as well.
- *Trajectory models*: Full 3D rigid-body dynamics of vehicles is implemented. Tire forces are generated by either a simple tire model or the more sophisticated TMEasy model. Vehicle features like ABS and also stability control can be accounted for.
- *Trailer models*: Fully customizable trailers can be attached to any vehicle. All the same model features apply to trailers as to normal vehicles. Forces are transmitted at the hitch to satisfy kinematic constraints with connected vehicles. It is possible to combine multiple trailers for B-trains and even more complex combinations. Hitches have user-definable properties, including rotational stiffness along each of three axes and maximum allowable hitch force before failure.
- *Terrain models*: Terrain models may be imported as 3D DFX graphics or designed by built-in 2D and 3D drawing tools. Parametric road shape specification is available.
- *MADYMO:* The optional MADYMO module allows FE modeling of vehicle occupant motions and loading (see also [57]). One can use the simulation already completed in PC

Crash, and then the MADYMO module will simulate the motions of a Hybrid-3 crash test dummy. Different types of seat belts can be specified, including a seat belt pretensioner when a lap and torso belt is used. Two different airbags (driver's and right front) can be specified. The results of a MADYMO simulation can be viewed as a 3D animation or in the form of diagrams.

- *Other features*: Simulation of a movable load is possible by using the multibody system of PC Crash. Its influence on the vehicle's driving behavior can be investigated. Additional features include the capability of defining and calculating brake force distributions between front and rear axle, a pedestrian and motorcycle model (multibody model) where the real vehicle shape is used in the calculation, scalable pedestrians by anthropometrical data, a preprocessor to define and configure multibody systems (pedestrians, motorcycles with drivers, etc.), the calculation of tire contact marks, and energy equivalent speed (EES) calculation for Crash-3 models.

PC Crash 2D is a constricted version of the full program, has no 3D capabilities, and allows only two vehicles and no trailers. Multibody models are not available in this version either.

41.5.3 VCRware

VCRware 2.0 is a product of Brach Engineering, located in Granger, Indiana. The following overview and product description reflect the product's development status when this book was published and is largely based on information and material available from the company's website [58].

VCRware is a suite of altogether eleven spreadsheets, based on MS-Excel, and allows the reconstructionist to analyze and reconstruct most cases of vehicular accidents. The documentation of this software suite and the theoretical basis for each of the programs is covered in detail in [7].

The Excel spreadsheet environment provides analysis functions that allow the user to determine the value of an input parameter to achieve a specified or desired value of some spreadsheet output without the need for iterative evaluation. For instance, the user can easily determine in one step the drag factor needed to stop a vehicle within a given distance at a certain initial speed. Also, complex problems such as maximization and minimization with multiple variables can be handled and enable the user to automate the time-consuming iterative process typically necessary to perform many reconstruction tasks. In addition, statistical tools for the analysis of the uncertainty in calculations using Monte Carlo techniques can be conveniently used in conjunction with VCRware.

With regard to vehicle dynamics, the most important spreadsheets are as follows:

- *Articulated vehicle impact*: For two vehicles, which may be articulated or not, with known physical parameters, orientations in a reference frame, and initial velocity components, this spreadsheet uses planar impact mechanics (see [59]) to calculate the final velocity components after the impact and also delta-V values and the energy loss.
- *Critical speed formula*: Determines the (critical) speed of a single vehicle making yaw marks over a circular path following a sudden steer maneuver for a given frictional drag coefficient and measured curve coordinates (see [7,60]).
- *Planar impact mechanics analysis*: A very useful spreadsheet to calculate the final velocity components, the delta-V values, and the energy loss from planar impact mechanics, for two vehicles with known physical parameters, orientations, and collision centers. See [7] for a comprehensive documentation of the underlying model.
- *Low-speed vehicle impact analysis*: Analysis of a low-speed front-to-front or front-to-rear collision of two vehicles using point-mass collision mechanics including the collision coefficient of restitution and vehicle roadway drag, when appropriate (see also [61]).
- *Crush stiffness coefficients from vehicle to barrier test*: This spreadsheet determines crush stiffness coefficients using data from a vehicle-to-barrier test.

- *Energy loss and speed change from CRASH3*: A spreadsheet to calculate the energy loss and delta-V values using the CRASH3 algorithm for a two-vehicle collision.
- *Vehicle–pedestrian collision analysis*: The user can calculate the times, velocities, pedestrian throw distance, and vehicle braking distance, corresponding to the various events and secondary events of a vehicle–pedestrian (or bicycle rider, when appropriate) collision. A reference covering basics of this kind of accidents is [62].
- *Vehicle and semitrailer dynamics program*: Calculates the planar motion of a vehicle alone or a vehicle pulling a semitrailer as function of time. Driver control modes include locked-wheel braking, lane-change maneuver, or arbitrary steering. Individually, locked wheels, drive train drag, and uniform acceleration can be simulated.

41.5.4 Other Software

As mentioned already, there are quite a large number of software products available to assist in accident analysis and reconstruction. Most of them have dedicated webpages and can be easily found by a search engine using suitable search words. In addition to that, Ref. [8] may be helpful since it discusses about seven more software packages to more or less extent.

41.6 SPECIAL TOPICS IN ACCIDENT ANALYSIS

Due to the variety of motorized and nonmotorized vehicles, pedestrians, and even animals that populate roads, there are quite a number of accident scenarios other than car to car collisions. The following sections will give a brief introduction to the peculiarities of some of these accidents and their reconstruction.

41.6.1 Motorcycle Accidents

From the statistics, it is known that motorcycle accidents do contribute significantly to the numbers, especially when it comes to severely injured and killed participants in accidents. One of the reasons for this is the fact that PTWs are among those vehicles with high potential for acceleration and velocity on one hand but with very limited passive safety for the rider on the other hand.

Also single-track vehicles are unique among other vehicles since they are inherently unstable with respect to their upright position at rest and at most speeds (see Chapter 35). This may be of importance with certain single vehicle accidents, where vehicle instability is the cause of an accident. There is rarely evidence for such kind of incident other than observation by the rider and, in severe cases, sometimes skid marks on the road.

The precrash phase of a PTW has to be analyzed differently compared to regular motor vehicles since PTWs still mostly have two independently operating braking systems [63]. Even with skid marks at the accident scene due to a locked wheel (mostly the rear wheel), the braking deceleration could have been within a rather wide range and may be difficult to estimate [64]. Furthermore, the PTW rider may have the choice to make an evasive lane-change maneuver instead of trying to stop the vehicle by just braking.

The crash of a PTW against another vehicle may look very different depending on which part of the opponent vehicle is struck by the PTW and also depending on the mass ratio of both vehicles (see, e.g., [65]). Permanent deformations at the front of a PTW are used to reconstruct the impact velocity, but they do not give very reliable results. Impact mechanics may be applied to analyze the collision, but attention has to be paid to the rider, who may interact with the handlebar, with the other vehicle or even may separate early from the PTW.

Rest positions of a PTW and the rider are very useful pieces of information to reconstruct the post-collision speeds and trajectories. Deceleration parameters need to be chosen carefully, since the kind of

PTW and type of ground have a significant influence on the sliding friction. The post-crash trajectories of both PTW and rider also may be travelled to a large part in the air and therefore with almost no friction.

A comprehensive discussion of many aspects of motorcycle accidents and extensive references are found in the books [9,10,12,66], the latter including many results from crash tests.

41.6.2 Accidents Involving Pedestrians

In most cases of accidents involving pedestrians, the dynamics of the hitting vehicle does not play a major role in the accident scenario. Since pedestrians and vehicles are normally using separate areas of the streets, conflicting situations almost only occur when pedestrians enter the areas used by vehicles. This may legally happen on a crosswalk, and the vehicle driver may run a red light, or it may illegally happen when, for example, a pedestrian attempts to cross a road where he or she is not supposed doing this, enters the lane of the approaching vehicle, and is being hit.

The task of reconstructing a vehicle–pedestrian accident practically always starts with the questions of visibility and recognition of the pedestrian by the vehicle driver. The main purpose is to locate the position and the point in time when it seems reasonable that the driver could initiate an action to avoid the accident. Of course, the same considerations apply to the pedestrian if he or she has not the right of way. Mainly, this question is a matter of perception, recognition, and reaction time, influenced by human factors like health and mental condition, medication, alcohol or drug usage, and environmental factors like daylight and weather conditions.

Mostly, the motion of the vehicle can be assumed to be of constant speed or of decelerating at a constant rate, in the precrash phase, and thereafter until the rest position is reached. Due to the large mass ratio of a vehicle in relation to a pedestrian, the collision causes only a minor or even negligible change of speed for the vehicle. Speed and distance versus time can be calculated for the vehicle, and for the pedestrian as well, from kinematic formulas as presented in Section 41.3.1.

The most challenging part in vehicle–pedestrian accidents is the reconstruction of the collision speed of the vehicle. If the position of the initial pedestrian contact and the rest position of the vehicle are known from some evidence, then this postimpact distance can be used to calculate the collision speed for the vehicle. If this is not possible because the vehicle did not stop or the deceleration cannot be determined, then one may try to use the throw distance of the pedestrian instead. There are empirical results available from tests with dummies and with cadavers but also equations derived from more or less simple mechanical models. The motion of a pedestrian, who is stroke by a vehicle, is quite complex, starting with one or more contacts with the vehicle, then a phase of free flight follows, and the final rest position is reached after some rolling and/or sliding on the ground. Depending on the goals of the accident reconstruction, it might be sufficient to use approximate models as summarized in [7], but occasionally sophisticated multibody dynamics software like MADYMO [57] may be needed to capture the complex interaction during the collision between the vehicle and the pedestrian.

A detailed discussion of the various aspects of vehicle–pedestrian accidents and related references are found in the books [7,9,10,17,32].

42.1 INTRODUCTION

The body of the vehicle is primarily designed to carry the occupants and cargo, the vehicle powertrain, and the chassis, and, only after, to mitigate human injury of occupants or other road users. Vehicle structures and systems experienced a dramatic change in their configuration during the past 30 years to accommodate the requirements for an improved protection of passengers and cargo in the event of a crash. The research area of vehicle passive safety, which deals with the study of structural components of the vehicle and the different types of occupant restraint and protection systems, addresses all events from the moment a crash starts until it is over. During this time period, it is necessary to control the vehicle

deformation so that it progresses from the exterior to the interior, maintaining the occupants' survival space as intact as possible, to shape the profiles of the energy absorption. By exploiting properly structural components and vehicle safety systems, the occupants have not to be exposed to high accelerations or impact forces, and all the occupant protection systems, such as seat belts, airbags, seat positions, and configurations, that control the occupant kinematics have to be managed. The aim of this chapter is to provide some historical background on the developments in automotive vehicle passive safety, to present requirements and regulations for their design and approval, and to propose and demonstrate some of the numerical tools used in the design and analysis of vehicles for crashworthiness.

Since automotive vehicles have to share the road among themselves and with other users, the potential for accidents exists, as highlighted in the advertisement presented in Figure 42.1, regardless of all measures taken to avoid collisions. Vehicle passive safety drew the interest of the different actors on the automotive-related fields since the early days of automobiles. The protection of occupants subjected to impact loading or to high acceleration started with the pioneering work of Hugh DeHaven, an air crash survivor often referred as the father of crashworthiness, who developed the initial studies on injury biomechanics and published the first work on this topic [1]. During the 1950s, John Paul Stapp, colonel of the U.S. air force, developed an experimental program to evaluate the human tolerance to extreme accelerations in order to establish the limits for human tolerance. Colonel Stapp [2] is well known not only for the testing program that he developed but also because he performed some of the experiments on himself, being the first human that willingly decelerated from about 1000 km/h to a full stop in about 1.4 s using the setup shown in Figure 42.2. He has his

name given to a series of conferences, Stapp Car Crash Conference, that is being run annually since 1961 [3]. Many other individuals and groups contributed during the years after the World War II for studies in impact biomechanics that led to the developments that made possible the occupant protection systems that are implemented in commercial vehicles today. For a review on these developments, the interested reader is referred to a review by Mackay [4] or to the work of Schmitt et al. [5].

Although the first works aimed at understanding the biomechanics of injury have been developed during the mid-twentieth century, the first proposal for restraint systems in automobiles dates from 1903 and consists in the seat belt patent by Lebau [6], shown in Figure 42.3. However, seat belts have not been used in road vehicles until after the World War II. The three-point seat belt, a standard used today in all automobiles, was invented in 1959 by the Volvo engineer Nils Bohlin. Based on findings on human tolerance to impact and high accelerations and on the available technology, the mandatory seat belts usage, for driver and front passengers, was first introduced in several countries: from Oceania, in the early 1970s; in most European countries by the mid-1970s; and later in the United States by the mid-1980s [7]. The mandatory use of seat belt for rear passengers was introduced by the mid-1980s and early 1990s [8].

Another of the passive safety systems widely used in automotive vehicles is the airbag, its invention credited, independently, to the German Walter Linderer and to the North American John Hetrick who in 1951 registered the first patents for its early designs. Although the invention of the airbag resulted from simple observation, without any use of the knowledge on injury biomechanics, the principles involved in this device were further explored by General Motors, Ford, and Mercedes-Benz, among others, during the 1960s when proper sensing equipment and the ignition of a gas generator propellant to inflate the airbag were designed. From the first commercial vehicle using airbag for the driver, the 1973 Oldsmobile Toronado, passing by the 1980 S-class Mercedes-Benz until current vehicles, the airbag's acceptance as being one of the most important passive safety systems in a car grew continuously. Since 1997, all new cars produced in the United States are required to have front airbags for the driver and passenger. Almost all vehicles produced today worldwide have, besides the mandatory front airbags, also side airbags and, in many of them, thorax and knee airbags. A common setup in many current commercial vehicles is similar to that presented in Figure 42.4.

A perceived requirement to protect the occupant, until the 1960s, consisted in having stiff automobile bodies that would not deform during a crash. This construction concept was first disputed by Barény [9], an engineer for Mercedes-Benz, who proposed in 1952 that the vehicle strength should increase from the exterior of the car to its interior so that the progressive crushing would be responsible

FIGURE 42.4 Airbags used in current cars for occupant protection in frontal and side impact.

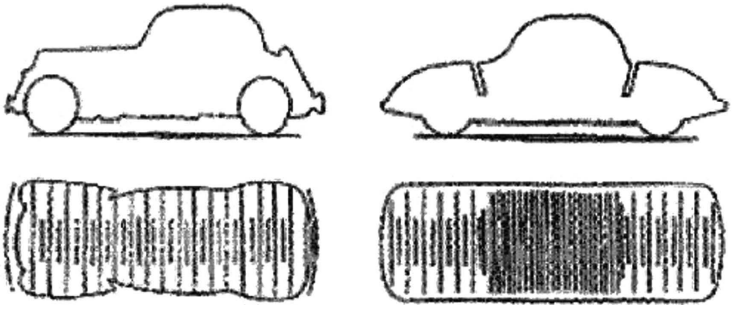

FIGURE 42.5 The crumple zone concept proposed by Barény. (From Barényi, B., Kraftfahrzeug, Insbesondere zur Beförderung von Personen, Deutsches Patentamt Nr. 854157, 30, 1952.) The density of the transversal lines is a representation of the vehicle body stiffness.

for energy absorption during a crash, as shown in Figure 42.5. Although the vehicle body is designed to carry the main vehicle components and the occupants, the concept of a crumple zone has been refined and widely applied to all vehicles in production today being the body in white of the vehicle responsible for absorbing over one-quarter of the total kinetic energy during a crash. Still it is important that the survivable cell of the vehicle is maintained basically intact not only to avoid intrusions that would decrease this space but also to ensure that the different safety systems are not compromised.

Having established most of the basic principles and systems in which the automotive vehicle occupant protection is based, the emphasis is put on the implementation of the structural arrangements and systems where they matter more. The analysis of the accident statistics serves as the basis to define the priorities for the development, implementation, and regulation of passive safety in road vehicles. Figure 42.6 shows a typical distribution of car accidents in Europe [10–12] and the incidence of fatalities for each collision category [12]. For instance, front accidents account for about 48% of the total accidents and for 40% of the accidents with fatalities. Therefore, it is no surprise that the front structure of the vehicles and occupant protection systems for front crash were the first deserving attention.

The crash–injury recording systems existing in many countries are generally based in basic police reports linked with hospital records. Although not always reliable, the situation has improved dramatically over the past years and the accident statistics provide the most important source of information for the decision-making policies in passive safety [4]. However, in what minor injuries are concerned, there is still a strong underreporting and improved links between hospital and police reporting is needed.

Being an important part of the evaluation of injury in traffic accidents, the medical reporting has to be based on some form of quantification of injury that can be understood by medical personnel,

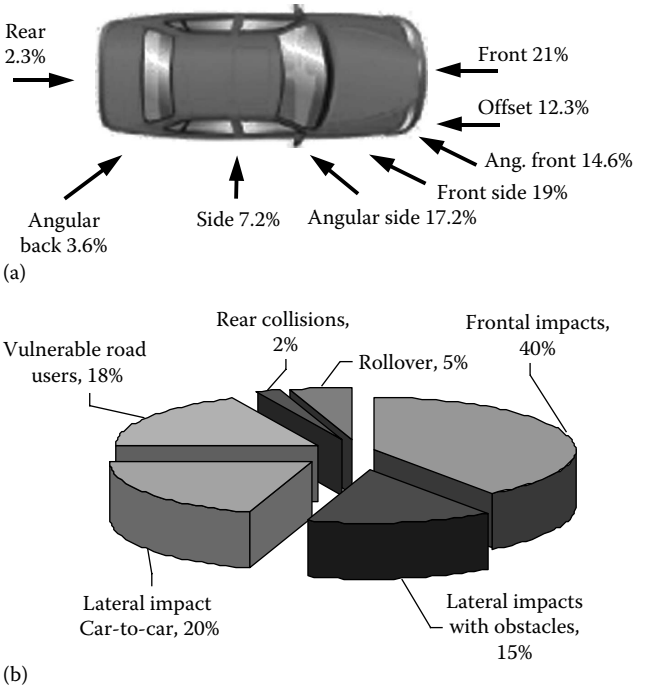

FIGURE 42.6 Accidentology analysis: (a) distribution of vehicle collision locations (From Seiffert, U. and Wech, L., *Automotive Safety Handbook*, SAE International, Warrendale, PA, 2003.) and (b) fatality rate for the individual collision categories. (From Klanner, W., Status report on future development of EuroNCAP programme, *Proceedings of the 17th ESV Conference*, Amsterdam, the Netherlands, 2001.)

engineers, and regulators alike. Injury scaling is defined as the numerical classification of the type and severity of an injury. The schemes proposed for ranking and quantifying injuries are either anatomic, physiologic, or impairment, disability, and societal loss scales [13]. Among the anatomic scales, the Abbreviated Injury Scale (AIS), published in 1971 and updated several times afterward [5,14], provides a classification of injuries resulting from traffic accidents based on medical diagnosis. The AIS classification is described in Table 42.1 together with the fatality rate associated to each score [13]. Table 42.2 presents examples of the types of injury sustained to achieve each score.

It should be noted that the AIS is not a linear scale and that it is not accepted universally as a score for injury. One of the main criticisms is that the AIS does not access multiple injuries.

TABLE 42.1
AIS and Fatality Rate Associated to Each Score

AIS	Severity Code	Fatality Rate (Range%)
0	No injury	0.0
1	Minor	0.0
2	Moderate	0.1–0.4
3	Serious	0.8–2.1
4	Severe	7.9–10.6
5	Critical	53.1–58.4
6	Not survivable	100

TABLE 42.2
Examples of AIS Scores per Body Region

	Body Region				
AIS	Head	Thorax	Abdomen and Pelvic Contents	Spine	Extremities and Bony Pelvis
0					
1	Headache or dizziness	Single rib fracture	Abdominal wall: superficial laceration	Acute strain (no fracture or dislocation)	Toe fracture
2	Unconscious less than 1 h; linear fracture	2–3 rib fracture; sternum fracture	Spleen kidney or liver: laceration or contusion	Minor fracture without any cord involvement	Tibia, pelvis, or patella: simple fracture
3	Unconscious 1–6 h; depressed fracture	≥4 rib fracture; 2–3 rib fracture with hemo- or pneumothorax	Spleen or kidney: major laceration	Ruptured disk with nerve root damage	Knee dislocation; femur fracture
4	Unconscious 6–24 h; open fracture	≥4 rib fracture with hemo- or pneumothorax; flail chest	Liver: major laceration	Incomplete cord syndrome	Amputation or crush above knee; pelvic crush
5	Unconscious more than 24 h; large hematoma	Aorta laceration (partial transection)	Kidney, liver, or colon rupture	Quadriplegia	Pelvic crush (open)
6	—	—	—	—	—

The Injury Severity Score [14], based on the AIS for the different body regions, is preferred by some authorities, while others chose different classifications. However, it is important to note also that when a relation between the injury scales and the injury criteria used in the evaluation of performance of automotive vehicles can be established, such vehicles can be designed for improved occupant protection. Both the injury criteria and the crash tests used in the design and in the evaluation of the car passive safety performance are presented and discussed in the following section. After, the use of these criteria and tests in regulations for the design and analysis of automobiles is presented for scenarios of front, side, and rollover crashes.

42.2 MEASURING OCCUPANT PROTECTION

The design of vehicles for improved passive safety requires that, in one hand, there are numerical and experimental tools for the quantification of the occupant injury during a crash and, in the other hand, standard crash scenarios, representative of the most important types of accidents, are clearly defined. The quantification of the potential for human injury in a vehicle crash is defined by using injury criteria for the different body parts. The standard vehicle crash scenarios are defined in regulations by most of the international traffic authorities and consumer groups.

42.2.1 Injury Criteria for Different Body Parts

The injury criteria used in different regulations for the approval of vehicles, or for rating their performance with respect to passive safety, are reviewed here. It should be noted that many other injury criteria have been proposed, for different body parts, their application being restricted to particular user groups. However, due to the actual criticism received by some of the current injury criteria used

in regulation or because the protection of other body segments becomes relatively more important, it is possible that new criteria get approved or that the existing are reviewed to include more updated scientific knowledge [15].

42.2.1.1 Head Injuries

The *Head Injury Criterion* (*HIC*) is probably the best known of the injury criteria used worldwide. This criterion, using the head translation acceleration, is computed by [16]

$$HIC = \max\left[\frac{1}{t_2 - t_1}\int_{t_2}^{t_1} a(t)\,dt\right]^{2.5}(t_2 - t_1) \tag{42.1}$$

$a(t)$ being the head acceleration, $(t_2 - t_1)$ a predefined window on time during the crash event, and *max* the largest value obtained for the integral in any time window during the crash event. Some regulations require that $(t_2 - t_1) = 36$ ms, for which the criterion is designated as HIC_{36}. The maximum value for the HIC_{36}, or for its European equivalent Head Protection Criterion (*HPC*), is 1000 for both Federal Motor Vehicle Safety Standards (FMVSS) and Economic Council for Europe (ECE) regulations. In some regulations the period of time used for the calculation of the criterion is 15 ms, 700 being the maximum for the HIC_{15} when applied to a 50th percentile male.

When dealing with the contact of occupants with the internal structures of the vehicle, the *3 ms criterion* (a_{3ms}) is used in several European and North American regulations. This criterion is defined as the mean acceleration level obtained for an impact duration of 3 ms [5]. The values of a_{3ms} must always be below 80 g. Such as for the *HIC*, also the a_{3ms} is based on the Wayne State Tolerance Curve [17] that only accounts for head translation accelerations.

The attempt to consider translational and angular head accelerations in a single criterion has been proposed by Newman [18] with the *Generalized Acceleration Model for Brain Injury Threshold* (*GAMBIT*), which is expressed as

$$G(t) = \left[\left(\frac{a(t)}{a_c}\right)^n + \left(\frac{\ddot{\alpha}(t)}{\ddot{\alpha}_c}\right)^m\right]^{1/s} \tag{42.2}$$

in which $a(t)$ and $\ddot{\alpha}(t)$ are the head translational and angular accelerations, respectively, n and m are empirical constants to fit the data available, and a_c and $\ddot{\alpha}_c$ are critical values for the translational and angular accelerations. Although this HIC has the potential to include multidirectional accelerations, it has not been validated yet and, consequently, is not included in any of the regulations [19].

42.2.1.2 Spinal Injuries

The injuries on the human spine during traffic accidents have particular incidence for the cervical spine, or neck, and less for the thoracic and lumbar spines. Although the neck injuries appear to be lower than the head injuries in general collisions, for crash scenarios characterized by rear-end contact, a great number of injuries are at the cervical spine level [19]. Even minor injuries may have long-term consequences as, for instance, those due to whiplash.

The *Neck Injury Criterion* (*NIC*), developed by Boström et al. [20], takes into account the changes on fluid pressure on the compartments of the cervical spine and relates those to neck injuries. The *NIC* is defined by

$$NIC(t) = 0.2\,a_{rel}(t) + \left[v_{rel}(t)\right]^2 \tag{42.3}$$

where $a_{rel}(t)$ is the relative acceleration in the anterior–posterior direction, between the head center of mass and the first thoracic vertebra, and $v_{rel}(t)$ the relative velocity. The risk for a minor injury has been found to be limited by 15 m^2/s^2. Although this criterion is used in accidentology studies, its application in many kinematic conditions is questionable [5].

The U.S. National Highway Traffic Safety Administration (NHTSA) proposed the N_{ij} *NIC* to account for the injuries in frontal impacts in severe conditions, as those involving airbag deployment or high accelerations [21], given by

$$N_{ij} = \frac{F_Z}{F_{int}} + \frac{M_y}{M_{int}} \tag{42.4}$$

where F_Z and M_y are the axial and sagittal bending moment, respectively, while F_{int} and M_{int} are the respective critical intercept values, established for appropriate dummies. For instance, F_{int} = 4500 N in compression and tension, M_{int} = 310 Nm in flexion, and M_{int} = 125 Nm in extension are all defined for the 50th percentile dummy [5]. The N_{ij} is calculated for the linear combination of axial forces, tension or compression, and bending moments, extension or flexion. The four values calculated combining an axial force with a moment, designated by N_{te}, N_{tf}, N_{ce}, and N_{cf}, should not exceed 1.0 for each loading combination.

Due to the increasing relative importance of other loading cases and of the prevention of injury for low-speed impacts, other injury criteria, addressing the neck, are being proposed. Among these, the *Neck Protection Criterion* (N_{km}), by Schmitt et al. [22]; the *Intervertebral Neck Injury Criterion* (*IV-NIC*), by Panjabi et al. [23]; the *Neck Displacement Criterion* (*NDC*), by Viano [24]; or the *Lower Neck Load Index* (*LNL*), by Heitplatz [25] address different features of the neck injury mechanisms. However, either due to limited validation, limited range of application, or other reasons, these criteria are yet being investigated and have not been included in any passive safety regulations yet.

42.2.1.3 Thoracic Injuries

After the head and the neck injuries, the thorax is the most critical region to protect in vehicle accidents. Although there are few long-term disabilities due to thorax injuries, the victim either dies soon after or recovers completely [19]. In terms of vehicle passive safety, the important injuries to protect are those resulting from blunt trauma that can result in rib fractures, lung contusion, or vessel disruptions.

The limits on the *acceleration and force* that the thorax can withstand are included in some regulations for frontal impact. The tolerance level for forces on the thorax is 3.3 kN for the sternum and 8.8 kN for chest and shoulders, while the tolerance level for acceleration using the a_{3ms} is 60 g [5]. For lateral impacts the tolerance levels are 7.4 kN for AIS0 and 10.2 for AIS3 [26]. However, Viano [27] pointed out that for a 25% probability of AIS4 or higher, the tolerance level is 5.5 N for forces and 45.2 g for the lateral acceleration on the T8 vertebra or 31.6 g if the lateral acceleration is measured in the T12 vertebra.

For side impact the *Thoracic Trauma Index* (*TTI*) relates the injuries to the maximum lateral acceleration measured in the struck side of the rib cage and lower thoracic spine, taking into account the subject age and weight [5]. The *TTI* is given by

$$TTI = 1.4Age + 0.5(a_{RibY} + a_{T12_Y})\left(\frac{M}{M_{std}}\right) \tag{42.5}$$

where

Age is the age of the subject in years
a_{RibY} is the maximum lateral acceleration of 4th and 8th ribs on the struck side
a_{T12Y} is the maximum absolute acceleration of the 12th thoracic vertebra
M is the subject mass
M_{std} = 75 kg. The threshold values for *TTI*, in some regulations, are 85 g in a SID dummy for a four-door car and 90 g for a two-door car

The thorax *Compression Criterion* (*CC*) has been shown to correlate well with the AIS [5]. The chest deflection is measured for the 50th percentile male, with and original chest size of 230 mm. For instance, a compression of 40% of the chest correlates well with a severe injury AIS4.

It is observed that the soft tissue injury is not only compression dependent but also time–rate dependent. The *Viscous Criterion* (*VC*), which correlates well with the risks for thoracic injuries [28], is given as

$$VC = v(t)\, c(t) \tag{42.6}$$

in which $v(t)$ is the velocity of deformation of the thorax and $c(t)$ is the instantaneous compression function calculated as the ratio of the thorax deformation by the initial torso thickness. The maximum of the *VC*, VC_{max}, correlates well with injury risk. For a 25% probability of severe injuries, AIS4 or larger, the tolerance level is VC_{max} = 1 m/s [28], which is the limit value used in regulations.

By putting together the compression and acceleration responses, the *Combined Thoracic Index* (*CTI*) for frontal impact is defined as [21]

$$CTI = \frac{A_{max}}{A_{int}} + \frac{D_{max}}{D_{int}} \tag{42.7}$$

where

$A_{max} = a_{3ms}$ of the resultant acceleration of the spine in g
A_{int} the critical intercept value which is 85 g for the 50th percentile Hybrid III dummy
D_{max} the deflection of the chest in mm
D_{int} the critical intercept value, which is 102 mm for the same dummy

42.2.1.4 Abdominal Injuries

A large amount of work is being put on the development of suitable criteria for abdominal injuries. The strength and physiological alterations of the internal organs in the face of external loading or accelerations are being tested in order to define thresholds for injury and suitable descriptors [5]. However, owing to the complex nature of the problem, not many conclusions on the use of injury criteria are published for abdominal injuries, the *Abdominal Peak Force* (*APF*) being the only measure used in regulations. The *APF* is determined by using the Euro-SID dummy and it is required to be less than 2.5 kN, internal force, or 4.5 kN, external force.

42.2.1.5 Pelvic Injuries

Clinically the pelvic injuries are characterized by fractures of the pelvic ring and sacrum or associated injuries [5]. It has been shown that forces higher than 10 kN and accelerations in excess of 100 g can be sustained if the loading is done through the greater trochanter and iliac wing [29]. This leads to the *Pelvis Lateral Acceleration (PLA)* criterion, used in the standard FMVSS 214, that specifies a limit of 130 g can be withstood by the pelvis before injury. However, it should be noted that the threshold set by the PLA criterion is for loading of the whole pelvis. If only the greater trochanter is loaded, fracture can occur at about half of this threshold.

42.2.1.6 Lower Extremity Injuries

The large improvements in head, neck, and thorax protection and the consequent decrease in fatalities due to injuries in the upper body made the lower extremity injuries relatively more important in recent years. The *Tibia Compression Force Criterion* (*TCFC*) is defined as the maximum force transmitted to each tibia of the test dummy along its axial direction. The maximum value acceptable for the *TCFC* is 8 kN in some European regulations. The FMVSS regulations specify a maximum compression force of 10 kN for the hip–thigh–knee [5].

The *Femur Force Criterion* (*FFC*) uses the compression force on the femur and its duration, measured in ms. The European regulations specify that the *FFC* must be under 7.58 kN if applied longer than 10 ms.

Other criterion, resulting from static bending testing by Yamada [30], is the *Tibia Index* (*TI*), which is calculated as

$$TI = \frac{M}{M_{crit}} + \frac{F}{F_{crit}} \tag{42.8}$$

in which M is the bending moment and F the compressive force, while M_{crit} and F_{crit} are intercept values that take the values of 225 N m and 33.9 kN, respectively, for the 50th percentile male. The European regulations specify that *TI* must not exceed 1.3 in each tibia.

42.2.1.7 Relation between Injury Criteria and Occupant Protection

The injury criteria scores are not always directly related to the existence of injuries in case of a crash but specify thresholds for occupant protection to which some rating may be associated. A relation between injury criteria scores and protection levels is described in Table 42.3 [31].

At this point it should be noted that the relations between the scores of the injury criteria and the actual mechanisms of injury are not generally well mapped. Even the relations between the scores of the AIS and the injury criteria are not clearly defined, although there is a large body of work done to relate them. The interested reader is referred to the work of Schmitt, Niederer, and Walz [5] for more detailed information on this subject.

TABLE 42.3
Injury Parameter Cutoff Values Associated with Possible Injury Protection Ratings

Body Region	Parameter	IARV[a]	Good–Acceptable	Acceptable–Marginal	Marginal–Poor
Head and neck	HIC_{15}	700	560	700	840
	N_{ij}	1.0	0.8	1.0	1.2
	Neck axial tension (kN)	3.3	2.6	3.3	4.0
	Neck contraction (kN)	4.0	3.2	4.0	4.8
Chest	Thoracic spine acceleration (a_{3ms})	60	60	75	90

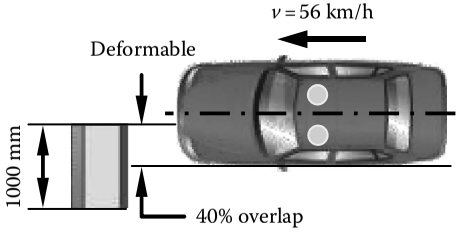
42.2.2 Regulations for Automotive Crash Testing

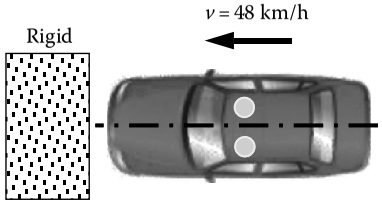
Real-world crashes are complex events for which it is not possible to define crash scenarios to foresee all possible combinations of outcomes. Using the background of the accident analysis and the statistical data available, such as that presented in Figure 42.6, it is possible to set the priorities for occupant protection [10,12]. The definition of the limits of human tolerance to impact and the identification of the means to measure the biomechanical outcomes of impact led to the establishment of performance criteria that can be effectively used in vehicle design and analysis. The definition of a number of crash scenarios representative of the most important classes of accidents that can be standardized, enabling the assessment of the vehicle safety by means of biomechanical criteria, was the next necessary step, which led to the passive safety standards used today [4,5,10]. The requirements for some of these standards are summarized in Tables 42.4 through 42.6.

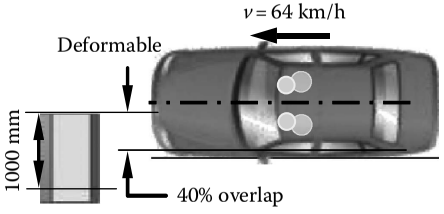
The regulations for passive safety tests, which all vehicle models must pass before being approved, reflect the priorities in occupant protection defined with the mechanisms described before. The official standards in Europe are defined by the ECE and designated by ECE R++, while in the United States of North America, the regulations are defined by the NHTSA and comprised in the FMVSS, designated by FMVSS+++. Also in Asia and Oceania, there are several organizations responsible for issuing regulations, which are mostly similar to their European and North American counterparts. Also the different New Car Assessment Programs (NCAPs) have sets of testing programs that differ, to a certain extent, from those used by the different official organizations. Due to their public acceptance, the EuroNCAP tests are listed here. Notice though that the harmonization of the NCAP tests is not yet done [32].

The frontal impact test regulations for the ECE, FMVSS, and EuroNCAP are summarized in Table 42.4. In all tests the Hybrid III dummy is used and the deformable barrier used in some of the tests is completely defined in the regulation also.

The side impact regulations for the ECE, FMVSS, and EuroNCAP are summarized in Table 42.5. All tests use impacting barriers, with characteristics defined in the standards, and side impact dummies. Notice both dummies and barriers used for the European and for the North American tests are different. In particular, the barriers not only have different geometries and material properties but also have different heights, therefore engaging different parts of the car.







The pole test for side impact is included in the FMVSS regulations but not in the European regulations. The EuroNCAP test also uses the pole impact test as an optional form of evaluating the side protection of vehicles, for all those that achieve a maximum score in the standard's side impact test. These tests, described in Table 42.6, assess effects of the intrusion of the side of the vehicle on the occupant safety and can represent the contact not only with stationary objects but also with moving vehicles, such as motorcycles.

The rear impact tests, used in the European and North American regulations, described in Table 42.7, are designed to address the stability of the fuel system only. However, with the growing relative importance of the occupant injuries resulting from rear-end strikes, such as the whiplash, it is foreseen that they will be introduced in legislation as a form to quantify occupant safety protection also.

Besides the front, side, and rear-end impact tests, the rollover tests are also used in regulation but with the objective of assessing the fuel container performance, roof crush resistance, and windshield retention, as in FMVSS216 and FMVSS208. Several regulations are also in place to define the compliance of the exterior of the vehicle with femur and head impacts of vulnerable road users [41,42].

It should be noted that although the full-scale tests imposed by the regulations are of fundamental importance, they serve as a reliable final check but not as tools for the development of new car models [43]. The standards are translated into a set of component performance ratings that are checked by specially developed tests that make part of internal standards of each car company. Ardoino [43] refers that the development of a car in FIAT required about 70 full-scale crash tests; 80 crash simulation tests, that is, sled tests; 250 component tests; and over 50 virtual tests in a computer. With the

evolution of computer technology and fidelity of computer models, the balance between the numbers presented is changing dramatically, but still the idea that component testing, virtual or experimental, is required and not subjected to international regulations is valid.

42.2.3 Anthropometric Testing Devices: Dummies

Regardless of the crash tests being experimental or virtual, the use of Anthropometric Testing Devices (ATDs), better known as crash test dummies, is fundamental to evaluate the vehicle performance in terms of passive safety. The ATD should not be confused as human substitutes but simply as measuring devices as they are intended to measure, with biofidelity, the crash response in terms of accelerations, forces, and deflections of selected points. All dummies have dimensions and masses based on their human counterparts. Each ATD is designed to be used for crash tests in a given direction and cannot, or should not, be used to measure the crash effects in general directions. The development of omnidirectional dummies is still a research topic that is not close to be implemented in any practical application. Certainly the ongoing research on advanced human body models and the understanding of biologic material behavior and physiologic and neurological resistance of the human structures will provide important advancements in such research [44,45].

The frontal impact dummy that is used in all regulations related to frontal impact is the 50th percentile male Hybrid III dummy, shown in Figure 42.7. In various testing setups, the 5th percentile female and the 95th percentile male dummies are also used to cover most of the human population. Also the Test device for Human Occupant Resistant (THOC) dummy is used for frontal impact, although it is not applied in any official regulation.

Contrary to the situation in what front impact dummies are concerned, for side impact the FMVSS and the ECE regulations prescribe the use of different side impact dummies, that is, they prescribe the use of the U.S.-SID and Euro-SID1 dummies presented in Figure 42.8, respectively. In Figure 42.9, numerical models of the side impact dummies, using the finite element (FE) method and multibody (MB) dynamics procedures, are displayed. Some of the major differences between the Euro-SID and the U.S.-SID concern the mechanical components of the torso. Due to the many differences between the dummies, their measuring capabilities, and respective biofidelity, several efforts are being made to obtain unified side impact dummies that can be used worldwide. The evolution of the European dummy (Euro-SID2), the Biofidelic Side Impact Test Dummy (Bio-SID), and the world-SID represents some of the developments in this direction.

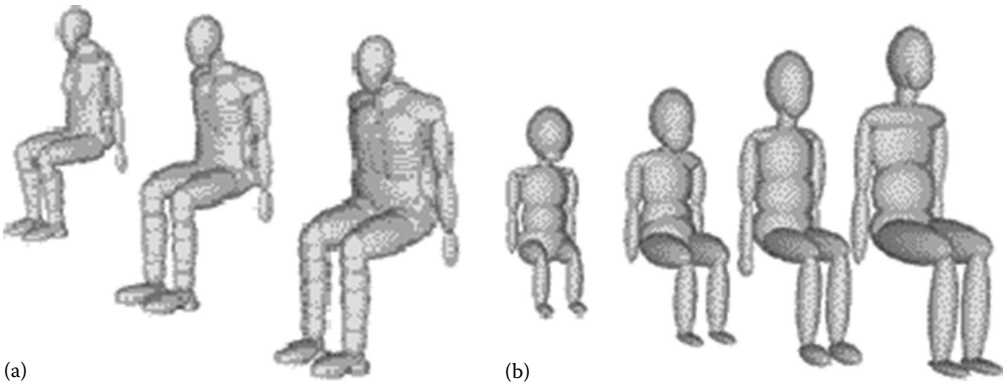

FIGURE 42.10 Examples of MB crash dummy models: (a) Hybrid III dummy family (top), 5th%, 50th%, and 95th%; and (b) CRABI 12-month and TNO child dummies (bottom), P3/4, P3, P6, and P10. (From Wismans, J., Design tools: Human body modelling, In: J. Ambrósio, ed., *Crashworthiness: Energy Management and Occupant Protection*, Springer, Vienna, Austria, pp. 333–377, 2001.)

Although only some of the dummies are used in official regulations, there are complete families developed and used commercially, such as those presented in Figure 42.10. Besides the physical ATD sold by different commercial companies, the software developers also include fully validated models of these families of dummies together with their software. Basically all FE and MB commercial codes used for passive safety include these dummy models [48–51].

Besides the front and side impact dummies, there are dummies also developed for rear-end impact and for other interior special purpose tests. Although the Hybrid II has been used for rear-end impact, its neck is not biofidelic enough for this crash scenario. The Biofidelic Rear-End Dummy (BioRID) has an improved spinal representation that presents biofidelic kinematics for rear-end impacts [5]. Several efforts are also being made to develop suitable standing pedestrian and passenger dummies. The POLAR dummy is an example of these attempts. However, not only is there still a large amount of research to be done before these dummies provide reliable and biofidelic responses, but also regulations requiring their use have not yet been released.

42.2.4 Impact Barriers

The impact barriers play a fundamental role in the crash tests in regulations as normalized representations of collision partners. Both the FMVSS and the ECE regulations prescribe the complete geometry, mass, and material characteristics of the impact barriers. For instance, the regulation FMVSS214 for side impact protection specifies the impact barrier shown in Figure 42.11.

The ECE R94, for frontal impact, specifies not only the geometric and material characteristics for the impact barrier but also the specifications for its construction. The certification of the barrier includes collecting samples at prescribed locations and ensuring that their force–deformation performance matches the specifications listed in the standard [33]. The procedure described in the standard must be followed for physical construction of the impact barrier and a proper equivalent mathematical model must be used to validate any virtual deformable barrier that is used in numerical models. Similar procedures, properly specified in the respective regulations, should be followed for all other types of impact barriers used in crash tests.

42.3 STRUCTURAL FEATURES AND SYSTEMS FOR PASSIVE SAFETY

The passive safety of vehicle occupants starts with the design of vehicle structures, able to exhibit controlled deformations with suitable energy absorption characteristics and undeformed, or with limited intrusion, occupant survivable cells. After ensuring the proper characteristics of the vehicle structure,

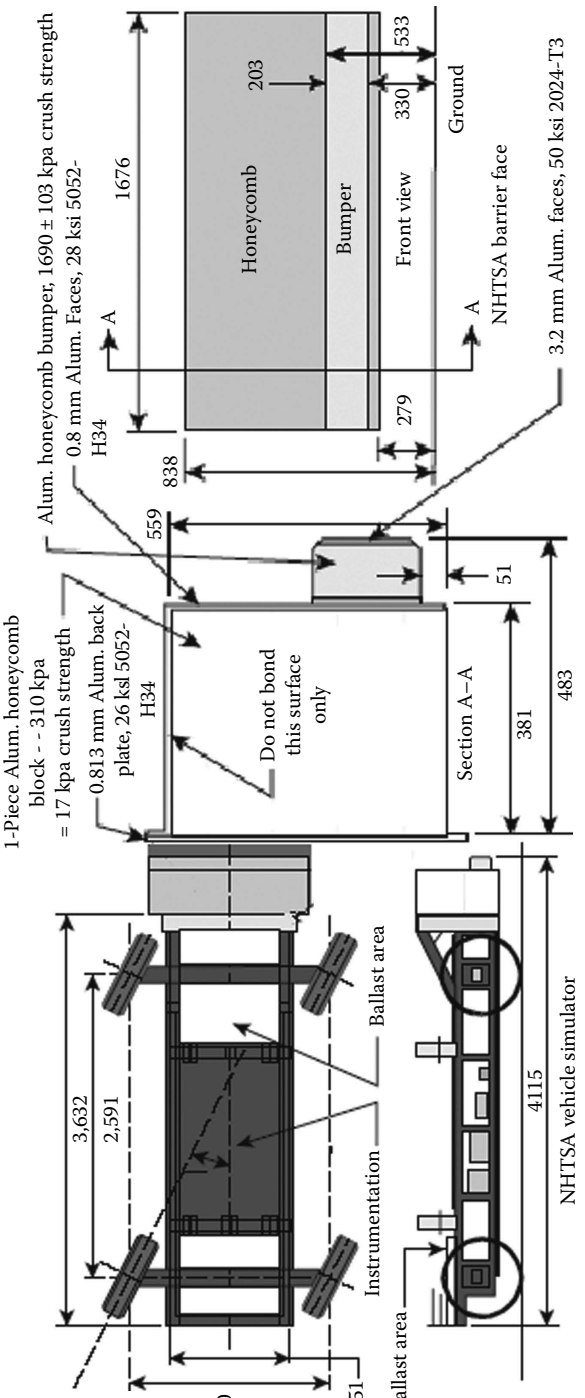

FIGURE 42.11 Impact barrier for the FMVSS214 regulation. (From National Highway Traffic Safety Administration, Federal motor vehicle safety standard no 214, Side Impact Protection. Code of Federal Regulations Part §571.214, pp. 666–677, 2004.)

generally in the body in white, safety equipment, such as seat belts and airbags, can be installed to ensure an effective protection of the occupant. The structural requirements for the vehicles protection in frontal and side impacts and for rollover are overviewed here. A brief overview of protection systems, emphasizing seat belts and airbags, is presented afterward.

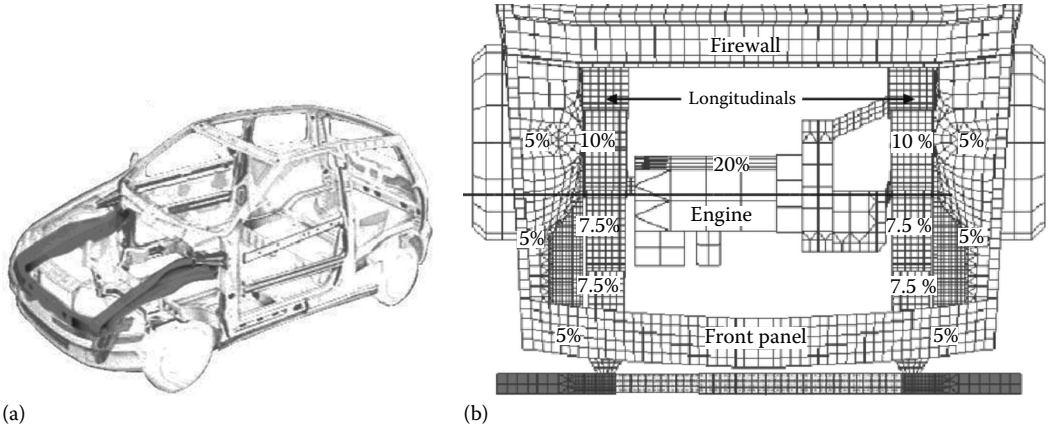
42.3.1 Vehicle Structure for Crashworthiness

Although the body of the vehicle is primarily designed to carry the powertrain, occupants, and cargo, its passive safety performance has become more and more important. Regardless of the many variations on the arrangements of the front structure of a vehicle, observed in cars by different manufacturers, the main structural components responsible for the controlled deformation and energy absorption are the longitudinal beams, shown in Figure 42.12a.

In a front crash, other structural parts of the vehicle perform a role in the energy absorption characteristics of the vehicle. A typical distribution of the energy absorption characteristics of the front structural components is presented in Figure 42.12b [52]. According to Wittemann [52], the longitudinal beams are responsible for about 50% of the total energy absorption capability of the front of the vehicle, the remaining 50% being the energy absorbed by the deformation of the bumper, front panel, wheel wells, engine, etc. Moreover, typically 50% of the energy absorption occurs in the first half of the vehicle front, that is, between the bumper and the engine, while the remaining 50% of energy are absorbed in the second half of the front, that is, between the engine and the firewall.

Most frontal crashes are either offset or oblique crashes, as shown in Figure 42.6. Regardless of the structural arrangement of the vehicle front that ensures that, even when the crash is offset, the complete front energy absorbing structure is still loaded, the relative contribution of the different vehicle front structural components to the total energy dissipation varies with impact orientation and with the vehicle velocity. Table 42.8 presents a typical distribution of the energy absorption by the different structural elements in frontal crashes [53].

Note that in frontal crashes the survivable space for the occupants must be maintained and the windshield preserved. Furthermore, at least one of the doors must open without tools after the crash. To achieve the integrity of the structure and systems to the rear of the firewall and A-pillar, the sidewalls must be connected to the wheel housing and the force applied to the A-pillar must be transmitted by the doors and side beams to the B-pillar [10].



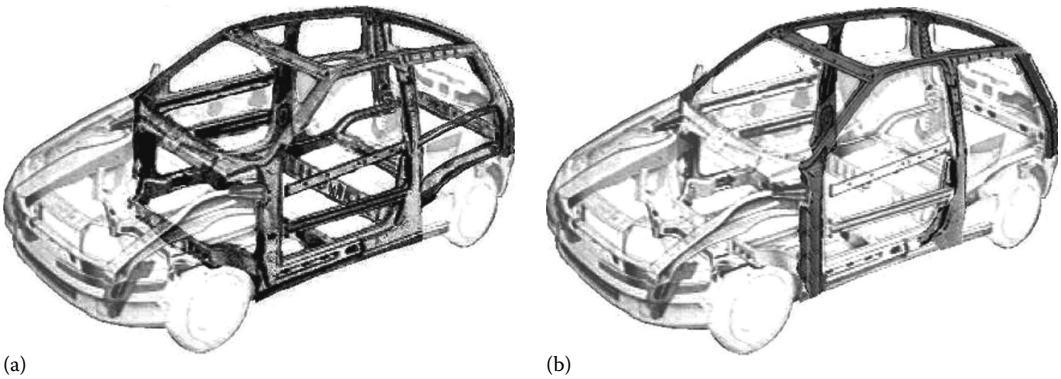


FIGURE 42.12 Energy absorption components in the front of the vehicle for frontal impacts: (a) crash-relevant structural reinforcements in a typical small car; (b) typical energy absorption characteristics of the structural components of the vehicle front. (From Wittemann, W.J., Improved vehicle crashworthiness design by control of the energy absorption for different collision situations, PhD dissertation, Technical University of Eindhoven, Eindhoven, the Netherlands, 1999.)

(a) (b)

FIGURE 42.13 Energy absorption components in the vehicle for side and roof impacts: (a) structural reinforcements for side impacts; (b) structural reinforcements for rollover protection.

Historically, after the front protection, the side impact became the highest priority in vehicle passive safety. The typical structural components of the vehicle responsible for limiting intrusion to the occupant compartment and managing the structural energy absorption are shown in Figure 42.13a. It should be noted that the complete elimination of intrusions in the survivable space of the occupants is not possible for general side impacts, but it is clearly excessive for pole impacts. The strength characteristics of the A- and B-pillars, door reinforcements, strong hinges, efficient locks, and good connections of the doors to sill and rocker of the chassis are some of the structural characteristics of major importance in side impact.

The importance of rollover fatalities in vehicle accidents is much lower than what has been observed for front and side impact but is becoming more and more important as the other passive safety problems are being solved. The typical structural components of the vehicle responsible for the occupant protection in a rollover are shown in Figure 42.13b. The actual regulations only impose the static strength of the roof to be verified, by the regulation FMVSS216, and prescribe a dynamic rollover test to ensure the windshield integrity and that the fuel tank and lines have no leakages.

42.3.2 Vehicle Interior Protection Systems

The most important protection safety systems in the interior of the vehicle are the seat belts and the airbags, followed by the seats and headrests. Although technological developments in the design of more efficient and intelligent occupant protection systems are occurring at a very fast pace, their objectives remain the same, that is, to guide the occupant kinematics to a more favorable configuration in order to mitigate injury. To achieve this objective, both the restraint systems and the airbags require crash sensors, crash sensing criteria, inflators and bags for the airbags, pretensioners, load limiters and belts for the seat belts, and a suitable vehicle interior [54]. In this text only some of the principles of the functions of the protection systems in the vehicle interiors are reviewed. For more detailed information, the reader is referred to the works of Chan [54] on the fundamentals of crash sensing and Seiffert and Wech [10] that addresses general occupant protection. Virtually all commercial vehicles sold today use three-point seat belts for the front occupants in a configuration shown in Figure 42.14a. The anchorage points of the seat belts are generally located in the B- and C-pillars, for the front and rear seat belts, respectively, as shown in Figure 42.14c. In some arrangements, the anchorage points are placed in the seats.

The seat belts with retractors allow controlling the kinematics of the occupant, as shown in Figure 42.14c [4]. It can be noticed that although the body of the occupant is well protected, the head may hit the steering wheel. Therefore, the use of airbags is still required together with seat belts, with their size and pressure being larger in the United States than in Europe to protect both belted and unbelted drivers. It is required that the vehicle structure, where the anchorage points are located, is able to withstand the loads due to the operation of the seat belts. Furthermore, in order to prevent excessive loading of the occupants, due to the retraction systems, the seat belts may be equipped with force limiters also [54,55]. Finally, the correct operation of the seat belts requires that the seats, themselves, have their seat plate reinforced to avoid submarining, that is, to avoid that during deceleration the body of the occupant sinks in the seat and the lower seat belt slips to the abdomen of the occupant increasing the risk for internal injuries [5,56,57].

Airbags for driver and front occupant, such as those presented in Figure 42.15a, are mandatory in all new vehicles in the market. The FMVSS208 specifies that the airbags should protect belted and unbelted passengers, while the ECE specifies the performance of the airbag for belted occupants only. Consequently, the airbags fitting vehicles sold in the North American market are larger and operate with higher pressures, as they may be contacted by head and torso, than those fitting vehicles for the European market that are intended only for head contact [5,10].

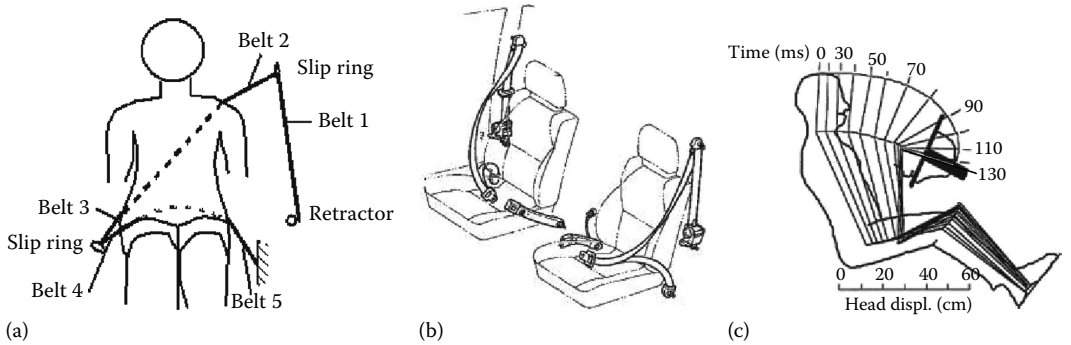

FIGURE 42.14 Seat belts in current vehicles: (a) assembly for the front seats; (b) three-point seat belt with anchorage points (From Introduction in injury biomechanics, In: J. Ambrósio, ed., *Crashworthiness: Energy Management and Occupant Protection*, Springer, Vienna, Austria, p. 305, 2001); (c) occupant excursion with standard retractor seat belt for a 50 km/h sled test. (From Mackay, M., A review of the biomechanics of impacts in road accidents, In: J. Ambrósio, M. Pereira, and F. Pina da Silva eds., *Crashworthiness of Transportation Systems: Structural Impact and Occupant Protection*, Kluwer Academic Publishers, Dordrecht, the Netherlands, p. 115, 1997.)

(a) (b)

FIGURE 42.15 Airbags in a vehicle: (a) front airbags; (b) side airbags for the head and driver thorax.

In lateral collisions, the three-point seat belts do not play a major role in controlling the occupant kinematics. The occupant protection relies mostly in limiting the intrusion of the occupant compartment, on the padding of that compartment, and, if available, on the side airbags, such as the ones presented in Figure 42.15b. The curtain airbags are intended to minimize head injury, while the thorax side airbags provide cushioning for the thorax and lower torso favoring a more compliant contact between the intruding side structure of the vehicle and the occupant. In any case, for both front and side airbags, the airbags need to be contained by the surrounding structure, windows, and windshield.

Besides the seat belts and the airbags, the seats also play a fundamental role on the occupant interior passive safety [5,10]. The seat plate must be reinforced to avoid occupant submarining [56,57]. The geometry of the seat must be such that, in case of side impact, the padding helps support the occupant and protects the pelvic area. Also the headrest plays an important role, especially in rear-end collisions or in the rebound phase of the front crashes, thus helping to minimize whiplash-related injuries. The use of suitable foams for the headrest, able to perform well at different temperatures, and the reduction of the distance between the head and the headrest lead to improvements on the prevention of the whiplash injury [5,58]. Finally, active systems acting over the kinematics of the seats, and able to dissipate some of the kinetic energy of the occupant and seat, are used as optional protection systems in some vehicles [55,59,60].

42.4 NUMERICAL METHODS IN VEHICLE PASSIVE SAFETY

Up until the early 1970, crash studies relied almost exclusively in experimental testing that focused mostly in full-scale testing and in the development of relevant testing scenarios [61]. In a review work, Tidbury [62] stressed the facts that not only the costs associated with experimental testing are very high but also the results cannot be generalized to other impact situations, neither can such methods be used during the design of new vehicles. Therefore, the need for accurate numerical procedures became apparent at that time, and it is even more evident today with the advances in computer power and computational mechanics. The earlier numerical methods used for vehicle crashworthiness were based on the use of lumped masses and nonlinear springs. The models built with these methods, known as lumped parameter models, used lumped masses to represent parts of the vehicle, such as the engine block or the passenger compartment, considered rigid during the analysis, and springs to represent the structural elements responsible for the deformation energy management [63]. The lumped parameter models are mostly 1D or 2D and they include the most very simplified representations of the suspension elements of the vehicles.

The first numerical model for the simulation of the vehicle occupant biomechanics proposed by McHenry [64] was a 2D model that included four articulated rigid bodies and the occupant restraint system. Later, Lobdell [65] proposed a lumped parameter approach with similar numerical characteristics to that used for vehicle structural impact for the simulation of human thorax loading.

The developments of lumped parameter biomechanical models continued through the years of 1970 and 1980 in parallel with the development of models for the structural impact of vehicles but without the synergies associated to the use of a common numerical framework.

The generalization of the vehicle structural and occupant biomechanical models to become fully 3D required another type of numerical methodologies. The MB dynamics methods provided the framework in which more advanced developments could be undertaken. The plastic hinge approach, proposed by Nikravesh and Chung [66] to represent the structural dynamics of road vehicles in crash situations, uses a general MB representation where the full vehicle is described and the structural systems are divided into several rigid bodies connected by kinematic joints to which nonlinear springs, representing the structural deformation, are associated. This approach has been further developed by several authors [67,68] and applied to the crashworthiness of road and rail vehicles proving to be a versatile and efficient methodology to deal with structural crashworthiness, especially in the initial phases of the vehicle design, when extensive reanalysis is required. Still with little or no contact to the developments in structural crashworthiness, the MB methodologies began to be extensively applied in the development of biomechanical models of vehicle occupants. Starting in the initial work of McHenry [64] and going through the developments of Robbins et al. [69] and Fleck et al. [70], the use of MB dynamics methodologies for occupant biomechanics reached a level of maturity that allowed it to become the most popular numerical approach used today in impact biomechanics. The acceptance of the MB-based models by the vehicle industry led to the successful development of commercial occupant simulation computer codes, such as SOMLA [71] and MADYMO[48].

The continuous increase in computer power and the development of the FE method ensured the feasibility of FE-based models for the study of the structural crashworthiness of vehicles. One of the first successful attempts to apply nonlinear FE to the prediction of a vehicle crush was reported by Thompson [72]. Belytschko and Hsieh [73] proposed the FE developments that defined the framework of their use in structural crashworthiness. During the 1970 decade, several nonlinear FE codes suitable to crashworthiness applications were released. Among these the codes DYNA3D by Hallquist [74] and WHAMS by Belytschko [75] are of special importance as they served as the backbone of the codes LS-DYNA [49] and of PAM-CRASH [50] and RADIOSS [51], respectively, which are the most common FE codes used in crash analysis. The application possibilities of this method are being expanded in order to allow for the complex modeling of vehicle and integrated occupants, but still, the representation of the suspension systems of the vehicles and of systems responsible for their active safety is not yet present in the FE models, unless at the cost of a large computational effort. The amount of information required for large systems is still too high, making the application of FEM codes suitable only for the analysis phase of structural and biomechanical systems. For the early design phases, the MB models are still the primary numerical tool used in simulation [67].

Though the features of the different numerical methodologies based on MB dynamics and on FE include most of the ingredients required for the crash analysis, the models more commonly developed neither integrate the structural crashworthiness with the occupant biomechanics nor take into account the overall dynamics of the vehicle. Applications that include either low and medium vehicle impact speeds or multiple impacts or long contact periods or even for which the alignment between vehicles is important for the outcome of the crash are examples of cases for which the vehicle dynamics associated to the suspensions and to the wheel road contact can play an important role. Traditionally the most common numerical techniques for vehicle dynamics modeling are based on MB dynamics methodologies, which are the same for vehicle impact models and for occupant biomechanics modeling. No reason exists for not taking advantage of their features to develop accurate and efficient vehicle models for passive safety.

In this work it is shown that procedures based on MB dynamics provide a unified framework for the development of design and analysis tools of crashworthy structures and of occupants. The models developed are computationally efficient in today's computers to allow for the extensive

reanalysis cycles required in the optimal design of vehicles for crashworthiness. Furthermore, in applications for which the structural patterns of deformation are not known beforehand or for which subcomponent FE models are available, the MB dynamics methods enable the effective coupling between the lumped parameter models and the FE description of the structural deformations.

42.5 MULTIBODY DYNAMICS-BASED ANALYSIS TOOLS: BASICS

A typical MB model is defined as a collection of rigid or flexible bodies that have their relative motion constrained by kinematic joints and that are acted upon by external forces, as shown in Figure 42.16. In the particular case of a vehicle, many MB subsystems can be identified corresponding to suspensions, engine, transmission, body components, and interior components.

The generic MB system is made of *nb* bodies. For the sake of simplicity, in what follows all bodies in the system are considered rigid bodies. The equations of motion for the system of unconstrained rigid bodies are represented by [77]

$$\mathbf{M}\ddot{\mathbf{q}} = \mathbf{g} \tag{42.9}$$

where

M is the mass matrix, which includes the masses and inertia tensors of the individual bodies
$\ddot{\mathbf{q}}$ is the acceleration vector
g the vector with applied forces and gyroscopic terms

The rigid bodies describe components of the vehicle for which the deformation can be neglected in the framework of crashworthiness applications.

The relative motions between the bodies are constrained by kinematic joints, which can be mathematically described by a set of *nc* algebraic equations, written in compact form as

$$\Phi(\mathbf{q}, t) = \mathbf{0} \tag{42.10}$$

The kinematic joints are used to represent the restraints that restrict the relative motion between the system components. Hinges on the suspension systems and on the steering system are examples of features that can be modeled with kinematic joints. However, if the deformations on these elements are of importance for the application envisaged, such as the bushings of the suspension joints in stability and maneuverability studies, the kinematic joints are modeled as force elements [77].

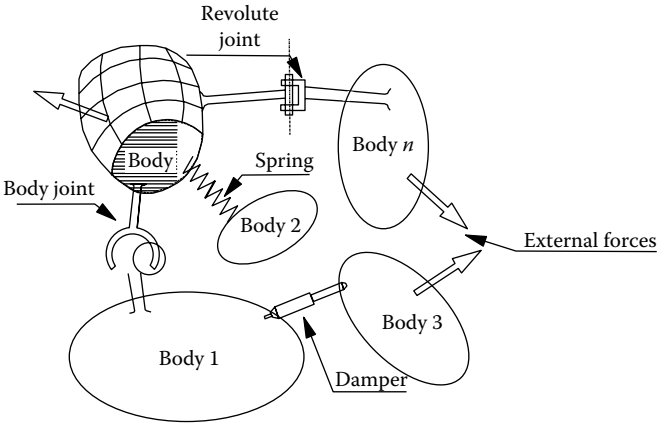

FIGURE 42.16 Generic MB system.

The kinematic joints are also used to represent the deformation mechanisms of structures as part of the plastic hinge technique.

The first and second time derivatives of Equation 1.10 constitute the velocity and acceleration constraint equations, written as

$$\begin{aligned} \dot{\Phi}(\mathbf{q},t) &\equiv \mathbf{D}\,\dot{\mathbf{q}} = \mathbf{v} \\ \ddot{\Phi}(\mathbf{q},\dot{\mathbf{q}},t) &\equiv \mathbf{D}\,\ddot{\mathbf{q}} = \ddot{\gamma} \end{aligned} \tag{42.11}$$

D being the Jacobian matrix. Usually the effect of the kinematic joints for a system of constrained bodies is included in the set of equations (42.9) by adding to the right-hand side the equivalent joint reaction forces $\mathbf{g}^{(c)} = -\mathbf{D}^T\lambda$, where λ is a vector with *nc* unknown Lagrange multipliers, leading to

$$\mathbf{M}\,\ddot{\mathbf{q}} = \mathbf{g} - \mathbf{D}^T\boldsymbol{\lambda} \tag{42.12}$$

Equation 42.12 has *nb* + *nc* unknowns that must be solved together with the second time derivative of the constraint equations. The resulting system of differential algebraic equations is

$$\begin{bmatrix} \mathbf{M} & \mathbf{D}^T \\ \mathbf{D} & \mathbf{0} \end{bmatrix} \begin{bmatrix} \ddot{\mathbf{q}} \\ \boldsymbol{\lambda} \end{bmatrix} = \begin{bmatrix} \mathbf{g} \\ \boldsymbol{\gamma} \end{bmatrix} \tag{42.13}$$

Notice that the solution of Equation 42.13 presents numerical difficulties resulting from the need to ensure that the kinematic constraints are not violated during the integration process.

For the forward dynamic analysis of an MB system, it is required that the initial conditions of the system are given. With $\mathbf{q}^0$ being the position vector and $\dot{\mathbf{q}}^0$ the velocity vector, Equation 42.13 is assembled and solved for the unknown accelerations, which are in turn integrated in time together with the velocities. The numerical methods used must include either constraint violation corrections or their stabilization, especially for long simulation times.

The force vector, appearing in Equation 42.13, includes all forces applied to the components of the vehicle and its occupants described as rigid bodies. Contact forces due to impact, tire/road interaction, springs and dampers, or passive safety restraint systems represent some of the relations that must be included in the force vector. Note that some of the most important modeling efforts of vehicle systems are often done on finding suitable parameters to use the force constitutive relations of the different elements. The development of tire models suitable for different types of automotive studies is just an example of this complexity.

42.5.1 Contact Detection and Contact Models

A set of contact surfaces is defined for the calculation of the external forces exerted on the model when the bodies contact other objects or different body segments. These surfaces are ellipsoids and cylinders with the form depicted by Figure 42.17a for a human body model and in Figure 42.17c for the components of the U.S.-SID crash dummy. When contact between components of the biomechanical model is detected, a contact force is applied to such components in the point of contact. Friction forces are also applied to the contact surfaces using Coulomb friction. Note that the characterization of the surfaces in contact is important for general applications of the biomechanical model.

The numerical procedures for contact detection in crash applications are similar to methodologies used to detect contact in other types of applications. Let a body of the system get close to a surface during the motion of the MB system, as represented in Figure 42.18. Let the impacting surface be described by a mesh of patches. In particular, let the triangular patch, where node *k* of the body

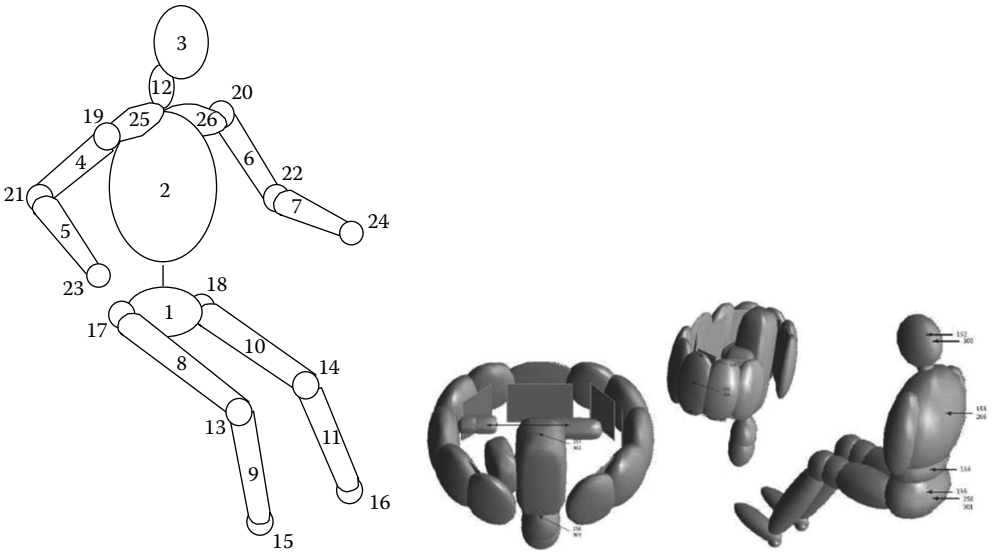

FIGURE 42.17 Representation of contact surfaces in human surrogates: (a) biomechanical model of the human body; (b) U.S.-SID model with internal parts of the thorax and complete model. (From TNO Automotive: MADYMO Manuals, Versions 6.2. TNO MADYMO BV., Delft, the Netherlands, 2004.)

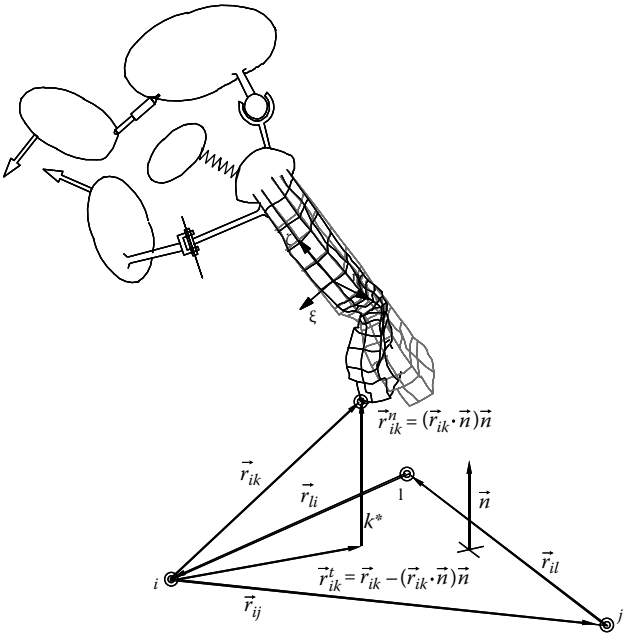

FIGURE 42.18 Detection of contact between an MB component and a triangular patch.

will impact, be defined by points *i*, *j*, and *l*. Note that node in this context means either a point of a rigid body or a nodal point of the FE mesh of a flexible body. If the node (or point) *k* is inside the patch and behind its surface with a penetration $\delta > 0$, there is a contact force applied in the body in its position. Although there are several contact models available to find such forces, a continuous force model is used here.

Let the contact force between two bodies or a system component and an external object be a function of the pseudo-penetration δ and pseudo-velocity of penetration $\dot{\delta}$ given by

$$\mathbf{f}_{s,i} = \left(K\delta^n + D\dot{\delta}\right)\mathbf{u} \tag{42.14}$$

where

K is the equivalent stiffness
D is a damping coefficient
$\mathbf{u}$ is, in this context, a unit vector normal to the impacting surfaces

The hysteresis dissipation is introduced in Equation 42.14 by $D\ \dot{\delta}$, the damping coefficient being written as

$$D = \frac{3K(1-e^2)}{4\dot{\delta}^{(-)}}\delta^n \tag{42.15}$$

This coefficient is a function of the impact velocity $\dot{\delta}^{(-)}$, stiffness of the contacting surfaces, and restitution coefficient e. The generalized stiffness coefficient K depends on the geometry material of the surfaces in contact, which for the contact of a sphere and a flat surface is [78]

$$K = 0.424\sqrt{r}\left(\frac{1-\nu_i^2}{\pi E_i} + \frac{1-\nu_j^2}{\pi E_j}\right)^{-1} \tag{42.16}$$

where ν_l and E_l are Poisson's ratio and Young's modulus associated to each surface and r is the radius of the impacting sphere. The nonlinear contact force is obtained substituting Equation 42.15 into Equation 42.14, written as

$$\mathbf{f}_{s,i} = K\ \delta^n\left[1 + \frac{3\left(1-e^2\right)}{4}\frac{\dot{\delta}}{\dot{\delta}^{(-)}}\right]\mathbf{u} \tag{42.17}$$

This equation is valid for impact conditions, in which the contacting velocities are much lower than the propagation speed of elastic waves, that is, $\dot{\delta}^{(-)} \le 10^{-5}\sqrt{E/\rho}$.

The contact forces between the node and the surface include friction forces modeled using the Coulomb friction model. The dynamic friction forces in the presence of sliding are

$$\mathbf{f}^{friction} = -\mu_d f_d\left(\frac{\left|\mathbf{f}_{s,i}^n\right|}{\left|\dot{\mathbf{q}}_k\right|}\right)\dot{\mathbf{q}}_k \tag{42.18}$$

where

μ_d is the dynamic friction coefficient
$\dot{\mathbf{q}}_k$ is the velocity of point k

The dynamic correction coefficient f_d is expressed as

$$f_d = \begin{cases} 0 & \text{if } \left|\dot{\mathbf{q}}_k\right| \le v_0 \\ \left(\left|\dot{\mathbf{q}}_k\right| - v_0\right)\Big/\left(v_1 - v_0\right) & \text{if } v_0 \le \left|\dot{\mathbf{q}}_k\right| \le v_1 \\ 1 & \text{if } \left|\dot{\mathbf{q}}_k\right| \ge v_1 \end{cases} \tag{42.19}$$

The dynamic correction factor prevents the friction force to change direction for almost null values of the nodal tangential velocity, which would be perceived by the integration algorithm as a high-frequency response, forcing it to reduce the time step size. The friction model represented by Equation 42.19 does not account for the adherence between the node and the contact surface. The interested reader is referred to the work of Wu et al. [79] for a comprehensive discussion on the topics of stiction and sliding in MB dynamics.

42.5.2 Plastic Hinge Approach to Structural Deformations

The methodology reported here uses the plastic hinge approach, suitable for overloaded members in which localized areas of the structure experience the plastic deformations. Plastic hinges usually occur near member's joints, weak areas of the element, and load application points. This observation is important since it allows identifying their location well in advance of the simulation. The concept of plastic hinge is visualized in Figure 42.19 for the bending of a simple supported beam.

At the plastic hinge point, it is necessary to apply a kinematic joint, which describes the kinematics of the deformation, and a generalized spring element that is used to represent the constitutive characteristics of deformation. Such constitutive spring element must represent the elastic–plastic stiffness of the member and the energy absorption characteristics when plastic deformations occur. This spring element can be used with the common types of joints applied, in MB modeling, as depicted in Figure 42.20, for one-axis bending, two-axis bending, and torsion and axial crushing.

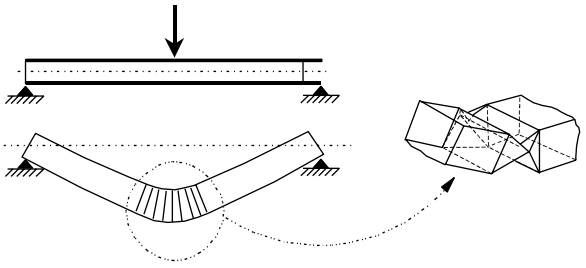

FIGURE 42.19 Localized deformations on a beam and a plastic hinge.

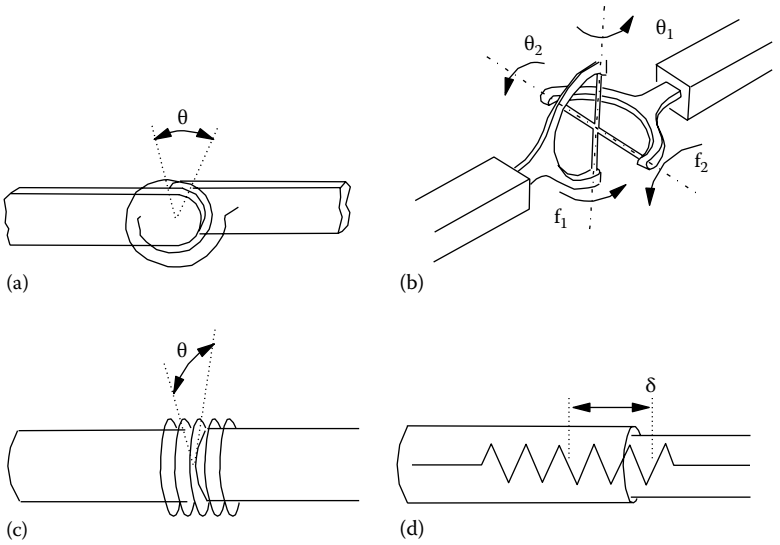

FIGURE 42.20 Plastic hinge models for different load joints: (a) one-axis bending; (b) two-axis bending; (c) torsion; (d) crushing deformation.

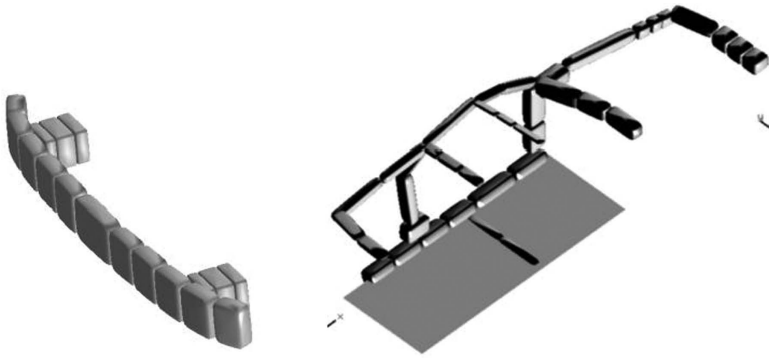

FIGURE 42.21 Plastic hinge models for vehicle substructures: bumper and frame.

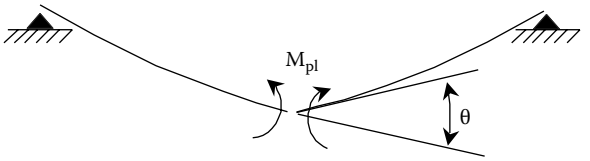

FIGURE 42.22 Plastic hinge bending moment versus rotation angle.

In order to describe the use of the plastic hinge approach, take the structural subsystems represented in Figure 42.21. Each structural component can be modeled as a collection of rigid bodies connected by joints and nonlinear spring elements. Depending on the particular location of the component and on the deformation expected, a choice for each joint type is required and necessary to ensure that the correct deformation mechanism can develop.

In the particular case of a flexural plastic hinge, the spring stiffness is expressed as a function of the change of the relative angle between two adjacent bodies connected by that plastic hinge, as shown in Figure 42.22. For a bending plastic hinge, the revolute joint axis must be perpendicular to the neutral axis of the beam and to the plastic hinge bending plane simultaneously. The relative angle between the two adjacent bodies measured in the bending plane is

$$\theta_{ij} = \theta_i - \theta_j - \theta_{ij}^0 \tag{42.20}$$

where $\theta_{ij}^{\,0}$ is the initial relative angle between the adjacent bodies. Note that for the case of flexible adjacent bodies, the relative angular values also include information on the nodal rotational displacements.

The constitutive relation of the plastic hinge is represented by a load–deformation curve, such as the one presented in Figure 42.23. These constitutive relations are obtained through analytical, experimental, or computational results. In this work, the methodology of identifying the constitutive laws of the plastic hinges is based on the use of FE models of the structural subsystems. A nonlinear static FE analysis is performed for each structural member to identify the force–displacement curve of each plastic hinge.

The constitutive models identified by static FE analysis do not take into account some of the dynamic effects that are exhibited by structural elements when subjected to relatively fast deformation processes. In fact, some of the materials used in vehicle structures are strain rate sensitive, which requires a modification of the constitutive models identified by static elastic–plastic analysis. Steels exemplify the type of materials that are strain rate sensitive, while aluminums are not. A dynamic correction factor is used to account for the strain rate sensitivity [80]:

$$\frac{P_d}{P_s} = 1 + 0.07\, V_0^{0.82} \tag{42.21}$$

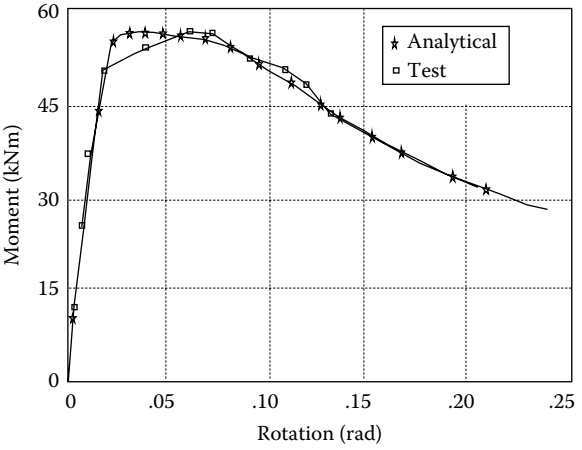

FIGURE 42.23 Plastic hinge bending moment constitutive relationship.

where

P_d and P_s are the dynamic and static forces, respectively

V_0 is the relative velocity between the adjacent bodies

The coefficients appearing in Equation 42.21 are dependent on the type of cross section and material. A detailed description of the application of plastic hinge to crashworthiness can be found on Refs. [66–68].

42.6 DEVELOPMENT OF A VEHICLE MODEL FOR FRONT IMPACT

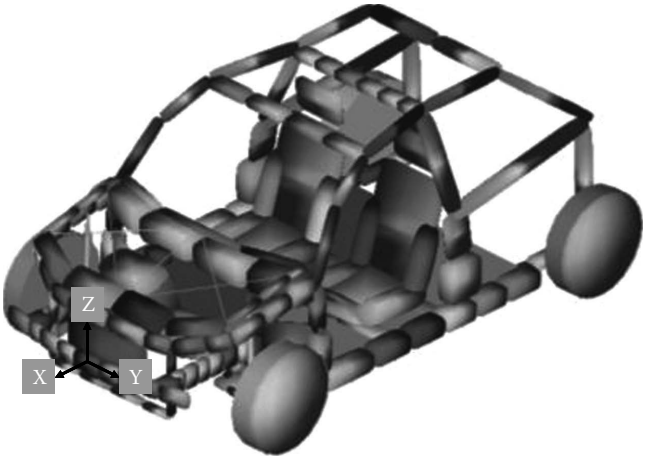
The construction of a vehicle MB model for front impact is used here not only to exemplify how tests in regulation can be used for vehicle development but also to show that even with a generic description of the vehicle structure and mechanical components, it is possible to achieve models that have a crash response similar to that of an existing vehicle that is not fully known. In this sense the vehicle model developed is designated as a generic vehicle. For the sake of using available resources, the development of the MB generic model presented in this work is based on a previously developed detailed FE model of a small car. The crash response of the FE model is used as reference for the final development of the MB model. Note that the existence of the detailed FE model is not mandatory for the development of the MB model. A vague geometric description of the vehicle structural subcomponents and suspension systems or even the real vehicle would suffice for this development. In this case, the reference crash response required for the final development of the MB model could be the experimental data of the real vehicle, if it exists, or published data from ECE, NHTSA, or EuroNCAP tests of vehicles of the same class or even fictitious crash response data with the behavior targeted for the vehicle. The model presented is part of the European project APROSYS-SP7 [81].

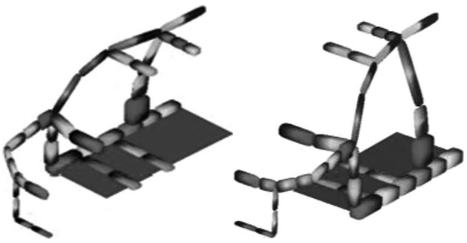
The RADIOSS [51] FE model, shown in Figure 42.24, is a generic car model of a nonexisting vehicle developed by Centro Ricerche FIAT (CRF) [82]. In the MB model of the vehicle, only the structural impact-resistant components are considered. Such structural components are represented in the vehicle shown in Figure 42.24. In a side impact crash application, the door panels are extremely important, and, therefore, they are also included in the model. In a frontal impact, all structural elements are important from the front of the vehicle up to the B-pillar. In both side and front impacts, the rear of the vehicle does not play a role, and, therefore, its structural components are not considered as such but are still included as rigid elements to account for their mass and inertia.

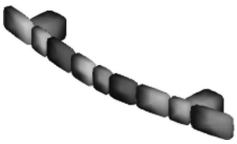
FIGURE 42.24 FE model of a generic car model. (From Puppini, R. et al., Generic car (FE) models for categories super minis, small family cars, large family executive cars, mpv and heavy vehicle, Technical Report APROSYS AP-SP7-0029-A, 2005.)

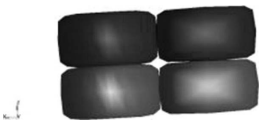
The first part of the procedure consists in using the geometry of the FE vehicle model and of its structural components to develop the geometry of the MB vehicle model, so that both models have the same dimensions. It is important to underline the importance of correct dimensioning of the vehicle since it has a crucial importance in all deformation processes including intrusions, mechanisms of deformation, and energy absorption. The second part of the procedure consists in dividing the vehicle components in substructures that can be independently modeled by "strings" of rigid bodies connected by plastic hinges. In each of the substructure models, there are specific plastic hinge constitutive equations added to each one of the kinematic joints that connect the rigid bodies in the "string" [66–68]. These constitutive equations are obtained through the use of FE substructural models, deformed with suitable loading cases using ABAQUS FE [83]. The final modeling step of the procedure consists in the MB submodel assembly. The MB code MADYMO [48] is used to represent the model developed as it allows the representation of the plastic hinges and all forms of constitutive equations by point and Cardan restraints. The complete MB vehicle model for frontal impact crash is presented in Figure 42.25.

The MB generic car model is divided into fifteen subsystems, presented in Table 42.9; the vehicle chassis model substructures and all equivalent MB subsystem models are represented. Among these









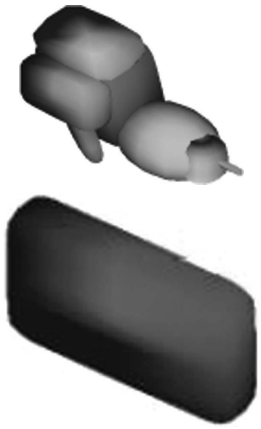


FIGURE 42.25 MB model of the generic car.

elements, the front and rear suspension systems and wheels are also included. Also the interaction between the road surface and the tire is included in the models through the use of a suitable tire model. Because the emphasis of the development of the model is on the structural components and not on other mechanical components of the vehicle, no more details on the suspension systems are presented here.

The rear of the vehicle does not play a role in any of the crash cases for which the MB model is developed. Figure 42.26 represents the rear of the vehicle as a collection of rigid bodies connected by bracket joints, that is, kinematic joints that restrain any relative degree of freedom between the bodies they connect. Thus, for computational purposes, the whole rear vehicle subsystem is considered as a single rigid body that has the mass and inertia properties of the same substructure of the reference vehicle. It should be noted that for the model of the rear of the vehicle, a single rigid body would suffice. If it is necessary to apply the MB vehicle model for rear crashes, the bracket joints

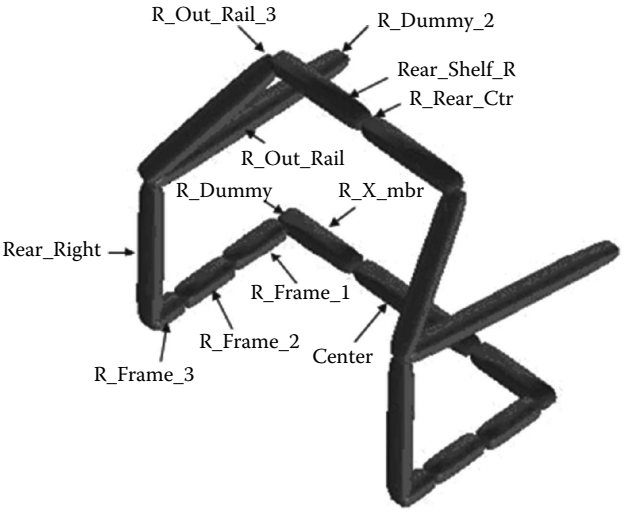

FIGURE 42.26 Vehicle rear subsystem assembly.

can be substituted by other kinematic joints and constitutive equations can be associated to them completing in this form the plastic hinge modeling that enables the subsystem MB model to be used for rear crash analysis.

The constitutive equations for the plastic hinges used to represent the deformation of the vehicle structures are identified here through nonlinear FE static analysis of each of the structural components for different loading cases. Although any suitable nonlinear FE code can be used for this purpose, the FE code ABAQUS is used here for the nonlinear static analysis. It must be noticed that such constitutive behavior may be defined as a design objective or obtained by experimental testing of structural subcomponents. The structural characteristics of the plastic hinges are identified using the explicit method in ABAQUS. The first step to obtain an FE model to calculate the plastic hinge equation is to isolate the part of the FE model of the substructure where the plastic hinge is located. Figure 42.27 shows the FE model of the generic car bumper in ABAQUS [83]. For the material plasticity law, a Johnson–Cook constitutive model is selected [84].

Figure 42.28 represents a piece model of the bumper frame that is used to evaluate the plastic hinge constitutive equation. The plastic hinge presented here is located in the right side of the model. This plastic hinge is associated to one or more kinematic joints in the bumper frame system model [81]. The nonlinear FE analysis required to obtain the plastic hinge constitutive equations consists in fixing one side of the model and applying moments or traction/compression forces on the other side. In the MB model of the bumper, moments are applied to identify the constitutive equation of the plastic hinge and a revolute joint is used to describe the mechanism of deformation of this hinge. Only a bending moment about each axis is applied to find the constitutive behavior of

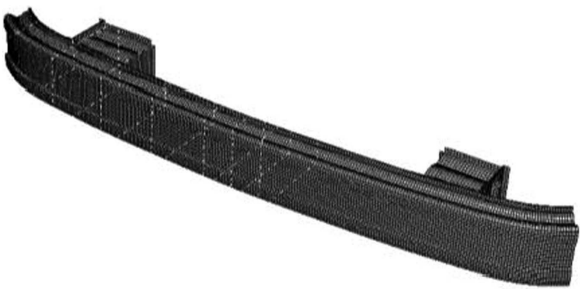

FIGURE 42.27 Bumper FE model in ABAQUS.

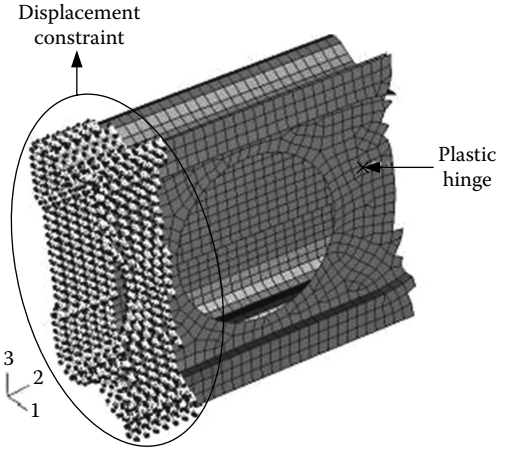

FIGURE 42.28 Boundary conditions for the loading of the bumper frame system model.

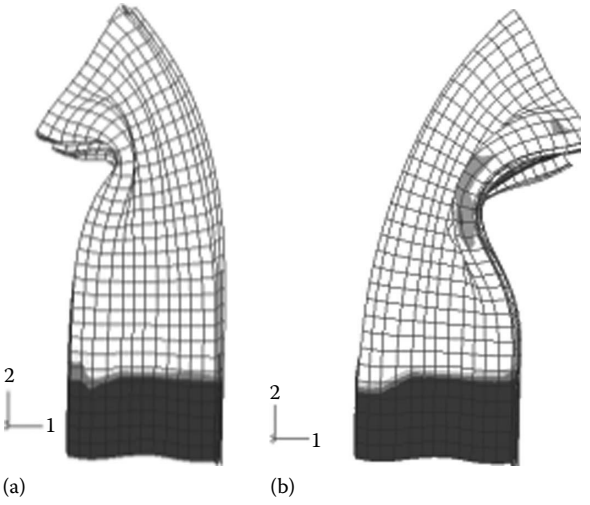

FIGURE 42.29 Bumper deformations for moments applied in counterclockwise (a) and clockwise (b) directions.

the hinge in each direction. The plastic hinge constitutive equation reflects the response of the substructure under the loading case described. Figure 42.29 presents the behavior of the plastic hinge as a deformation of the structure clockwise and counterclockwise moments

The function obtained for the loading case is presented in Figure 42.30. It results from applying bending moment that leads to rotations in the interval [−1, 1] radians to the FE model of the substructure element. The graph shown in Figure 42.30 cannot be directly implemented in the MB model. The constitutive behavior of the plastic hinge is approximated by a piecewise linear function during a loading and an unloading path, representing elastic unloading, parallel to the first segment of the function. The number of segments that are used to represent the load–deformation curve should be small and without large oscillations in the loading path.

Note that the process must be repeated for all plastic hinges considered in the model of the vehicle. The elastic deformations that are observed in the FE model of the structural components between the plastic hinges are not represented in the MB model. This leads to an increased stiffness of the MB structural models that can be compensated by artificially decreasing the stiffness of the

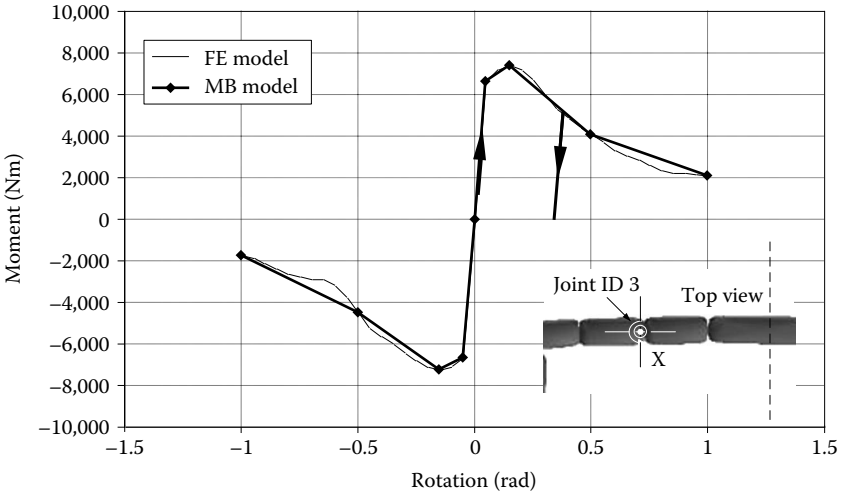

FIGURE 42.30 Constitutive relation for the plastic hinge defined by the revolution about joint *Z* axis.

plastic hinges. Such corrective measures are applied during the validation (correlation) of the MB model with the reference crash behavior and not at this modeling stage.

The MB model of the vehicle is simulated in a crash test that corresponds to the FMVSS208 front crash with a rigid barrier. The vehicle model is used as developed using the procedure outlined, and, therefore, it is not yet validated, that is, there is no assurance that its crash response matches a reference crash behavior. The crash response of the vehicle can be measured by accelerations and velocities in selected points of the structure or by evaluating the energy absorption during the crash event. For vehicle models equipped with dummies, which is not the case in the current analysis, measures of injury of different body parts are relevant not only to describe the quality of the model but also for validation purposes.

The validation process, with respect to the reference behavior obtained from the equivalent FE model [82], consists in modifying the plastic hinge constitutive relations, criteriously, to have a better correlation between the reference FE vehicle model and the MB model responses. Through a trial and error procedure, the plastic hinges of the different parts of the vehicle have been adjusted. The model obtained is tested for the same case as the original vehicle and the outcome is displayed in Figures 42.31 through 42.33 that show the crash response of the validated vehicle. The acceleration signals are filtered with a CFC 60 filter.

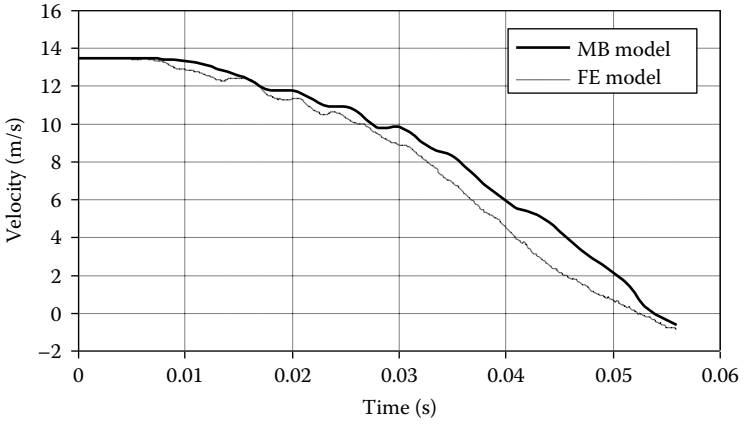

FIGURE 42.31 Left B-Pillar above sill velocities for the vehicle in frontal impact.

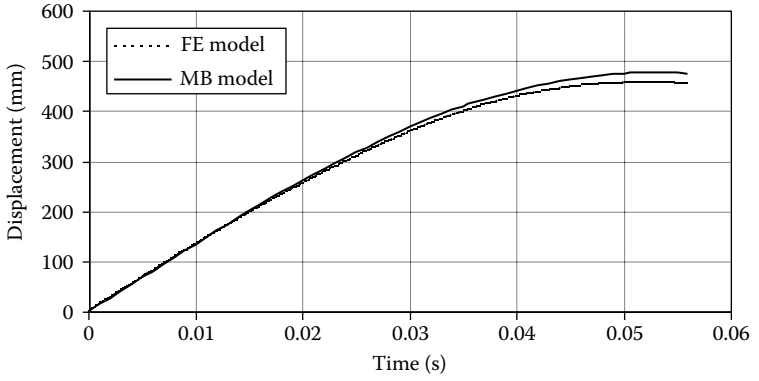

FIGURE 42.33 Left B-Pillar displacements of the vehicle in frontal impact.

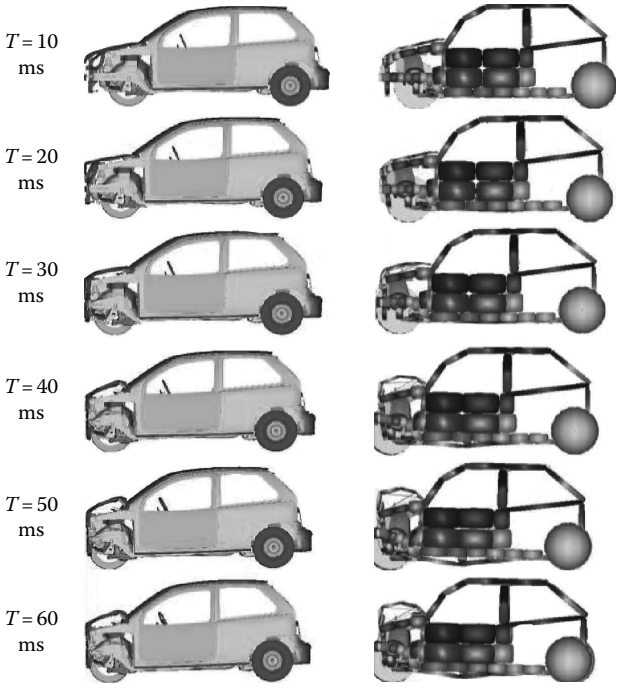

FIGURE 42.34 MB and FE models deformations in the frontal crash test.

The validated model correlates well with the response of the reference model. The pattern of deformation that both models exhibit, shown in Figure 42.34, also demonstrates that the mechanisms of energy absorption are similar in both models. Although the correlation represented by Figure 42.34 is purely qualitative, quantitative results for the correlation of the energy absorption of the different subsystems have also been obtained, and they confirm the results presented.

42.7 DEVELOPMENT OF SIDE IMPACT PROTECTION SYSTEMS

The aim of the study described here, part of project APROSYS-SP6 [85], is to devise an actuator that can be deployed about 200 ms before the actual crash starts that improves the occupant protection. Due confidentiality reasons, the procedure presented is used to evaluate the seat repositioning and door interior trimming instead of the system that has finally been achieved. An MB model of a vehicle Chrysler Neon, shown in Figure 42.35, developed according to the methodologies described previously is analyzed in the crash scenario described in the regulation FMVSS 214 for the purpose of devising a precrash deployment system that helps improve the occupant protection in a side impact. The analyses of the MB models are carried using the code MADYMO [48]. The starting point is the MB model for the Chrysler Neon in which the actuator has to operate.

The kinematic joints represented in Figure 42.36 are set according to the expected mechanisms of deformation that the vehicle can experience for the side crash tests. Caution must be exercised if the model is to be used in any other type of side impact test besides the ones prescribed in the FMVSS 214 or ECE 95 regulations. It is assured that not only the regions of the vehicle for which deformations can happen are properly described in the model but also the potential pairs of contact are defined.

The energy absorption of the vehicle side structure in the test configuration can only be realized when it is included in the complete vehicle. Because all structural plastic deformations are contained in the domain of the side structure, the remaining of the chassis can be considered rigid. The attachments between the rigid bodies of the side structure and the rigid body of the chassis are realized by the crushable elements. The plastic deformation energy that these elements account for is due to the deformation of the structure surrounding the roof, sill, A-pillar, and C-pillar. If the deformation of these crushable elements exceeds a given limit, it can be argued that the plastic deformations of the side structure exceed the modeled region of the vehicle, and, therefore, the validity of the model can be questioned.

Figure 42.37 shows the results obtained for the simulation of the FMVSS 214 side crash test in terms of head, pelvis, thoracic vertebras, and midrib accelerations. The U.S.-SID injury criteria corresponding to this simulation are presented in Table 42.5. The value of TTI is above the maximum acceptable value specified in FMVSS 214 and the value for the PLA is also quite high but below the limit specified in the norm. The velocities of different points of the structure and dummies match those obtained in the experimental test.

The contact forces for the dummy presented in Figure 42.38 have not been measured in the experimental test. It is observed that the peak forces for the pelvis, thorax, and head occur simultaneously. The pelvic contact force predicted by the simulation is clearly larger than the forces carried by the head and by the thorax. This is mainly due to the proximity of the seat and occupant driver

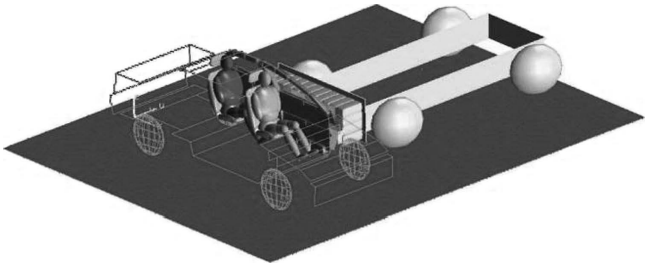

FIGURE 42.35 MB model for the Chrysler Neon in the side impact test defined by FMVSS 214.

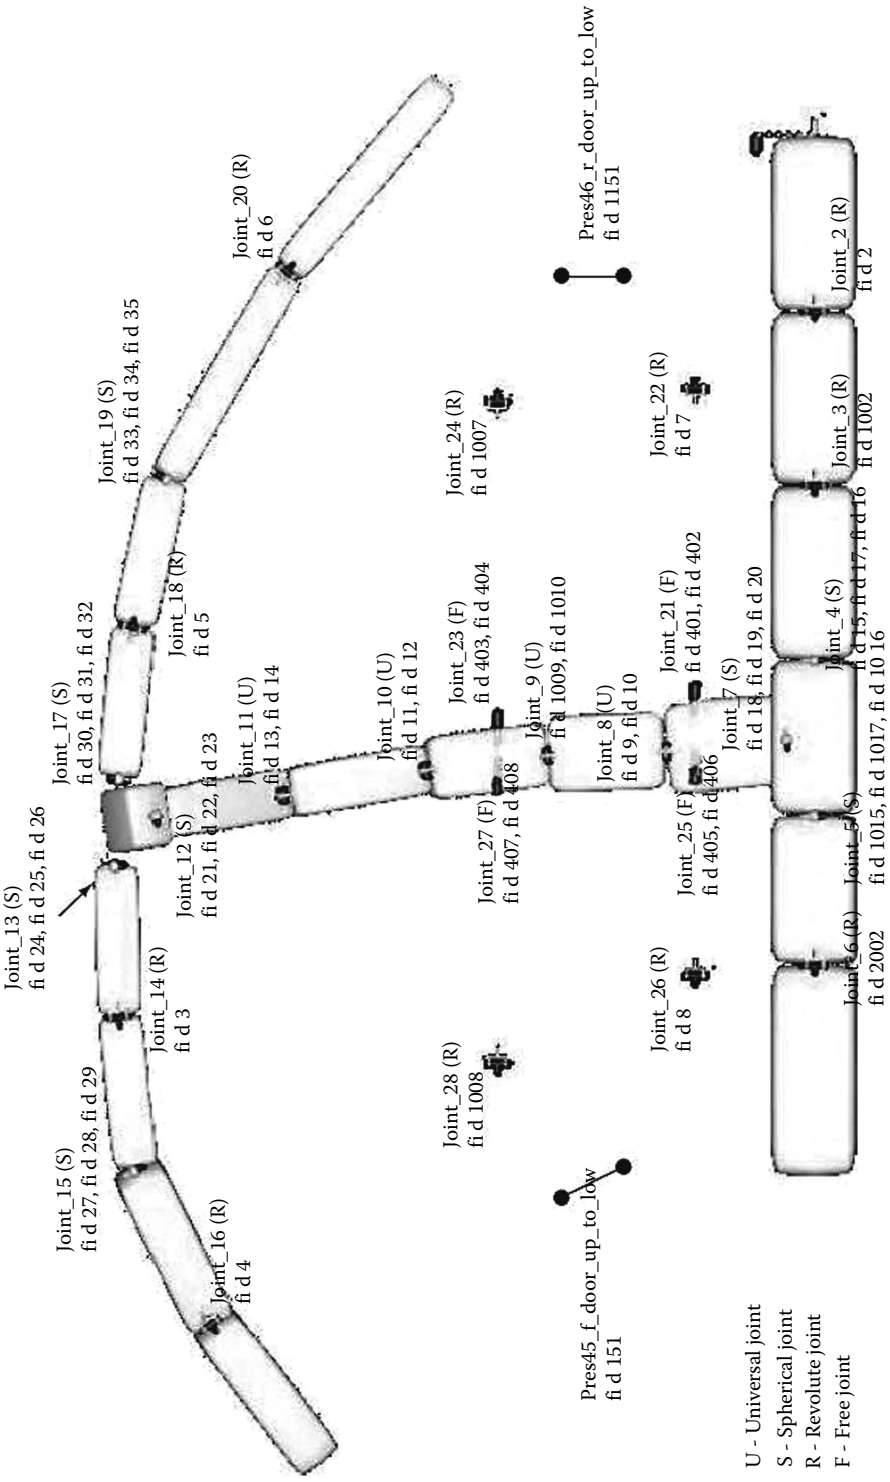

FIGURE 42.36 Kinematic joints for the side structure representation.

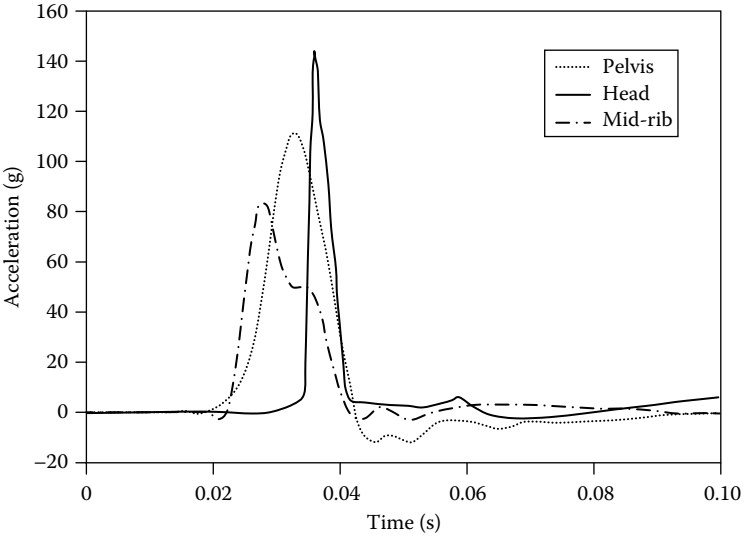

FIGURE 42.37 Side component accelerations for parts of the dummy during impact.

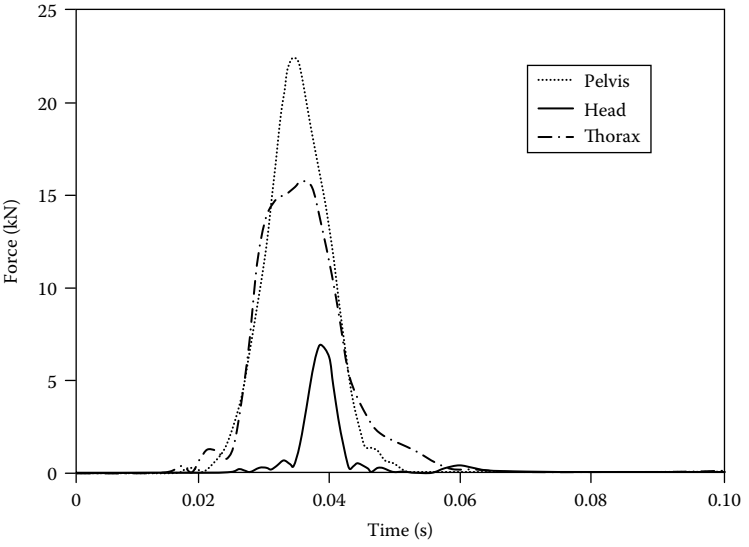

FIGURE 42.38 Contact forces in the pelvic region, thorax region, and head.

pelvis to the B-pillar, which is directly struck by the barrier. The B-pillar motion and the occupant kinematics are displayed in Figure 42.39 for different instants of time. It is clear that the B-pillar intrudes the vehicle passenger compartment, with special incidence in its lower part. The intrusion of the B-pillar leads to contact with the driver's seat and pushes it to the vehicle interior.

The results of the simulation also show the importance of modeling the suspension of the vehicle and the contact between the tires and the ground. The vehicle roll and its lateral displacement play an important role in the progression of the crash event. The energy dissipated by the suspension and friction between tires and ground cannot be neglected for lower impact speeds.

The results for the side impact demonstrate the reliability of the MB model of the vehicle and occupants used in this crash scenario. Extensive reanalysis of the complete vehicle is only possible when the computation time for each analysis is low. To appraise the computational efficiency of this methodology, the time required for each simulation of the vehicle side impact with the MB

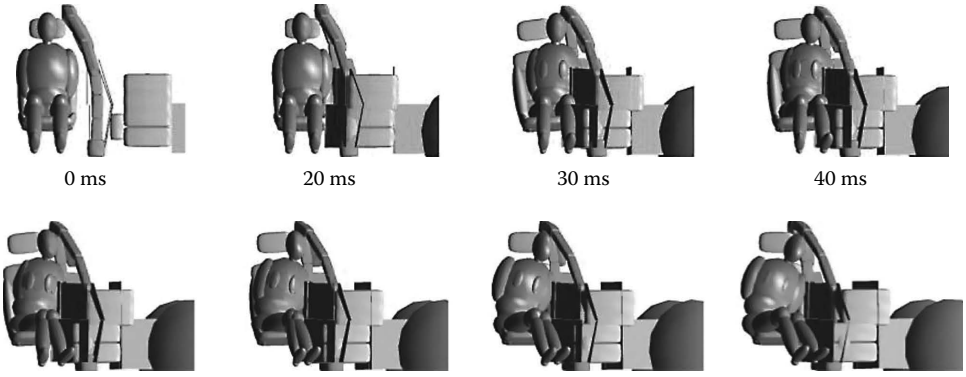

FIGURE 42.39 Sequence of images for the side crash.

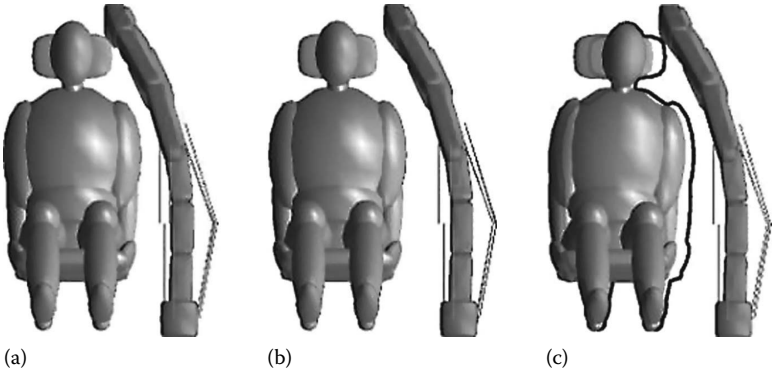
formulation is measured in minutes, while the simulation of the equivalent model in FE, for the same test conditions, is measured in days. The evaluation of the benefits of having the driver sitting in a different position is studied in different simulations. The main objective is to find if repositioning the driver's seat in a favorable side crash position should be considered as an effective side protection strategy. Note that the precrash actuation solution used in the APROSYS-SP6 project [85] is different from that reported here, although the methods used are the same.

The first strategy moves the driver sitting positions to the interior of the vehicle by 5 cm, as shown in Figure 42.40, so that the space between the driver and the intruding door is increased. In Figure 42.40c, the dark outline shows the seat and dummy initial positions and the solid dummy drawing shows the seat and dummy positions for the simulation. The repositioning of the occupant and seat further to the interior of the vehicle, by 5 cm, leads to an improvement of the PLA and of the TTI, as shown in Table 42.10. It should be noted that the position of the seat must be followed by the seated occupant, who is assumed to be correctly seated.

Analyses of the seating scenario with small perturbations of the occupant position indicate that the injury criteria are sensitive to position changes of the dummy as well as changes in the pelvic and thorax velocities, caused by the seat movement. This indicates that if the change on the seat position inside the car is to be made in a short period of time, the effective repositioning of the occupant must also to be pursued. Finally, note that the improvements on the injury criteria happen independently of the increase in intrusion registered in the side structure of the vehicle. The increase of intrusion is explained by the removal of the seat to a more interior position in the vehicle reducing in this form the intrusion resistance.

In the second scenario, the driver sitting position is relocated to the back of the vehicle by 15 cm, as shown in Figure 42.41, to be seated in a region of the vehicle exposed to reduced intrusion



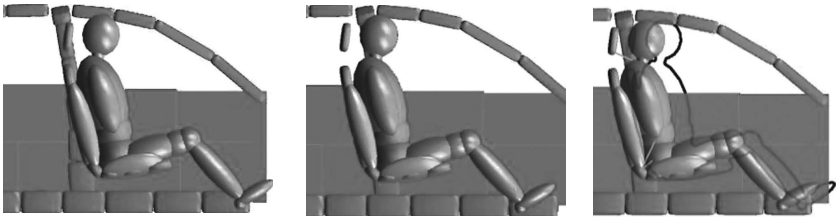


FIGURE 42.40 Driver sitting position: (a) original; (b) located 5 cm to the interior of the target vehicle; (c) difference in the seating positions.

TABLE 42.10
Injury Criteria and Their Variations for the Driver Lateral Translation

	Injury Criteria Value	
Sideway	**PLA (<130 g)**	**TTI (<85 g)**
Initial design	110.23	87.83
Driver seat 5 cm to interior	81.13	77.16
Change in injury index (%)	−26.4	−12.15

(a) (b) (c)

FIGURE 42.41 Driver sitting position: (a) original; (b) further back by 15 cm in the target vehicle; (c) difference in the seating positions.

displacement and speed. Placing the seat more to the back of the vehicle is more effective at pelvic level, which is probably due to the fact that intrusion and intrusion velocity values are lower closer to the B-pillar than in the region corresponding to the middle of the door.

The results presented in Table 42.11 indicate that some improvement of the dummy injury criteria can be obtained by moving the seat backward in the vehicle prior to the crash. The decrease in the PLA is consistent with what was previously determined in simulation. The differences between the magnitudes of the decrease of the PLA are due to the final positions of the dummy relative to the horizontal intrusion profile in the car side structure. A large difference is observed for the TTI in the simulation. This is due to the fact that for simulation, the distance between the thorax of the dummy and the door is altered due to the seat belt restraint.

Pulling the driver's seat backward prior to the occurrence of a side crash improves the protection level. However, a more detailed analysis of the model must be undertaken to ensure that not only the seat is moved but also that the occupant moves with it. The possible benefits of rotating the driver's seat in the target vehicle in such a way that the driver is displaced more to the interior of the vehicle, as seen in Figure 42.42, are investigated here also.

In order to ensure that the occupant moves with the seat to the precrash position, a seat-mounted seat belt is used to improve the coupling of the dummy's torso movement with that of the rotating seat.

TABLE 42.11
Injury Criteria and Their Variations for the Driver Forward Translation

	Injury Criteria Values	
Forward–Rearward	**PLA (<130 g)**	**TTI (<85 g)**
Initial design	110.23	87.83
Driver seat moved back 15 cm	73.76	41.87
Change in injury index (%)	−33.08	−52.33

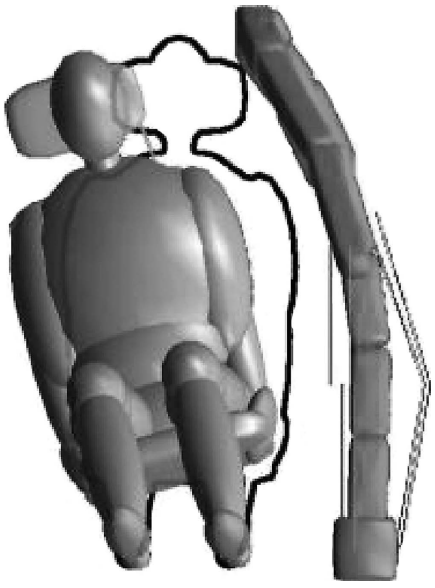

FIGURE 42.42 Rotation of the driver's seat prior to the side impact.

If a protection strategy involving the movement of the driver's seat is to be implemented, further analysis of this model, using a seat belt model that can slide on the dummy, has to be used. Furthermore, some additional devices might be required to assure that the torso movement follows that of the seat.

Table 42.12 shows the results for TTI and the PLA measured in the side direction. The results presented in Table 42.12 show that the rotation of the seat in the direction of the interior of the target vehicle can be a very efficient protection strategy in the event of a side crash. In fact, reductions of up to 45% and 50% are obtained in the PLA and TTI if the seat is rotated by 16°.

The limitation of the intrusion of the door and B-pillar allows for the space between the occupant and the interior of the door to be used for the lateral excursion of the occupant in case of a side impact. The 3-point seat belts and the seat shape are not effective restraints for this occupant side motion. Therefore, the interior of the vehicle, and the door in particular, must have a compliance that helps in reducing injury when it is hit by the occupant during a side impact [86,87]. The part of the study described here exemplifies the use of the numerical tools to develop the functional requirements for a deployable/retractable equipment that can not only limit the lateral excursion of the occupant but also increase the interior compliance of the vehicle for side impact scenarios.

TABLE 42.12
Injury Criteria Forces and Their Variations for the Driver's Seat Rotation

	Injury Criteria Values	
Seat Rotation	**PLA (<130 g)**	**TTI (<85 g)**
Initial design	110.23	87.83
Injury criteria	61.64	42.95
Change in criteria (%)	−44.08	−51.1
	Pelvis	**Thorax**
Contact force change (%)	−30.05	−57.53
Resultant acceleration change (%)	−43.11	

A set of simulations is carried out to evaluate the side crash protection potential of having an improved cushioning for the pelvis and thorax consisting of specifically designed crush pads, that is, pads in the interior of the door that can occupy the space in between the occupant and the door as schematically shown in Figure 42.43a. For this purpose, two crush pads are modeled in order to provide independent cushioning of the thorax and pelvis, as seen in Figure 42.43a. These cushioning devices were inserted into the intruding door in a manner that all the free space between the door and the dummy can be used for cushioning and thus to contribute to the side crash performance improvement. It is considered that each of the pads behaves according to the force–deflection curves presented in Figure 42.43b. Note that the values for the pad stiffness are fictitious being only used here to demonstrate the concept.

The simulation where no damping is included in the results is reported in Table 42.13 for reference. Note that the model with no damping is rather unrealistic, as there all materials have some internal damping. The results presented in Table 42.13 show that for "soft" and for "stiff" pad materials, the amount of internal damping present in the material plays an important role in the side crash outcome.

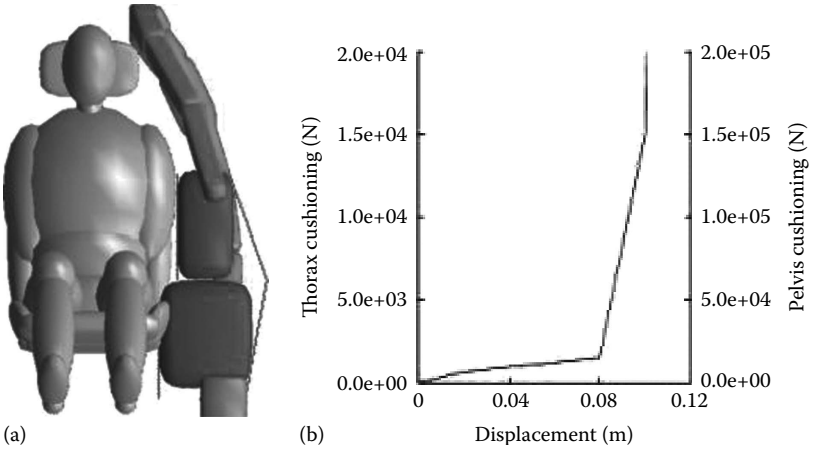

FIGURE 42.43 (a) Location for the door cushioning, that is, crash pads at the pelvic and thorax level; (b) force–displacement curve describing the material behavior of the cushioning pad.

TABLE 42.13
Injury Criteria Values for Different Values of the Pad Material Damping

	Injury Criteria Values	
Door Interior Padding	**PLA (<130 g)**	**TTI (<85 g)**
Initial design	110.23	87.83
No damping	82.77	83.29
Low damping	79.55	75.68
Medium damping	69.21	66.06
High damping	72.82	80.36
	Percentage Change in Injury Criteria Values	
Door Interior Padding	**PLA**	**TTI**
No damping	−24.92	−5.17
Low damping	−27.83	−13.84
Medium damping	−37.21	−24.79
High damping	−33.94	−8.51

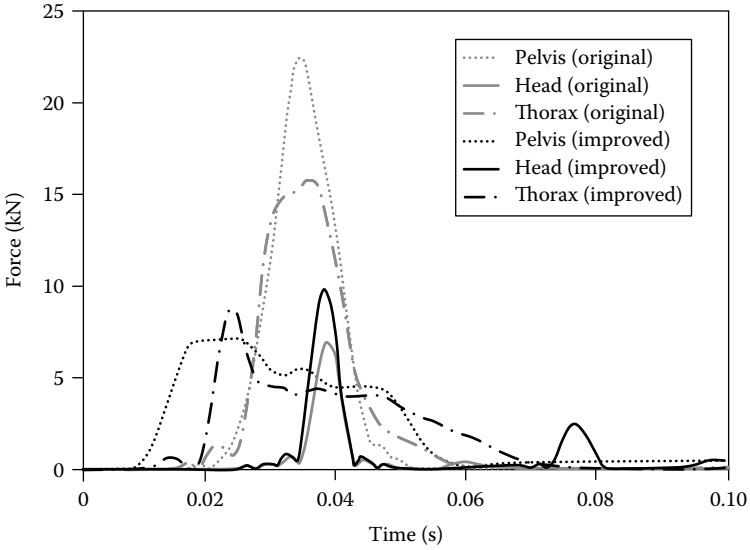

FIGURE 42.44 Dummy contact forces for the initial design and improved designs.

The existence of some internal damping in the pad material is beneficial in what the injury criteria of the driver are concerned. The material damping contributes to the decrease of the contact forces within reasonable values, but if this damping assumes a high value, the contact forces increase again.

Figures 42.44 and 42.45 illustrate the improvements obtained by the use of the optimized crush pads. The peak forces in the order of 25 kN, at the pelvic level, observed for the original design are now reduced to about 10 kN. The lack of compatibility intrusion profile with the occupant rotation that leads to head contact with high forces in the original vehicle is compatible for the new design due to a more upright position of the occupant and more compliance in the contact areas.

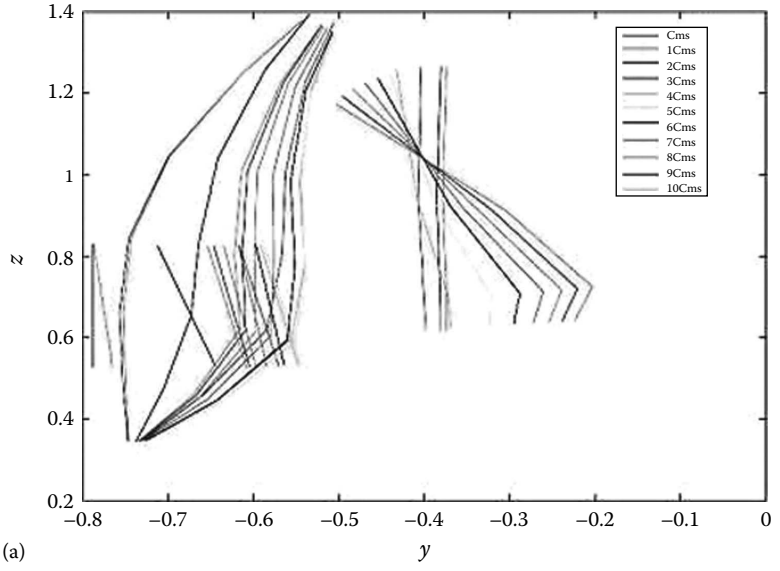

FIGURE 42.45 Intrusion and dummy displacement: (a) initial design.

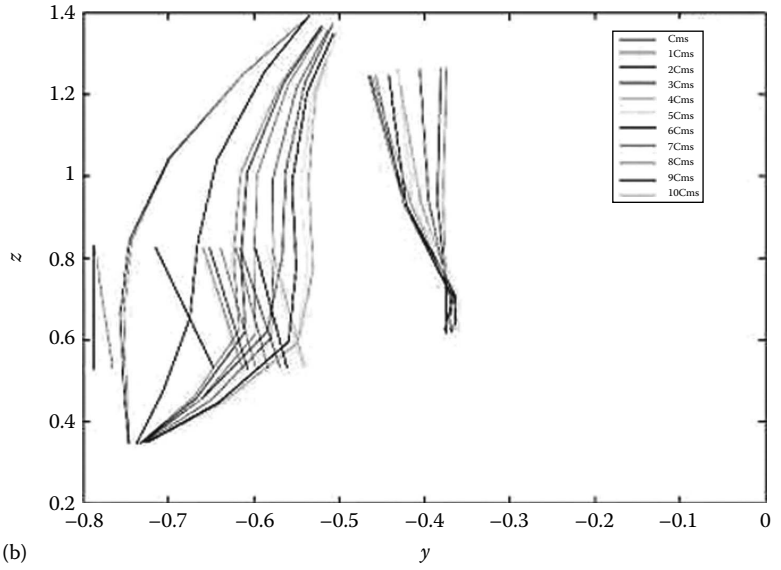

FIGURE 42.45 (continued) Intrusion and dummy displacement: (b) improved design.

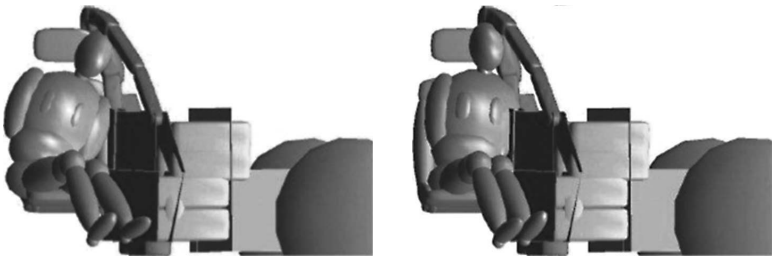

FIGURE 42.46 Dummy displacement at 80 ms for (a) initial design; (b) improved design.

The occupant position at the instant of contact with the side structure of the vehicle for the initial vehicle and for the new design is presented in Figure 42.46. Even the qualitative observation of both cases allows concluding that a more serious pelvic and thorax impact exists for the original design of the vehicle.

42.8 CONCLUSIONS AND TRENDS IN FUTURE DEVELOPMENTS

Occupant protection in automotive vehicles has improved greatly during the past decades as a result of concurrent efforts that integrate vehicle structural solutions with interior occupant protection systems. The strategic lines for this continuous evolution in crashworthiness are defined not only by accidentology analysis, which allows to identify the priorities for occupant protection, but also by technological developments in sensors, sensing algorithms, and interior equipment, which widen the range of decisions to be taken during a crash event, and even before it starts, and enable fitting the characteristics of the protection systems to the individual car occupant. The regulations used for crashworthiness are mostly regional, taking into account the different automobile markets and accident profiles.

Numerical methodologies play a fundamental role on the advancement of vehicle passive safety. Not only the computational mechanics aspects are in constant development, providing more reliable material models, better tools to model structures and systems, faster and reliable algorithms for the

solution of the dynamic equilibrium equations of the vehicles and their subsystems, and improved contact algorithms, but also they are also supported by advanced graphical interfaces, which allow for better look and feel and for defining more detailed and precise information. The constant improvements in computer power ensure that the models developed can be more advanced, better integrated, and more predictable in a reasonable time. The actual difference between FE-based methods and MB dynamic methods has the tendency to diminish as these procedures will be more integrated. Finally, the full integration of other numerical methodologies, such as optimization tools and real-time control paradigms, will increase the importance of the computational methods on the vehicle design.

The development of more advanced knowledge in the human mechanisms of injury; in the modeling of human tissues, organs, and structures; and in the physiologic response to impact will certainly impact the current regulations, the design of the currently used occupant protection systems, and the design of the vehicle structures. Today only ATDs are used in regulations and in internal norms of different companies. Other human occupant surrogates are used, mostly for impact biomechanics research. The test dummies are designed to collect data for prescribed directions of loading and do not include any representation of muscle activation and, consequently, cannot represent realistic human behavior for general crashes. The research on human body modeling is expected to have an impact on the development of more advanced dummy designs and eventually lead to the realization of omnidirectional dummies that include some level of muscle bracing when used in lower impact velocities. Also, advances in the definition of injury criteria are expected as a result of advances in human body modeling. Certainly the regulations will continue to be regional, at least while the car markets are different, but the measuring devices are expected to be unified.

Other aspects of automotive passive safety in which major developments are expected concern all those that can benefit from the integrated use of the many sensor devices existing in the vehicles today. Not only these devices allow for adjusting the deployment of the interior protection devices to the particular characteristics of the crash and of the occupant, but also they already allow for precrash actions that prepare the vehicle and the occupant for a foreseeable crash. The development of new materials and structural solutions will extend the range of the precrash systems from the level of the systems to the actual vehicle structure. Finally, it is expected that many of the aspects of active and passive safety are more and more integrated so that all phases of the vehicle operation can take advantage of common resources, leading to a more integrated vehicle safety.

ACKNOWLEDGMENTS

Automotive Engineering

Featuring contributions from leading experts, the ***Road and Off-Road Vehicle System Dynamics Handbook*** provides comprehensive, authoritative coverage of all the major issues involved in road vehicle dynamic behavior. While the focus is on automobiles, this book also highlights motorcycles, heavy commercial vehicles, and off-road vehicles.

The authors of the individual chapters, either from the automotive industry or universities, address basic issues, but also include references to significant papers for further reading. Thus the handbook is devoted both to the beginner, wishing to acquire basic knowledge on a specific topic, and to the experienced engineer or scientist, wishing to have advanced information on a particular subject. It can also be used as a textbook for master courses at universities.

The handbook begins with a short history of road and off-road vehicle dynamics followed by detailed, state-of-the-art chapters on modeling, analysis and optimization in vehicle system dynamics, vehicle concepts and aerodynamics, pneumatic tires and contact wheel-road/off-road, modeling of vehicle subsystems, vehicle dynamics and active safety, man-vehicle interaction, intelligent vehicle systems, and road accident reconstruction and passive safety.

- Provides extensive coverage of modeling, simulation, and analysis techniques
- Surveys all vehicle subsystems from a vehicle dynamics point of view
- Focuses on pneumatic tires and contact wheel-road/off-road
- Discusses intelligent vehicle systems technologies and active safety
- Considers safety factors and accident reconstruction procedures
- Includes chapters written by leading experts from all over the world

This text provides an applicable source of information for all people interested in a deeper understanding of road vehicle dynamics and related problems.
